In comparing the sleep EEG profile of depressive dementia with that of primary degenerative dementia plus secondary depression, Buysse et al. (85) found a more predictable decrease in Hamilton Rating Scale for Depression scores following night-long sleep deprivation, a higher percent of REM sleep and greater phasic REM activity/intensity, and a longer first REM period on the second recovery night following sleep deprivation in patients with depressive dementia. The differences in REM sleep rebound permitted correct identification of 89% of the patients. Using a sophisticated statistical approach, Reynolds et al. (47) were able to classify 80% of patients with major depression or degenerative dementia from normal elderly subjects. However, in patients with a mixed picture of depression and dementia, discrimination dropped to 64%.

*Neurochemistry.* The most consistent neurochemical abnormality in primary degenerative dementia is region-specific deficits in the brain cholinergic system. This is particularly relevant because of the close relationship between memory functions and cholinergic transmitters. The most specific reduction is in the enzyme choline acetyltransferase. The reduction of this enzyme tends to parallel the distribution of the neuropathological changes in different brain regions; concentrations of choline acetyltransferase are lower in the temporal cortex and hippocampus. In addition, there is atrophy and loss of cholinergic cell bodies in the nucleus basalis of Meynert in the basal forebrain (86). The most profound cholinergic deficit is in early-onset Alzheimer's disease, and the least deficit is in multi-infarct dementia, Huntington's disease, Parkinson's disease, and depression. No reproducible biochemical changes have been found at postmortem in depression, and there have been essentially no postmortem neurochemical studies of depressive dementia.

The assumption that a single neurotransmitter deficit is responsible for the cognitive impairment of degenerative dementia is probably too simplistic. The same assumption is too simplistic for depression. Lower brain concentrations of norepinephrine, serotonin, and dopamine have been reported in patients with primary degenerative dementia (34, 87). Patients with depression have also been found to have reduced CSF concentrations of norepinephrine and serotonin (88). Somatostatin, a neuropeptide and putative neurotransmitter widely distributed in the CNS, is lower in several areas of the hippocampus and neocortex in primary degenerative dementia. Lower levels of somatostatin have also been reported in depression (89). Similarly, arginine vasopressin, a neurohypophysial peptide, is lower in the CSF of patients with primary degenerative dementia, unipolar depression, and Korsakoff's syndrome (90).

A related and extensively studied neuroendocrine measure is the dexamethasone suppression test. This test does not discriminate between age-matched patients with differing types of depression and dementia disorders. A number of studies have demonstrated a nonsuppression rate in nondepressed patients with primary degenerative dementia as high as that reported in major depression (71).

*Peripheral markers in platelets.* Because blood platelets are embryologically related to synaptic membranes they are thought to reflect the condition of the CNS. They also may prove to map to genes associated with Alzheimer's disease. To the extent that this is true, at least three different abnormalities of platelet membranes may have important associations with abnormalities in the brains of patients with depression and or degenerative dementia. Imipramine binding sites are associated with presynaptic serotonin reuptake, and elderly patients with depression appear to have fewer of these sites than do patients with degenerative dementia and control subjects (91). It is not known what the overlap might be in patients with depressive dementia. Platelet membrane fluidity, which can influence a variety of cell functions such as receptor activity, appears to be greater in patients with early-onset Alzheimer's disease than in age-matched control subjects or elderly depressed patients (44).

Platelet monoamine oxidase activity increases with aging, particularly in women. Alexopoulos et al. (19) suggested on the basis of a series of studies that platelet MAO activity is higher in patients with degenerative dementia with and without depression and in patients with depressive dementia than in nondemented depressed patients.

## DISCUSSION

The majority of the historical, clinical, neuropsychological, and neurobiological research reviewed suggests that the cognitive impairment seen in depressive disorder during late life is real, not pseudo or simulated. Methodological problems occurred in each type of research reviewed. Despite these problems, the consensus of the research taken together is fairly consistent. The neuropsychological literature suggests that depressive dementia is somewhat closer in both scores and pattern to primary degenerative dementia than to major depression without dementia. It is as if the common factor of dementia in depressive dementia and primary degenerative dementia has more weight than the common factor of depression in major depression with and without dementia. The consensus of the neurobiological research is that cognitive impairment of depression is associated with a variety of organic abnormalities. Again, findings in dementia of depression are more like findings in degenerative dementia than in normal aging or depression without dementia. These primarily cross-sectional studies make it clear that depressive dementia and primary degenerative dementia are not identical and they do not occur together at all points in the history of their disease course. What is at issue is if, how, and why these differing disorders sometimes evolve into a common phenotypic presentation.

It seems clear that we cannot easily extrapolate from major depression to depressive dementia in an attempt to define the cognitive impairments and phenomenology of the latter. In some patients, cognitive impairment is severe enough to meet four of five *DSM-III-R* criteria for dementia. The one criterion not met is the circular, exclusionary criterion "cannot be accounted for by any nonorganic mental disorder, e.g., major depression accounting for cognitive impairment." Such severe cognitive impairment may be "pseudo-degenerative dementia," but it is not pseudodementia. Some of the longitudinal data reviewed suggest that over time the severe cognitive impairment of depression may not even be "pseudo-degenerative dementia." Heuristically speaking, we would suggest there are a number of ways to arrive at the common endpoint of the phenotype of degenerative dementia. We suggest that depressive dementia involves a diathesis or vulnerability for this common final pathway or presentation.

There are other ways to interpret the longitudinal data on the poor prognosis of many depressed patients with severe cognitive impairment. It is possible that these patients would have developed primary degenerative dementia independently of any depressive disorder. It is also possible that these patients already were suffering from primary degenerative dementia in a latent form that became manifest under the stress of depression and then gradually became permanent over the years. The prevalence of poor prognosis found in several studies (11, 17) is higher than would be expected from the usual prevalence figures of severe dementia (22; *DSM-III-R*). Even if the high prevalence of Alzheimer's disease found in the East Boston study (25, 92) is used, the risk of poor prognosis in several studies is still greater than expected from simple co-occurrence. Given the lower rate of major depression in the elderly, the apparently greater long-term rate of dementia in major depression during late life is all the more striking.

These observations emphasize the common problem of confusing diagnosis, organicity, and prognosis. As Lipowski (93) pointed out before *DSM-III*, the diagnosis of organic is only pragmatic: "It helps to distinguish a class of disorders that are best managed if their occurrence is assigned to the primary dysfunction of the physical substrate of information processing. This distinction does not imply a clear cut dichotomy." If a dementia is in any degree reversible, it is not ipso facto a false dementia or pseudodementia. This is certainly true according to the operational philosophy of *DSM-III* and *DSM-III-R*. If a dementia is to any extent reversible at any point in its course, this does not mean it is devoid of an organic etiology. We suggest that the evidence reviewed here supports viewing the cognitive impairment of depression as a continuum intersecting an organic degenerative continuum with a corresponding continuum of reversibility-irreversibility. Accordingly, using the term "depressive pseudodementia" appears to be as inappropriate as equating the terms "psychosomatic" and "psychogenic." In many respects it would be useful to have a qualifying *DSM-IV* category for major depressive disorder to denote severe cognitive impairment, analogous to the qualifier of depression for primary degenerative dementia.

### *Clinical Implications*

There are several clinical implications of the continuum point of view. This viewpoint helps lower unrealistic expectations of psychiatrically curable dementia. The viewpoint discourages stereotypically equating the concepts of reversibility, treatment, and cure. Instead, it provides a rationale for more aggressive treatment of "excess disability" (94) in patients with any degree of dementia. The continuum perspective acts to discourage a dichotomous approach to treatment that considers some patients treatable and others not treatable. The perspective also militates against the segmentation of biological and psychological treatments. Most elderly patients with cognitive impairment from depression have clear depressive symptoms qualifying for major depression. It is on the basis of, for example, the presence of intrapsychic depressive symptoms and characteristic sleep disturbance rather than the claim or presence of cognitive impairment that somatic treatments are recommended. Otherwise, an empirical trial of antidepressants for all elderly patients with severe cognitive impairment could result in unnecessary or even dangerous side effects. Similarly, patients with primary degenerative dementia who have sufficient depressive symptoms should be treated. However, patients with primary degenerative dementia who also have major depression should not necessarily be treated with somatic therapy. In the only double-blind study we found of antidepressants in Alzheimer's disease with major depression, supportive psychosocial therapy was as effective as somatic therapy (95). This also underscores problems inherent in a dichotomous organic versus nonorganic view.

These treatment implications do not imply a nihilistic attitude toward depression or dementia. Rather, they are meant to emphasize the importance of obtaining a good history and conducting a thorough mental status examination (cognitive and affective) as the basis for a treatment plan to alleviate primary or secondary impairment from depressive symptoms. Reliance on good clinical skills should decrease emphasis on expensive ancillary technologies for the differential diagnosis of depressive dementia and primary degenerative dementia of the Alzheimer type. Some of these technologies (e.g., neuroimaging) are useful for diagnosis, detection, and treatment of vascular disease components, such as multi-infarct dementia. At this time, however, most ancillary technologies have their primary role in research. Of great importance for the spectrum approach to treatment is long-term follow-up. For early detection and alleviation of incipient depressive and dementing symptoms, all disorders along the depression-dementia spectrum need to be traced and treated longitudinally.

### *Research Implications*

Clinical information and longitudinal follow-up should also form the basis of future research. Neuropsychological testing, sleep electroencephalography, neuroimaging techniques, and biochemical and neuropathological investigations all have primary importance in research. Longitudinal cost-effectiveness studies using these techniques would also be of relatively more immediate clinical value. For example, what combination of clinical data best predicts which patients would benefit from which techniques? Results from such studies could provide greater empirical support for defining the appropriate diagnostic evaluation of patients and determining what these evaluations would cost.

When depressive dementia is viewed on a continuum with degenerative dementia, however, overlapping pathophysiological mechanisms rather than differential diagnoses become an important focus. If the co-occurrence of depression and dementia is not due to chance alone, there are at least three possible relationships to be systematically investigated. First, the co-occurrence could be due to an interaction and threshold effect. For example, given an underlying predisposition (e.g., genetic diathesis) to develop dementia (or depression), combined with the CNS insult from depression (or dementia), a threshold is reached for the expression of that predisposition (17, 26, 42).

One important approach for investigating this relationship would be to use the techniques of molecular biology to determine if the neuritic plaques and neurofibrillary tangles seen in the different prototypical conditions not only vary continuously but also are qualitatively identical (96, 97) in subjects and family members. Similarly, efforts should be made to compare regional brain differences in neurotransmitter concentrations in the different prototypical conditions.

Second, the abnormalities so far noted may represent damage from depression (or dementia) and its treatment rather than distal causal factors. An important implication of this possibility is that we must give greater attention to the accurate determination of the number and duration of depressive episodes and type of treatment (e.g., use and duration of anticholinergic antidepressants and their effect on acetylcholine synthesis) in patients with depressive dementia.

Third, both depression and dementia may include a common pathophysiology but do not lead to one another. For example, certain alterations in membrane structure and physiology may be necessary but not sufficient for both disorders. The research reviewed indicates a need for further investigation of functional as well as structural abnormalities in neural networks involving subcortical nuclei in both depression and dementia. In this regard, it would be valuable and pioneering to administer neuropsychological tests (which can suggest subcortical dysfunction) to patients with depressive dementia studied with PET as well as to administer mood measures to patients with degenerative dementia studied with PET.

Other research directions include studying similarities and differences in the long-term course of bipolar affective disorder compared with unipolar major depression in relation to the degenerative dementing axis. Future research should also study the longitudinal occurrence of neuropsychological and neurobiological abnormalities in more accurately determined early- versus late-onset depression.

In order to pursue these hypotheses and directions, future research should include the establishment of multidimensional clinical and biological measures over substantial 5–10-year follow-up periods. The use of continuous outcome measures (e.g., depression or cognitive scale scores) as well as categorical diagnoses is also indicated in order to cover the entire spectrum from successful aging (without the subtle and not so subtle effects of preventable medical conditions [98]) to aging with disabling depression and dementia.

# The *DSM-III-R* Impulse Control Disorders Not Elsewhere Classified: Clinical Characteristics and Relationship to Other Psychiatric Disorders

Susan L. McElroy, M.D., James I. Hudson, M.D., Harrison G. Pope, Jr., M.D., Paul E. Keck, Jr., M.D., and Harlyn G. Aizley, M.Ed.

*Objective: The authors reviewed available studies of* DSM-III-R *impulse control disorders not elsewhere classified in order to determine the relationship of these disorders to one another and to other psychiatric disorders. Method: The review focused on the demographic and clinical characteristics, phenomenology, family history, biology, and response to treatment of individuals with intermittent explosive disorder, kleptomania, pathological gambling, pyromania, and trichotillomania. Analysis was restricted to reports which either indicated use of operational diagnostic criteria or provided descriptions of the impulsive behavior detailed enough that patients could be judged as probably meeting the* DSM-III-R *criteria. Results: Although different impulse control disorders have different sex ratios, all have similar ages at onset and courses. Studies on phenomenology, family history, and response to treatment suggest that intermittent explosive disorder, kleptomania, pathological gambling, pyromania, and trichotillomania may be related to mood disorders, alcohol and psychoactive substance abuse, and anxiety disorders (especially obsessive-compulsive disorder). Biological studies indicate that intermittent explosive disorder and pyromania may share serotonergic abnormalities similar to those reported in mood disorders. Conclusions: The impulse control disorders not elsewhere classified appear to be related to one another and to mood, anxiety, and psychoactive substance use disorders. Thus, like major depression, obsessive-compulsive disorder, panic disorder, bulimia nervosa, and attention deficit hyperactivity disorder, they may represent forms of "affective spectrum disorder."*

(Am J Psychiatry 1992; 149:318–327)

Impulse control disorders are broadly defined as mental disorders characterized by irresistible impulses to perform harmful acts (1–4). In *DSM-III-R*, impulse control disorders are defined by three essential features: 1) failure to resist an impulse, drive, or temptation to perform some act that is harmful to the person or others, 2) an increasing sense of tension or arousal before committing the act, and 3) an experience of pleasure, gratification, or release at the time the act is committed. In addition, there may or may not be conscious resistance to the impulse, the act may be or may not be premeditated or planned, and immediately after the act there may or may not be genuine regret, self-reproach, or guilt (*DSM-III-R*, p. 321). Thus, the behaviors can be ego-syntonic and/or ego-dystonic.

Despite this elaborate definition, *DSM-III-R* does not have a formal category for impulse control disorders. Rather, it has a category termed "impulse control disorders not elsewhere classified," which includes intermittent explosive disorder, kleptomania, pathological gambling, pyromania, trichotillomania, and impulse control disorder not otherwise specified. Potential members of this latter residual category include repetitive self-mutilation (5), compulsive shopping ("oniomania") (6), compulsive sexual behavior (7), and compulsive facial picking (8). Also, alcohol and psychoactive substance use disorders and the paraphilias, although not described as impulse control disorders in

**TABLE 1. Overview of *DSM-III-R* Impulse Control Disorders Not Elsewhere Classified**

| Disorder and Studies | Description | Prevalence | M/F Ratio | Usual Time of Onset | Course |
|---|---|---|---|---|---|
| Intermittent explosive disorder (11, 15–21)[a] | Episodic aggressive outbursts | Rare? | M>F | Childhood, adolescence, or early adulthood | Episodic and chronic |
| Kleptomania (22, 23) | Impulsive or compulsive stealing | Rare? | F>M | Childhood, adolescence, or early adulthood | Episodic or chronic |
| Pathological gambling (24–34) | Compulsive or addictive gambling | 0.2%–3.3% | M>F | Adolescence or early adulthood | Episodic or chronic, occurs in "bouts" |
| Pyromania (20, 21, 35, 36)[b] | Repetitive failure to resist impulses to set fires | Rare? | M>F | Childhood, adolescence, or early adulthood | Episodic or chronic |
| Trichotillomania (37–44) | Compulsive hair pulling | Rare? | F>M | Childhood, adolescence, or early adulthood | Episodic or chronic |

[a] Most patients were described as having episodic behavioral dyscontrol, explosive rage, rage outbursts, or impulsive aggression. Although many had overt or subtle neurological abnormalities, some had no detectable neurological abnormalities and thus probably met the *DSM-III-R* criteria for intermittent explosive disorder.

[b] Most patients were described as being impulsive fire setters or impulsive arsonists; whether or not the patients experienced irresistible impulses to burn was not consistently documented.

*DSM-III-R,* are given as examples of such in the *DSM-III-R* section defining the impulse control disorders not elsewhere classified.

Despite their inclusion in the formal American diagnostic nomenclature since 1980 and a rich descriptive literature dating back to the late nineteenth century, the impulse control disorders as a group remain poorly studied. Except for alcohol and psychoactive substance abuse, little is known about them in terms of prevalence, demographic characteristics, course, associated psychopathology, family history, and response to treatment. Nor is it entirely clear why these individual conditions are grouped together. For example, while *DSM-III-R* characterizes impulse control disorders by the inability to resist "an impulse, drive, or temptation" to perform a harmful act, it does not explicitly require this criterion for intermittent explosive disorder, pathological gambling, pyromania, or the alcohol and psychoactive substance use disorders. Indeed, since nearly the inception of the concept of impulse control disorders, the validity of the so-called irresistible impulse has been questioned (9, 10), as has the diagnostic legitimacy of several specific impulse control disorders, including intermittent explosive disorder (3, 11), kleptomania (9, 12), and pyromania (9, 13, 14).

In an attempt to address some of these issues regarding *DSM-III-R* impulse control disorders not elsewhere classified, we surveyed the literature for studies of the epidemiology and phenomenology of these disorders and patients' associated psychopathology, family history, biology, and response to somatic and psychosocial treatments. We restricted analysis to reports which either indicated use of operational diagnostic criteria or provided descriptions of the impulsive behavior detailed enough that patients could be judged as probably meeting the *DSM-III-R* criteria. We omitted from analysis the paraphilias and alcohol and substance use disorders. Although given as examples of other impulse control disorders in *DSM-III-R* (p. 321), these disorders are presently assigned in *DSM-III-R* to separate diagnostic categories. Moreover, a detailed review of the paraphilias and alcohol and substance abuse, although needed, is beyond the scope of this article. We also omitted studies of behaviors meeting criteria for impulse control disorder not otherwise specified, because the number of patients studied (except for those with repetitive self-mutilation) was extremely small.

## PREVALENCE, COURSE, AND PATIENT CHARACTERISTICS

Information about the prevalence and course of the impulse control disorders not elsewhere classified and about patients' demographic and clinical characteristics is provided in table 1. All of these disorders, with the exception of pathological gambling (26, 34), are presumed to be rare (19, 22, 36, 37). Although certain *behaviors,* such as shoplifting, gambling, and fire setting, are common in the general population, studies have generally shown that only a small portion of such individuals perform the behavior in response to irresistible impulses and hence represent cases of true impulse control *disorders* (e.g., kleptomania, pathological gambling, and pyromania) (22, 25, 35, 36, 45, 46). Moreover, although many studies have examined large groups of individuals who display impulsive aggression (commonly called "episodic behavioral dyscontrol"), many of the individuals studied do not appear to have had intermittent explosive disorder according to *DSM-III-R* criteria, because the dyscontrol was attributed to a primary neurological or organic mental disorder (11, 15–18). Nevertheless, except for pathological gambling, the prevalences of these impulse control disorders in the general population have not been well studied, and some authors have speculated that certain impulse control disorders, such as episodic dyscontrol (17), kleptomania (22), and trichotillomania (40, 44), may be more common than realized.

Although these impulse control disorders have different sex ratios, they appear similar with respect to onset and course (see table 1). Most cases begin in adolescence or early adulthood (except for trichotillomania, a substantial number of cases of which begin in child-

**TABLE 2. Evidence From Phenomenologic Studies of Other Psychiatric Disorders in Patients With *DSM-III-R* Impulse Control Disorders Not Elsewhere Classified**

| Disorder and Studies | Degree of Association With Impulse Control Disorder[a]<br>Mood Disorders | Anxiety Disorders | Alcohol or Substance Abuse | Eating Disorders | Attention Deficit Hyperactivity Disorder | Personality Disorders |
|---|---|---|---|---|---|---|
| Intermittent explosive disorder (11, 16–18, 20, 21, 47, 48) | 1 | 1 | 3 | —[b] | 2 | 2 |
| Kleptomania (22, 23, 49–54) | 3 | 3 | 3 | 3 | —[b] | 1 |

[b] Insufficient data.

hood [44]) and follow a chronic course with exacerbations and remissions. However, little is known about the evolution of these disorders with advanced age.

## ASSOCIATED PSYCHOPATHOLOGY

Studies examining the relationship between these five impulse control disorders and other psychiatric disorders are summarized in table 2. Operational diagnostic criteria have been used to systematically study phenomenology in four studies of intermittent explosive disorder (N=24) (20, 21), three of which used the same cohort of patients and were extensions of the first, in one study of kleptomania (N=20) (23), in five studies of pathological gambling (N=99) (27, 28, 31–33), three of which presumably used virtually the same cohort of patients, and in two studies of trichotillomania (N=76) (41, 42). Although none of these studies was controlled, all but one (20, 21) showed high rates of mood disorder, ranging from 43% among 14 trichotillomanic patients (41) to 100% among 20 kleptomanic patients (23). Of 99 pathological gamblers, 83 (84%) displayed mood disorder (28, 31, 33), and of 64 patients with trichotillomania, 46 (72%) had mood disorder (41, 42). In the only follow-up study located (32), of 38 pathological gamblers who were "abstinent" 6 months after inpatient treatment, seven (18%) were "still significantly depressed" despite improvement in work and family life.

Only one study compared the ages at onset of impulse control disorder and of mood disorder (23). Among 20 patients with concomitant kleptomania and mood disorder, the onset of mood disorder preceded the onset of kleptomania by at least 1 year in 12 (60%), occurred within the same year in three (15%), and occurred after the onset of kleptomania in five (25%). In a study of 25 pathological gamblers (31), 18 (72%) experienced episodes of major depression around the time that they first stopped gambling. Thirteen (52%) subjects experienced additional major episodes of mood disorders (major depression in 11 and mania in two) either before they stopped gambling or afterward. Of note, particularly high rates of bipolar disorders (types I and II and cyclothymia) were reported in patients with kleptomania (60%) (23) and in pathological gamblers (32% and 46%) (28, 31). Furthermore, some patients with kleptomania and pathological gambling reported relationships between their impulse control disorders and mood symptoms: their irresistible impulses would alter in intensity or frequency when they were depressed or manic, or their impulsive behaviors would affect their affective symptoms. In particular, patients reported that stealing or gambling produced a pleasurable "rush" that alleviated their depressive or manic symptoms (23, 28). Interestingly, some patients likened this "rush" to their hypomanic or manic episodes (23).

Phenomenologic studies also have shown high rates of concomitant anxiety (23, 31, 41, 42), alcohol and psychoactive substance abuse (20, 21, 23, 27, 28, 31, 33, 41, 42), and eating disorders (23, 42) in patients with these impulse control disorders. Specifically, of 24 impulsive offenders (20, 21), all met the *DSM-III-R* criteria for alcohol abuse. Of 20 patients with kleptomania (23), 16 (80%) each met the *DSM-III-R* criteria for at least one anxiety disorder (panic disorder, 40%; agoraphobia, 5%; social phobia, 40%; simple phobia, 30%; obsessive-compulsive disorder, 45%); 12 (60%) met the criteria for an eating disorder (bulimia nervosa, 60%; anorexia nervosa, 30%); and 10 (50%) met the criteria for a psychoactive substance use disorder (most commonly alcohol, amphetamine, and cocaine). Of 49 pathological gamblers from two studies (31, 33), 11 (22%) each had at least one anxiety disorder, most commonly obsessive-compulsive disorder, panic disorder, generalized anxiety disorder, and simple phobia. Of 100 pathological gamblers from three studies (27, 31, 33), 42 (42%) had histories of alcohol or substance abuse. Finally, of 74 patients with trichotillomania from two studies (41, 42), 39 (53%) had histories of anxiety disorders (including generalized anxiety disorder, panic disorder, and obsessive-compulsive disorder) and 17 (23%) had histories of alcohol or drug abuse.

These findings are further supported by numerous case reports and case series of individuals with apparent impulse control disorders who also had concurrent or past mood disorders (22, 25, 38, 44–56, 60–64), obsessive-compulsive disorder (22, 35, 43), panic disorder (22, 50), eating disorders (22, 38, 50, 54, 62), or alcohol or substance abuse (16, 18, 22, 54). Studies have also shown relatively high rates of impulsive stealing or kleptomania among patients with eating disorders (22, 65, 66) and high rates of pathological or problem gambling among alcoholics (67). For episodic dyscontrol and pathological gambling, studies further suggest a relationship with attention deficit hyperactivity disorder (11, 16, 57) and personality disorder (12, 20, 21, 32).

We were unable to locate any systematic studies of individuals with rigorously diagnosed pyromania. Although there have been many studies of large groups of individuals who displayed impulsive fire-setting behavior (20, 21, 35, 36, 46), most of the individuals studied either were not clearly identified as having pyromania (20, 21) or did not appear to have pyromania as defined by the *DSM-III-R* criteria (35, 36, 46). Nevertheless, these studies consistently showed high rates of concomitant alcohol and substance use disorders (20, 21, 35), personality disorders (20, 21, 46), and depression (20, 21, 46). For instance, in a study of 22 impulsive arsonists (20, 21), 15 (68%) of whom met the *DSM-III-R* criteria for intermittent explosive disorder, 21 (95%) also met the *DSM-III-R* criteria for dysthymic disorder (N=18) or major depression (N=3), 20 (91%) met the criteria for alcohol abuse, and 20 (91%) met the criteria for borderline (N=17) or antisocial (N=3) personality disorder. Further, cases of individuals with apparent pyromania and concomitant mood disorder or obsessive-compulsive disorder have been reported (35, 58, 59). Finally, individuals with episodic dyscontrol have been reported to display high rates of fire-setting behavior (16).

## FAMILY STUDIES

Family studies of individuals with impulse control disorders not elsewhere classified are less extensive than phenomenologic studies. However, the most consistent findings have been high rates of mood and substance use disorders in the first-degree relatives of individuals with intermittent explosive disorder or episodic dyscontrol (some of whom probably had intermittent explosive disorder) (16, 17, 20, 21, 68, 69), kleptomania (23), and pathological gambling (27, 31, 33). For instance, Mattes and Fink (68) reported that of 132 first-degree relatives of 33 patients with temper outbursts (22 of whom had intermittent explosive disorder), 11% had depression and 8% alcohol or drug abuse. Linnoila et al. (69) found that 44 (81%) of 54 violent offenders and impulsive fire setters (29 with intermittent explosive disorder) had first- or second-degree relatives with alcoholism. Among 103 first-degree relatives of 20 subjects with kleptomania (23), 22 (21%) had major mood disorder and 21 (20%) had alcohol or substance use disorders. Among 175 first-degree relatives of 25 pathological gamblers (31), 18 (10%) displayed major mood disorder and 19 (11%) displayed alcohol abuse or dependence. Similarly, Ramirez et al. (27) found that 50% of 51 patients with pathological gambling each had an alcoholic parent, and Roy et al. (33) reported that 33% and 25% of 24 pathological gamblers each had a first-degree relative with mood disorder and alcohol abuse, respectively.

Although not as striking, relatively high rates of anxiety disorders (in particular, panic disorder, agoraphobia, and obsessive-compulsive disorder) have been reported in families of individuals with kleptomania (23) and trichotillomania (44). Other findings include high rates of obsessive-compulsive personality disorder in families of individuals with trichotillomania (43), high rates of violence (16, 17, 68) and attention deficit hyperactivity disorder (68) in families of individuals with episodic dyscontrol, and possibly higher than normal rates of the same impulse control disorder in the families of patients with intermittent explosive disorder (6.9%) (68), kleptomania (2%) (23), pathological gambling (23%) (27), and trichotillomania (5%) (44, 64). Finally, Winokur et al. (70) noted an apparently high prevalence of pathological gambling in the families of bipolar probands.

## STUDIES OF BIOLOGICAL TESTS

Studies of biological tests of subjects with impulse control disorders not elsewhere classified, summarized in table 3, have largely focused on the hypothalamic-pituitary-adrenal axis, on serotonin, norepinephrine, and glucose metabolism, and on EEG results. For the most part, the subjects have been individuals with impulsive aggression, impulsive fire setting, and pathological gambling. The most consistent findings have been abnormalities in serotonergic and, to a lesser extent, noradrenergic function (74, 75). For instance, Brown et al. (72) reported that a higher degree of impulsivity correlated with a higher aggression score and lower CSF 5-hydroxyindoleacetic acid (5-HIAA) but higher 3-methoxy-4-hydroxyphenylglycol (MHPG) concentrations in 26 men with personality disorders. Of note, the 11 subjects with histories of at least one suicide attempt had higher aggression scores and lower 5-HIAA and higher MHPG concentrations than the subjects with no history of suicide attempts. In a study of 58 violent offenders and impulsive fire setters, 33 (57%) of whom met the *DSM-III-R* criteria for intermittent explosive disorder, Virkkunen et al. (20, 21) found lower CSF concentrations of 5-HIAA and MHPG in the impulsive offenders and fire setters than in the nonimpulsive offenders and normal comparison subjects. Moreover, low 5-HIAA and MHPG concentrations were associated with a lifetime history of suicide attempts. More recently, Brown et al. (76) reported that mean platelet $[^3H]$serotonin uptake was significantly lower in 15 male outpatients with episodic aggression than in 15 nonaggressive comparison subjects.

By contrast, individuals with pathological gambling

**TABLE 3. Biological Findings on Patients With *DSM-III-R* Impulse Control Disorders Not Elsewhere Classified**

| | Relation of Biological Findings to Normal | | | |
|---|---|---|---|---|
| Disorder and Studies | Cortisol | 5-HT | Norepinephrine | Other[a] |
| Impulsive violent behavior (11, 16–18, 20, 21, 69, 71–76)[b] | No difference in urinary free cortisol | Lower CSF 5-HIAA; lower platelet 5-HIAA uptake | Lower CSF MHPG | Lower blood glucose on GTT;<br>EEG abnormalities |
| Pathological gambling (29, 33, 77, 78) | Suppression on DST | No difference in plasma 5-HIAA | Lower plasma and higher CSF MHPG[c]; higher urinary norepinephrine | Differential EEG activation |
| Impulsive fire setting (20, 21, 69, 73, 79) | No difference in urinary free cortisol | Lower CSF 5-HIAA | Lower CSF MHPG | Lower blood glucose on GTT |

[a] GTT=glucose tolerance test.

[b] Some, but not all, patients met the *DSM-III* criteria for intermittent explosive disorder.

[c] Only the centrally produced fraction of CSF MHPG was higher than normal. Total CSF MHPG was not higher than in comparison subjects.

**TABLE 4. Efficacy of Psychosocial Treatments for *DSM-III-R* Impulse Control Disorders Not Elsewhere Classified**

| | Rating of Efficacy[a] | | | | |
|---|---|---|---|---|---|
| Disorder and Studies | Insight-Oriented Psychotherapy | Behavioral Therapy | Group Therapy | Inpatient Treatment | Self-Help Groups |
| Intermittent explosive disorder (16, 17, 80) | 1/0[b] | —[c] | 1 | —[c] | —[c] |
| Kleptomania (22, 23, 50, 53, 81) | 1 | 1 | —[c] | —[c] | —[c] |
| Pathological gambling (82–88) | 2/0[b] | 2 | —[c] | 2 | 1 |
| Pyromania | —[c] | —[c] | —[c] | —[c] | —[c] |
| Trichotillomania (39, 44, 89–91) | 1 | 3 | —[c] | —[c] | —[c] |

[a] 3=Supported by one controlled study, 2=supported by at least one open study, 1=supported by single case reports or small case series, 0=not supported by balance of evidence, but limited evidence for efficacy may be present.

[b] Ratings of evidence for positive and negative findings, respectively.

[c] Insufficient data.

have been shown to have significantly lower plasma MHPG concentrations, greater centrally produced fractions of CSF MHPG, and greater urinary output of norepinephrine than comparison subjects, but similar CSF 5-HIAA concentrations (33). One study (77), however, demonstrated that pathological gamblers show normal suppression on the dexamethasone suppression test. Finally, studies have shown high rates of EEG and other neurologic abnormalities in individuals with intermittent explosive disorder (11), episodic dyscontrol (16–18), and pathological gambling (78).

## RESPONSE TO TREATMENT

Studies of psychosocial treatments of impulse control disorders not elsewhere classified are summarized in table 4. We were able to find only two controlled studies of any form of psychosocial treatment for the five impulse control disorders analyzed. In the first (86), imaginal desensitization was more effective than aversive therapy in reducing the urge to gamble, gambling behavior, and anxiety in 20 compulsive gamblers—at both 1 month and 1 year after treatment. In the second (91), habit reversal was twice as effective as negative practice training in suppressing hair pulling in 34 patients with trichotillomania. Open studies of psychoanalytic psychotherapy, various forms of behavioral therapy, and inpatient treatment using relatively large numbers of pathological gamblers have shown varying degrees of success (24, 30, 32, 85, 88). In addition, isolated case reports and case series have shown psychoanalytic or insight-oriented psychotherapy and behavioral therapy to be effective for kleptomania (22, 50, 53, 81), pathological gambling (83–85), and trichotillomania (39, 44, 90, 91). Case reports and case series have also shown some success of various forms of psychotherapy and behavioral therapy for children with fire setting typically not due to pyromania (92). However, a number of authors have commented on the difficulties involved in treating some of these individuals (especially those with intermittent explosive disorder, pathological gambling, pyromania, and trichotillomania), citing patients' refusal to take responsibility for their behavior, lack of insight, denial, concomitant legal difficulties, and alcohol abuse (40, 44, 82).

Studies examining the response of these impulse control disorders to pharmacologic treatments are summarized in table 5. We located no placebo-controlled trials and only two controlled trials of pharmacologic agents for individuals with impulse control disorders not elsewhere classified diagnosed by means of operational criteria. In the first, Swedo et al. (41) found clomipramine to be more effective than desipramine in the treatment of 13 women with trichotillomania. In the second, Mattes (11) reported that carbamazepine and propranolol were equally effective in reducing rage outbursts in 80 patients with a variety of diagnoses, including intermittent explosive disorder (N=51) and attention deficit disorder, residual type (N=38). Of note, the diagnosis of intermittent explosive disorder was associated with preferential response to carbamazepine, whereas the diagnosis of attention deficit hyperactivity disorder was associated with preferential response to propranolol. Additionally, a number of case reports and case series have shown a variety of thymoleptic agents to be effective in treating four of the five impulse control disorders analyzed. These included carbamazepine, lithium, desipramine, and clomipramine for apparent intermittent explosive disorder (47, 48, 93); amitriptyline, imipramine, nortriptyline, trazodone, fluoxetine, lithium, and valproate for kleptomania (22, 23, 51, 52, 54); lithium for pathological gambling (56); and imipramine, desipramine, clomipramine, isocarboxazid, fluoxetine, and lithium for trichotillomania (41, 43, 44, 60, 61, 63, 64). Also, individuals with kleptomania have been reported to respond to ECT (52). In most cases, the patients reported reductions in the frequency and intensity of their irresistible impulses and impulsive behaviors, usually after several weeks of treatment with doses of medication typically effective for mood disorder. In some instances, the irresistible impulses recurred after discontinuation of the medication and remitted again when the medication was reinstituted (52, 54). Finally, numerous case reports and open studies of individuals with impulsive aggression due to a variety of conditions (i.e., organic mental disorder, personality disorder, schizophrenia) showed amelioration of aggressive behavior in response to β blockers, carbamazepine and other antiepileptics, lithium, psychostimulants, antidepressants, and various hormonal manipulations (in particular, antiandrogen treatments) (15, 17, 93).

**TABLE 5. Efficacy of Pharmacological Treatments for *DSM-III-R* Impulse Control Disorders Not Elsewhere Classified**

| | Rating of Efficacy[a] | | |
|---|---|---|---|
| Disorder and Studies | Antidepressants | Lithium | Anticonvulants |
| Intermittent explosive disorder (11, 47, 48, 93)[b] | 1 | 1 | 3 |
| Kleptomania (22, 23, 51, 52, 54) | 2 | 1 | 1 |
| Pathological gambling (56) | —[c] | 1 | —[c] |
| Pyromania | —[c] | —[c] | —[c] |
| Trichotillomania (41, 43, 44, 60, 61, 63, 64) | 3 | 1 | —[c] |

[a] 3=Supported by one controlled study, 2=supported by at least one open study, 1=supported by single case reports or small case series, 0=not supported by balance of evidence, but limited evidence for efficacy may be present.

[b] Many patients, but not all, had neurological abnormalities.

[c] Insufficient data.

## DISCUSSION

Although long recognized, the impulse control disorders in general remain a mysterious group of conditions. Even their diagnostic validity, individually and as a category, remains in question. Authors doubting the legitimacy of these disorders have generally argued that afflicted individuals do not really experience "irresistible" impulses but, rather, have voluntary control over their impulsive behaviors, or that their impulsive behaviors are nonspecific symptoms secondary to other underlying psychiatric disorders. Nevertheless, the literature contains numerous descriptions, from different countries and different historical periods, of individuals who perform harmful behaviors in response to overpowering, uncontrollable, irresistible, or "morbid" impulses. These reports date back to the early nineteenth century, when Esquirol (94) introduced the term *monomanies instinctives* (instinctive monomanias) to describe a form of insanity characterized by performance of impulsive acts without motive, in response to "instinctive" or involuntary, irresistible impulses. Subsequent writers (14, 35) have described similar syndromes with terms such as "partial moral mania," "impulsive insanity," "psychopathic forms of reaction," or "impulse neuroses." Thus, the consistency of the description of the irresistible or morbid impulse makes it difficult to dismiss its validity as a specific psychiatric symptom. That the *DSM-III-R* impulse control disorders not elsewhere classified appear to share a similar core disturbance of impulsivity and compulsivity (the so-called "irresistible" or "morbid" impulse)—regardless of the behavior performed—further suggests that they are related and should be grouped together.

The available studies of these impulse control disorders also suggest that they may be etiologically related to a variety of other psychiatric or medical disorders, including obsessive-compulsive disorder, addictive disorders, mood disorders, impulse control disorders in general, and organic mental disorders. First, morbid impulses and their consequent acts resemble obsessions and compulsions. Thus, kleptomania, pathological gambling, pyromania, and trichotillomania have been hypothesized to be forms of obsessive-compulsive disorder (22, 35, 41, 44, 95). This conceptualization is supported by studies showing high rates of obsessive-compulsive disorder in individuals with kleptomania (22, 23), pathological gambling (31), and trichotillomania (41, 42), studies showing higher than normal rates of obsessive-compulsive disorder in the families of individuals with kleptomania (23) and trichotillomania (44), and the finding that clomipramine may be more effective than desipramine in the treatment of trichotillomania (41).

Second, others (52, 88) have postulated that certain impulse control disorders (especially kleptomania and pathological gambling) would be better conceived as addictive disorders. For instance, the irresistible impulse to steal or gamble resembles the urge to drink or use drugs, and the "high" sometimes experienced with stealing or gambling is similar to that induced by alcohol or drugs (22, 53, 96). Indeed, gambling has been described as inducing "a stimulating, tranquilizing, or pain-relieving response" (29), and "self-medication" of benzodiazepine withdrawal symptoms through the thrill of kleptomanic stealing has been reported (52). Further, pathological gamblers may develop tolerance (96) and physiological withdrawal symptoms—including tremulousness, headaches, abdominal pain, diarrhea, nightmares, and cold sweats—after abrupt discontinuation of gambling (97). Also, as reviewed in this paper, high rates of alcohol and substance abuse are seen among individuals with intermittent explosive disorder, episodic dyscontrol, kleptomania, pathological gambling, and impulsive fire setting, and high rates of pathological or problem gambling occur among individuals with alcohol or substance abuse (67). Finally, self-help groups based on Alcoholics Anonymous (e.g., Gamblers Anonymous) have been reported to be helpful in the treatment of some pathological gamblers (87).

Third, given the frequent occurrence of affective symptoms or mood disorders in individuals with each of the five impulse control disorders analyzed, the apparent relief of depressive symptoms in response to kleptomanic stealing and pathological gambling, and the response of intermittent explosive disorder, kleptomania, pathological gambling, and trichotillomania to treatment with thymoleptics, others have speculated that these impulse control disorders may be related to mood disorder (21–23, 28, 31, 47, 49, 51, 53).

Fourth, some authors have noted the phenomenologic similarities of alcohol and drug abuse, paraphilias, and bulimia nervosa to the *DSM-III-R* impulse control disorders not elsewhere classified (3). This observation plus the high rates of *other* impulsive behaviors in persons with these disorders have prompted some authors to suggest that *all* of these conditions should be viewed as sharing a fundamental problem in impulse control and thus should be classified as impulse control disorders. The impulsive behavior is seen either as a failure of self-soothing mechanisms or as an attempt to relieve a variety of uncomfortable symptoms (4, 5). Lacey and Evans (4), for instance, reported that a substantial number of patients with substance use disorders, eating disorders, "classic" impulse control disorders, self-harm, and personality disorders were characterized not just by the presenting symptoms but by multiple impulsive behaviors. They termed these individuals "impulsivists" and suggested that they had "multi-impulsive personality disorder." Indeed, cases of individuals displaying more than one "classic" impulse control disorder have been reported (23).

Finally, some authors (22) have postulated that impulse control disorders (especially intermittent explosive disorder, kleptomania, and pyromania) are caused by organic conditions that induce or increase impulsivity; such conditions include hypoglycemia, narcolepsy, head trauma, dementia, and epilepsy. The evidence supporting a relationship between the impulse control disorders and epilepsy, for instance, includes phenomenologic similarities between impulse control disorders and complex partial seizures (15, 17, 22) and reports of patients with intermittent explosive disorder and kleptomania who responded to treatment with antiepileptic agents (15, 17, 23).

None of these conceptualizations, however, seems sufficiently inclusive. The impulse control disorders not elsewhere classified share high comorbidity and other features not only with obsessive-compulsive disorder, alcohol and other substance use disorders, mood disorders, and eating disorders but also with anxiety disorders. What could account for this large overlap in features among these various disorders? In an earlier report (98), we summarized data suggesting that major depression and a group of seven other disorders—including obsessive-compulsive disorder, bulimia nervosa, panic disorder, and attention deficit hyperactivity disorder—represented a family of disorders sharing a possible common physiologic abnormality. We termed this hypothesized family "affective spectrum disorder." The apparent phenomenologic similarities of the impulse control disorders not elsewhere specified to obsessive-compulsive disorder and bulimia nervosa—both forms of affective spectrum disorder—together with evidence linking these impulse control disorders to several other forms of affective spectrum disorder (including panic disorder, obsessive-compulsive disorder, attention deficit hyperactivity disorder, and major depression) might be parsimoniously explained by the hypothesis that the impulse control disorders not elsewhere classified themselves are also forms of affective spectrum disorder. Note that this hypothesis does *not* argue that the impulse control disorders are caused by affective spectrum disorder but, rather, that they may share the same postulated underlying physiologic abnormality as the other forms of affective spectrum disorder.

This hypothesis derives support from many of the major findings reviewed in this paper. These include 1) high rates of mood disorders (as well as anxiety and eating disorders) among individuals with kleptomania, pathological gambling, trichotillomania, and behavioral dyscontrol and among members of their families, 2) findings of serotonin and norepinephrine abnormalities in episodic dyscontrol and impulsive fire setting similar to those occurring in depression (99, 100), and 3) the response of a variety of these impulse control disorders to thymoleptics. Viewing the impulse control disorders not elsewhere classified as forms of affective spectrum disorder would also account for a number of other individual or anecdotal observations noted in this paper. These include case reports describing individuals with concurrent pyromania and major mood disorder (58, 59), findings of high rates of attention deficit hyperactivity disorder among pathological gamblers and individuals with behavioral dyscontrol (16, 17, 57), and findings of EEG abnormalities in pathological gamblers similar to those in individuals with attention deficit hyperactivity disorder (78). Additionally, among patients with bulimia nervosa, stealing has been associated with greater degrees of depression and obsessive-compulsive behavior (65). Also, many patients with other impulse control disorders (e.g., compulsive shopping, compulsive facial picking, and paraphilias) have been reported to have concurrent mood disorders and to respond to thymoleptics (6, 8). Indeed, the link of impulse control disorders to alcohol abuse (given as an example of an impulse control disorder in *DSM-III-R*) could be explained in part by the high rates of mood disorders found among alcoholics (101).

The hypothesis that impulse control disorders are forms of affective spectrum disorder is, of course, affected by several methodological limitations. Most important is the lack of systematic, controlled studies of impulse control disorders using operational diagnostic criteria. For instance, we were unable to locate any controlled phenomenologic or family history studies and only two controlled drug treatment trials.

Second, it might be argued that impulsive acts are not disorders in themselves but are merely nonspecific behaviors exhibited with greater than normal frequency in patients with mood disorders. These behaviors decline with thymoleptic treatment because the underlying, or primary, mood disturbance is corrected. This argument, however, fails to account for the observation that some patients experience irresistible impulses in the absence of affective symptoms and that most patients with mood disorders do not demonstrate irresistible impulses to perform harmful behaviors.

A third criticism is that the affective spectrum disorder hypothesis does not directly explain 1) the phenomenologic similarity of these impulse control disorders to complex partial seizures and the apparently high rates of epilepsy, EEG abnormalities, and other neurologic abnormalities among individuals with episodic dyscontrol, 2) the experience of withdrawal symptoms when the impulsive behavior is abruptly discontinued, 3) case reports and clinicians' impressions that some impulse control disorders may be associated with personality disorder, and 4) the response of behavioral dyscontrol to nonthymoleptic agents, in particular, β blockers.

Nevertheless, these criticisms aside, several lines of evidence suggest that the *DSM-III-R* impulse control disorders not elsewhere classified, or, more generally, disorders characterized by irresistible impulses or urges to perform specific senseless or harmful behaviors, may share a biological abnormality with other forms of affective spectrum disorder. The nature of this biological abnormality is unknown. However, accumulating findings from animal and human studies have implicated central serotonergic transmission in the regulation of sleep, appetite, sexual activity, and mood (behaviors typically deranged in mood disorder) (99); in the genesis of major depression and mania (99), suicide (74), obsessive-compulsive disorder (102), bulimia nervosa (103), panic disorder (104), and alcoholism (105); and in the expression of impulsive behavior (74, 75). Animal studies, for instance, demonstrate that serotonin deficit states are important in the expression of impulsive aggression (74, 75). Low CSF 5-HIAA concentrations similar to those found in impulsive arsonists and impulsive violent offenders have been found in individuals who have attempted or completed suicide (especially violent suicide) and homicide (74) and in patients with mood disorder (99). Taken together, these lines of evidence suggest that impulse control disorders, like other forms of affective spectrum disorder, may share an abnormality in serotonergic transmission.

However, it does *not* follow from this hypothesis that all forms of impulsivity or compulsivity are linked to one another or to mood disorder. Impulsive and compulsive behaviors are evident in a variety of psychiatric and neurologic conditions, including mood disorders, personality disorders, schizophrenia, Tourette's disorder, and epilepsy, as well as in normal mental life. Thus, various impulsive and compulsive behaviors most likely have different forms and etiologies. At this point, it appears only that "classic" impulse control disorders—disorders marked by irresistible, involuntary, and specific impulses or urges to perform harmful or senseless acts—may be forms of affective spectrum disorder.

In summary, despite a rich descriptive literature dating back over 150 years and their inclusion in the formal American psychiatric nomenclature since 1980, the impulse control disorders not elsewhere classified remain little studied. Debate over their diagnostic validity lingers, but many have argued that these and other impulse control disorders are legitimate mental disorders causing significant morbidity and that they are more common than realized. Substantial preliminary evidence, reviewed in this paper, suggests that intermittent explosive disorder, kleptomania, pathological gambling, pyromania, and trichotillomania are, in fact, valid diagnostic entities; that they are related to one another and should be grouped together; and that they are related to mood disorder and other forms of affective spectrum disorder. Systematic, controlled studies using operational diagnostic criteria should be done to clarify the validity and nature of this relationship and to determine the relationship of these disorders to other impulse control disorders.

# Dissociation and Posttraumatic Stress Disorder in Vietnam Combat Veterans

J. Douglas Bremner, M.D., Steven Southwick, M.D., Elizabeth Brett, Ph.D.,
Alan Fontana, Ph.D., Robert Rosenheck, M.D., and Dennis S. Charney, M.D.

*Objective: This study compared current dissociative symptoms and dissociation at the time of specific traumatic events in Vietnam combat veterans with posttraumatic stress disorder (PTSD) and Vietnam combat veterans without PTSD. Method: Vietnam combat veterans who sought treatment for PTSD (N=53) were compared to Vietnam combat veterans without PTSD (N=32) who sought treatment for medical problems. Dissociative symptoms were evaluated with the Dissociative Experiences Scale. Dissociation at the time of a combat-related traumatic event was evaluated retrospectively with the modified Dissociative Experiences Questionnaire. The Combat Exposure Scale was used to measure level of combat exposure. Results: There was a significantly higher level of dissociative symptoms, as measured by the Dissociative Experiences Scale, in patients with PTSD (mean=27.0, SD=18.0) than in patients without PTSD (mean=13.7, SD=16.0). This difference persisted when the difference in level of combat exposure was controlled with analysis of covariance. PTSD patients also reported more dissociative symptoms at the time of combat trauma, as measured retrospectively by the Dissociative Experiences Questionnaire (mean=11.5, SD=1.6) than non-PTSD patients (mean=1.8, SD=2.1). Conclusions: Dissociative symptoms are an important element of the long-term psychopathological response to trauma.*

(Am J Psychiatry 1992; 149:328–332)

A relationship between dissociation and symptoms of posttraumatic stress has been hypothesized since the time of Pierre Janet (1–4). Janet coined the term dissociation as the opposite of association—literally, the lack of connection between one piece of memory or consciousness and another (1). According to his theory, susceptible individuals who respond to traumatic events with dissociation develop long-term changes in neurobiological systems. These result in dissociative responses to subsequent stressful events, increased general dissociative symptoms, and an increased risk for stress-related psychiatric disorders such as what is known today as posttraumatic stress disorder (PTSD) (5).

There have been isolated reports of dissociative symptoms in veterans of World War I, World War II, and the Vietnam war (6–15). In addition, a study conducted by Spiegel et al. found a significantly higher rate of hypnotizability in Vietnam veterans with PTSD than in other patient groups or in normal control subjects (16). Spiegel et al. concluded that Vietnam veterans with PTSD may have more dissociative symptoms than other veterans.

The recent development of standardized instruments has made the measurement of dissociative symptoms possible. However, only one study has been published in which dissociative symptoms were measured in Vietnam veterans with PTSD (17). In that study, patients

Received April 9, 1991; revision received Sept. 18, 1991; accepted Oct. 10, 1991. From the National Center for Post-Traumatic Stress Disorder and the Northeast Program Evaluation Center, West Haven VA Medical Center; and the Department of Psychiatry, Yale University School of Medicine, New Haven, Conn. Address reprint requests to Dr. Bremner, 116A1 West Haven VA Medical Center, 950 Campbell Ave., West Haven, CT 06516.

Supported by a grant from the National Center for Post-Traumatic Stress Disorder.

with PTSD had levels of dissociative symptoms that were higher than those of patients with temporal lobe epilepsy and comparable to those of patients with multiple personality disorder (17). There have been no published reports thus far comparing patients with PTSD to a control group of combat veterans without PTSD. If Janet's theory is correct, certain susceptible individuals—those who develop PTSD—would be more likely to develop dissociative symptoms than other less susceptible individuals.

This study was undertaken, therefore, to determine if there are higher levels of dissociative symptoms, both currently and at the time of traumatic events, in combat veterans with PTSD than in combat veterans without PTSD. An effort was also made to determine whether dissociation is specific to PTSD symptoms or whether it is associated with nonspecific psychiatric distress.

## METHOD

The subjects were 85 Vietnam combat veterans at the West Haven Veterans Administration (VA) Medical Center. The Vietnam combat veterans with PTSD (N=53) had sought treatment for PTSD and included patients consecutively admitted to the inpatient unit (N=34) of the National Center for Post-Traumatic Stress Disorder, Division of Clinical Neurosciences, West Haven VA Medical Center, during a 5-month period. Patients with PTSD were also from the outpatient clinic of the national center (N=19) and were selected from patients consecutively admitted during a 3-month period by clinicians who were willing to refer their patients to be interviewed. Vietnam combat veterans without PTSD (N=32) had sought treatment for medical problems and were patients consecutively admitted to the medical center's outpatient ambulatory care clinic during a 3-month period.

Patients included in the study were those with a history of combat exposure, defined as having received hostile or friendly fire or having received incoming artillery rounds. Patients were assigned to PTSD and non-PTSD groups on the basis of a diagnosis of current PTSD as measured by the Structured Clinical Interview for DSM-III (SCID) (18). Patients with a history of psychosis, organic brain syndrome, or a medical illness that would preclude participation were excluded from the study. Of the 89 Vietnam combat veterans contacted, 85 (97.4%) agreed to participate in the study.

Dissociative symptoms were evaluated with the Dissociative Experiences Scale (19). The scale is a 28-item, self-report instrument for the measurement of dissociative experiences; it has a test-retest reliability of 0.84 (20). The scale has been used in large population samples and has been shown to discriminate significantly between patients with dissociative disorders or other disorders and normal control subjects when a cutoff score of 30 is used (19–21). The scale is intended for use in screening for dissociative symptoms and is not a diagnostic instrument.

Higher levels of combat exposure were anticipated in the PTSD patient group than in the non-PTSD patient group. Level of combat exposure was assessed with the Combat Exposure Scale, a self-report measure that has been shown to have acceptable reliability and validity (22). High combat exposure is defined as a score of greater than 24 on the scale (T.M. Keane, personal communication, Oct. 15, 1990).

An additional component of the study involved a comparison of dissociative symptoms to PTSD symptoms and general psychiatric symptoms. For this purpose, patients were evaluated with the Mississippi Scale for Combat-Related Posttraumatic Stress Disorder, a validated measurement of current PTSD symptom severity (23). The Mississippi scale assesses the full range of PTSD symptoms and quantifies scope and severity of symptoms. General psychiatric symptoms were examined with the global scale of the Brief Symptom Inventory. The inventory is a validated self-report instrument that assesses a broad range of psychiatric symptoms (24).

Dissociation at the time of traumatic events was examined with the modified Dissociative Experiences Questionnaire, which was developed for the purposes of this study. The questionnaire is a clinician-administered instrument for the assessment of dissociative states at specific time points; it consists of six questions from the Dissociative Experiences Questionnaire (C. Marmar, unpublished) and seven questions from another dissociation scale in development at our center (J.D. Bremner et al., unpublished). The questionnaire assesses the areas of amnesia, depersonalization, and derealization. Score is determined by the total number of positive responses to the 13 questions about dissociative states. Patients were asked to relate their most traumatic combat-related event, and the questionnaire was used in the assessment of dissociative states at that time. Specifically, symptoms in the areas of amnesia, depersonalization, and derealization were assessed.

Data from the Dissociative Experiences Scale were analyzed with standard parametric statistical methods. Since we anticipated a higher level of combat exposure in the PTSD group than in the non-PTSD group, we used analysis of covariance to compare scores on the Dissociative Experiences Scale for the PTSD and non-PTSD groups while controlling for the difference in combat exposure. To assess the relationship between dissociation (Dissociative Experiences Scale), PTSD symptoms (Mississippi scale), and nonspecific psychiatric symptoms (Brief Symptom Inventory global score), bivariate correlations were performed between scores on the Mississippi scale, Dissociative Experiences Scale, and the Brief Symptom Inventory-global scale in a subgroup of 40 PTSD patients. In order to assess the relationship between PTSD symptoms and dissociative symptoms while controlling for nonspecific psychiatric symptoms, we performed multiple linear regression in this subgroup. Multiple linear regression was also used to assess the relationship between dissociation at the time of combat trauma (modified Dissociative Experiences Questionnaire) and current PTSD symptom se-

verity (Mississippi Scale for Posttraumatic Stress Disorder) in a subgroup of 51 patients with and without PTSD. Covariates adjusted for in the model were other combat-related variables including combat exposure, exposure to atrocities, and number of months spent in Vietnam. Two-tailed tests of significance were used in all the analyses, and significance was defined as p<0.05.

## RESULTS

There were no significant differences in any of the demographic variables measured between combat veterans with and without PTSD (table 1).

Scores of the PTSD patients on the Dissociative Experiences Scale were almost double those of the non-PTSD patients: 27.0 versus 13.7 (table 2). Scores greater than 30 were present in 41.0% of patients with PTSD, compared with 10.7% of non-PTSD patients ($\chi^2$=7.37, df=1, p<0.01).

Combat exposure, as measured by the Combat Exposure Scale, was significantly greater in the PTSD patients than in the non-PTSD patients (table 2). However, a significant difference in Dissociative Experiences Scale scores between the PTSD and non-PTSD groups persisted when the difference in combat exposure between the groups was controlled for with analysis of covariance (F=12.29, df=2, 59, p<0.05).

PTSD patients had higher levels of nonspecific psychiatric distress, as measured by the Brief Symptom Inventory (table 2). The relationship among dissociative symptoms, PTSD symptoms, and nonspecific psychiatric symptoms was examined in a subgroup of Vietnam combat veterans with PTSD. Bivariate analysis showed a correlation between dissociative symptoms (Dissociative Experiences Scale) and PTSD symptoms (Mississippi scale) (r=0.34, df=39, p=0.03), as well as between dissociative symptoms and nonspecific psychiatric symptoms (r=0.47, df=39, p=0.002). When the relationship between dissociative symptoms and PTSD symptoms was examined while nonspecific psychiatric symptoms were controlled for in the PTSD patients by using multiple linear regression, scores on the Mississippi scale were more strongly associated with scores on the Brief Symptom Inventory (beta=0.75, df=1, 37, p<0.05) than with scores on the Dissociative Experiences Scale (beta=0.02, df=1, 37, p=0.90).

A significant difference was also observed between the PTSD and non-PTSD groups in the level of dissociation at the time of combat-related traumatic events. Scores on the modified Dissociative Experiences Questionnaire were significantly higher in the PTSD group than in the non-PTSD group (mean=11.5, SD=1.6 versus mean=1.8, SD=2.1) (t=20.58, df=60, p<0.001). Dissociation at the time of combat trauma in a subgroup of patients with and without PTSD was associated with current PTSD symptom severity (measured by the Mississippi scale), determined by multiple linear regression. Covariates adjusted for in the model included level of combat exposure, participation in atrocities, and number of months in Vietnam. Dissociation at the time of the combat trauma showed the strongest association (beta=0.53, df=1, 45, p=0.0001); of the other variables included in the model, only participation in atrocities showed a significant association (beta=0.26, df=1, 45, p=0.02).

## DISCUSSION

In this study of Vietnam veterans there was a significantly higher level of dissociative symptoms in combat veterans with PTSD than in combat veterans without PTSD. The higher level of dissociative symptoms associated with PTSD persisted after the difference in combat exposure between the PTSD and non-PTSD groups was controlled for. In addition, level of dissociative symptoms was correlated with severity of PTSD symptoms as measured by the Mississippi scale.

These findings suggest that dissociation is associated with PTSD and that combat exposure alone does not explain the high levels of dissociative symptoms seen in veterans with PTSD. Certain individuals may be more susceptible than others to develop dissociative symptoms in response to the stress of combat. This may provide support for Janet's theory that susceptible individuals who respond to traumatic events with dissociation are at a higher risk of developing trauma-related psychiatric disorders such as PTSD.

The high rate of dissociative symptoms in patients with PTSD is consistent with other studies (17, 22, 25). PTSD patients' scores on the Dissociative Experiences Scale (mean=27.0, SD=18.0) were similar to those of a previously reported sample of Vietnam veterans with PTSD (mean=27.5) (17) and were higher than scores of a group of men between the ages of 41 and 50 who were selected from a general population sample (mean=8.7, SD=9.3) (28). Scores on the Dissociative Experiences Scale showed a wide range, as evidenced in the high standard deviations in both the PTSD and non-PTSD groups. It appears that there are subgroups of PTSD patients with high dissociative symptoms and other subgroups with low dissociative symptoms. In fact, inspection of individual Dissociative Experiences Scale scores in the PTSD patient group suggested that this was the case. There may be factors unrelated to combat that influence the level of dissociative symptoms in patients with combat-related PTSD. In addition, the non-PTSD patients in our study had higher scores on the Dissociative Experiences Scale (mean=13.7, SD=16.0) than men of the same age group from the general population sample. The wide range in scale scores in the non-PTSD group may be explained by the fact that there were some veterans in the non-PTSD group who suffered from partial PTSD. These veterans may have high levels of dissociative symptoms when compared to a cross-section of the general population, although not to the degree of patients who meet full criteria for PTSD.

Our findings also suggest a connection between dissociation at the time of combat trauma and the development of PTSD. There was a significant difference in dissociative response at the time of traumatic combat-related events between PTSD and non-PTSD patients, although the results should be interpreted with caution because of retrospective reporting. PTSD patients frequently reported experiences of amnesia at the time of traumatic events, such as one veteran who said, "After I saw my buddy hit, something inside of me died, and I don't remember anything that happened after that." Veterans also reported experiences of derealization, such as, "Everything seemed to be in slow motion," "Colors were blurred," "There was no sound," and "It seemed as if I were in a tunnel." Similarly, depersonalization was reported, as in the case of another veteran who said, "I felt myself separating from myself and looking down at the person who was in combat, and feeling sorry for him." Our findings are consistent with the literature, which suggests an association between trauma and dissociation (26–34).

What distinguishes individuals who are prone to dissociation at the time of combat trauma? One possibility is that discrete traumatic events may have a variable impact depending on the individual. PTSD patients in our study frequently reported dissociation after events that had personal significance for them, such as witnessing the death of a close friend. Another possibility is that degree of hypnotizability predisposes individuals to dissociation. Degree of hypnotizability has been associated with level of dissociative symptoms (35), and patients with PTSD have been found to have a higher degree of hypnotizability than other patient groups (16, 25). Variations in hypnotizability have been noted in the general population (36); these variations are stable over time (37). There is also some evidence which suggests that hypnotizability may have a genetic basis (38). Hypnosis has been advocated as a therapeutic treatment for posttraumatic stress disorder (39). Perhaps highly hypnotizable individuals are more likely to dissociate at the time of trauma and hence to develop trauma-related psychopathology.

It is important to note that dissociative symptoms do not appear to be uniquely associated with PTSD symptoms. Scores on the Mississippi scale were more strongly associated with scores on the Brief Symptom Inventory-global scale than with scores on the Dissociative Experiences Scale. It is possible that dissociation is associated with the higher level of nonspecific psychiatric symptoms seen in patients with PTSD and not with PTSD-specific symptoms that are measured by the Mississippi scale. Such conclusions should be made with caution, however, since the relationship between nonspecific psychiatric symptoms and specific PTSD symptoms in patients with PTSD is still under investigation. Future studies of combat veterans with psychiatric disorders other than PTSD are required in order to determine whether higher levels of dissociative symptoms are specific to PTSD.

# Exposure to Atrocities and Severity of Chronic Posttraumatic Stress Disorder in Vietnam Combat Veterans

Rachel Yehuda, Ph.D., Steven M. Southwick, M.D.,
and Earl L. Giller, Jr., M.D., Ph.D.

*Objective: The authors' objective was to explore aspects of trauma associated with severity of posttraumatic stress disorder (PTSD) in Vietnam veterans. Method: Several ratings of stress exposure and symptom severity were administered to 40 patients with combat-related PTSD. Results: A significant relationship was observed between exposure to atrocities and the impact of PTSD on veterans' lives, as measured by the Mississippi Scale for Combat-Related Posttraumatic Stress Disorder. Exposure to atrocities was also significantly correlated with current symptom severity. In contrast, combat exposure alone was not significantly associated with overall symptom severity. Both atrocity and combat exposure, however, were significantly related to reexperiencing symptoms. Conclusions: The data suggest that the enduring effect and severity of PTSD symptoms on an individual are associated more with exposure to brutal human death and suffering than the threat of death associated with combat.*

(Am J Psychiatry 1992; 149:333–336)

Several investigators have shown a relationship between the intensity of combat exposure and the subsequent development of posttraumatic stress disorder (PTSD) (1–4). In studies examining the role of particular wartime stressors on postwar adjustment, exposure to atrocities has also been reported to increase the risk of psychological and behavioral disturbance in veterans beyond that associated with exposure to combat (1–6) and has been found to increase the probability of developing PTSD in Vietnam veterans (1, 3, 5). One of these studies showed that participation in atrocities was specifically related to the development of PTSD, while not increasing the risk for development of other psychiatric disorders (5).

Some investigators have suggested that different types of traumatic, war-related experiences may be associated with different symptom patterns or subtypes of PTSD in Vietnam veterans. For example, Laufer et al. (3) demonstrated that combat veterans with PTSD who had participated in atrocities were more likely to have avoidant symptoms than were veterans who had witnessed, but had not participated in, such events. This group also demonstrated that war veterans with heavy combat experience were more likely to show intrusive rather than avoidant symptoms. Differentiating subgroups of PTSD patients by type of stress exposure or symptom profile may explain why certain patients are amenable to some forms of therapeutic interventions, while others remain treatment refractory. It has been shown, for example, that tricyclic antidepressants and monoamine oxidase inhibitors may be particularly useful for treating reexperiencing, but not avoidance, symptoms (7). In contrast, other classes of antidepressants, such as fluoxetine, may be particularly efficacious in treating avoidance symptoms (8).

Although both exposure to atrocities and intensity of combat have each been shown to independently contribute to the development of PTSD, it is not known whether or to what degree these variables affect symptom severity in those veterans who meet criteria for PTSD. Within the group of Vietnam veterans who suffer from PTSD (approximately 15% of combat veterans), there exists a wide range of severity of symptoms. Some individuals are able to maintain productive work and social lives, and others suffer from symptoms that are so debilitating that they are essentially unable to participate in the routine activities of everyday life. The aim of the present study was to investigate the effect of different war stressors (i.e., participation in atrocities and exposure to combat) on severity of chronic PTSD and depressive symptoms in both inpatients and outpatients still seeking and receiving treatment for PTSD symptoms.

## METHOD

Forty male Vietnam combat veterans with PTSD (age range=39–48 years; mean=42.3, SD=3.6) according to *DSM-III-R* participated in the study after providing informed consent. Patients fulfilling inclusion criteria were selected from patients consecutively admitted to either an inpatient brief treatment unit or an outpatient clinic and were studied 4 to 8 weeks after seeking treatment. Patients were excluded from study if they had a co-occurring organic, psychotic, or major medical illness or if they were seeking treatment primarily for other comorbid conditions such as substance abuse or affective disorder.

PTSD was diagnosed by consensus, on the basis of information from structured interview data, by using the Structured Clinical Interview for *DSM-III-R* (SCID) (9), reports from the treatment team, and scores on the Mississippi Scale for Combat-Related Posttraumatic Stress Disorder (cutoff score=107) (10). The Schedule for Affective Disorders and Schizophrenia (SADS) interview was used to obtain comorbid Research Diagnostic Criteria diagnoses (11).

The Figley Scale for Combat Posttraumatic Stress Disorder (C.R. Figley, R.H. Stretch, unpublished) and the Impact of Event Scale (12) measured symptom severity over the past week. The Mississippi PTSD scale measured both symptom severity and the effects of symptoms on the individual's life. Severity of depression was assessed with the Hamilton Rating Scale for Depression (13). Scores on all four symptom rating scales were intercorrelated (see Results).

The expanded Combat Exposure Scale (14) was used to assess type and frequency of combat exposure. The Atrocity Scale (E. Brett, R. Laufer, unpublished) was used to quantify exposure to and/or participation in particularly traumatic war-related behaviors on a scale of 6–36 (6=no experience of any atrocities, 36=active participation in all). The scale consists of six questions concerning war-related crimes such as torturing and killing of prisoners of war and civilians and mutilation of corpses. Subjects were asked to state whether they had 1) no experience of, 2) heard about, 3) witnessed, or 4) participated in the events. Test-retest reliability was r=0.86 for the Combat Scale and r=0.72 for the Atrocity Scale. Interrater reliability for the Combat Scale was r=0.92 and for the Atrocity Scale, r=0.80. Scores on the combat and atrocity scales were not significantly correlated (r=0.25, df= 38, n.s.).

Differences in symptom severity and severity of stressor between inpatients and outpatients were determined by using Student's t test (two-tailed). The relationship between symptom severity and severity of stressor was determined by using correlational analysis (Pearson's coefficient r).

## RESULTS

Exposure to atrocities and scores on the Mississippi scale were strongly associated (table 1). Atrocity scores were also correlated with scores on the Figley scale and Impact of Event Scale and with current severity of depression as measured by the Hamilton depression scale (table 1). In contrast, exposure to combat was not associated with scores on the Mississippi, Figley, impact of event, or Hamilton scales (table 2). Both atrocity and combat exposure were significantly correlated with scores on the Intrusive subscale of the Impact of Event Scale; neither measure was correlated with scores on the Avoidance subscale (table 1).

Inpatients were comparable to outpatients with respect to level of symptoms as assessed by scores on the Mississippi, Figley, and Hamilton scales, although there was a trend for scores to be higher on the Impact of Event Scale in the inpatient group (table 2). In regard to severity of particular symptom clusters, there was a significantly greater degree of intrusive symptoms in the inpatient group (table 2). Inpatients were similar on combat exposure but showed a significantly greater exposure to atrocities than outpatients (table 2).

## DISCUSSION

This study supports the notion that the type of trauma experienced by an individual, not only the amount, contributes to the severity of PTSD symptoms experienced over the course of the illness and to the impact of these symptoms on overall functioning. These results are consistent with the general notion that both severity and type of stressor may contribute to the course of psychopathology (15) and specifically with studies suggesting a role of exposure to atrocities in the development of PTSD and certain PTSD symptoms. We did not observe specific patterns of avoidance symptoms in veterans exposed to or participating in atrocities, as reported by other investigators (3). However, it may be that treatment-seeking veterans do not have as many avoidance symptoms as veterans selected from the general population.

The relationship between atrocity exposure and scores on the Mississippi scale was found to be particularly robust. The Mississippi scale represents a continuous measure of PTSD symptoms, including the effect of PTSD symptoms on the individual's life, and reflects both acute symptoms of PTSD and long-term or trait aspects of PTSD (10). Because individuals were included only if they had a Mississippi scale score of 107 or greater, the relationship between Mississippi scale scores and atrocity exposure in the present study represents the effect of atrocities on severity of the PTSD.

Scores on the state symptom measures, the Figley scale and Impact of Event Scale, were also positively correlated with atrocity exposure. The Figley scale was developed to measure current symptom severity in combat veterans in the three symptom clusters of PTSD (C.R. Figley, R.H. Stretch, unpublished). The Impact of Event Scale was developed to assess symptoms of PTSD, regardless of the stressor, but it inquires about only two symptom clusters of PTSD (12). Nonetheless, both scales showed a high correlation with each other, suggesting that they tap into similar dimensions of overall state severity.

In the present report exposure to combat was not correlated with overall PTSD symptom severity, whereas other reports have observed stronger relationships between severity of combat exposure and overall PTSD symptoms (1, 10, 16). In other studies, however, combat exposure and PTSD symptoms were assessed in larger groups of veterans, some of whom did not meet diagnostic criteria for PTSD. In the present study, there may have been a narrower range of PTSD symptoms because all veterans met diagnostic criteria for this disorder. Furthermore, the range of combat exposure in the present study was narrower than that in other published reports. Nonetheless, there was a significant correlation between combat exposure and intrusive symptoms, which supports the findings of Laufer et al. (3).

Inpatients and outpatients were compared to each other to determine whether these groups would differ with respect to severity of illness or stressor. Inpatients and outpatients did not differ with respect to total scores on symptom assessment of PTSD. However, inpatients showed a significantly higher level of intrusive symptoms. The higher level of intrusive symptoms in the inpatient group may reflect an overall increase in general distress leading to hospitalization and/or an exacerbation of intrusive symptoms in response to intensive war-focused therapy in the hospital. Inpatients also had a greater degree of exposure to atrocities but not combat, suggesting that exposure to atrocities and attending severity of illness may be more prevalent among veterans seeking inpatient treatment. Alternatively, the inpatient unit may provide an environment more conducive to the safe reporting of atrocities.

**TABLE 2. Scores of Inpatient and Outpatient Vietnam Combat Veterans With PTSD on Measures of Stressor Severity and PTSD Symptoms**

| | Inpatients (N=16) | | Outpatients (N=24) | |
|---|---|---|---|---|
| Scale | Mean | SD | Mean | SD |
| Combat Exposure Scale | 33.4 | 7.5 | 34.2 | 12.9 |
| Atrocity Scale | 17.7[a] | 3.4 | 14.4 | 3.3 |
| Mississippi scale | 128.2 | 16.6 | 124.8 | 15.5 |
| Figley scale | 37.3 | 8.7 | 33.3 | 8.6 |
| Impact of Event Scale | | | | |
| Intrusive subscale | 26.4[b] | 5.3 | 20.0 | 8.0 |
| Avoidance subscale | 19.9 | 7.8 | 20.5 | 9.9 |
| Total | 47.2[c] | 9.0 | 40.5 | 11.2 |
| Hamilton depression scale | 21.9 | 6.6 | 20.2 | 7.8 |

[a] t=3.08, df=37, p<0.005, two-tailed t tests for all comparisons.
[b] t=2.58, df=38, p<0.01.
[c] t=1.93, df=38, p<0.10.

Exposure to atrocities was also particularly related to severity of depression as measured by the Hamilton scale. We have recently reported a higher level of introjective or guilt-associated symptoms of depression in veterans with PTSD than in noncombat veterans with major depressive disorder (17). In addition, within the PTSD group, we found a wide range of guilt-associated symptoms, with some veterans experiencing few guilt-associated depressive symptoms and others experiencing many such symptoms. Clearly, exposure to atrocities has the capacity to evoke profound feelings of guilt, and it may be that veterans who have been exposed to atrocities have a greater tendency to experience symptoms of depression, particularly introjective symptoms.

A possible confounding factor in the present study is that PTSD is an episodic illness, and symptom severity may be more acute in various phases of illness, whereas exposure to combat and atrocities is a constant historical factor. Thus, it is not surprising that the greatest degree of correlation was observed between exposure to atrocities and the Mississippi scale, which taps into longer-term readjustment symptoms. A thorough evaluation of the relationship between stressor and symptom severity may require a multiaxial approach using several instruments and data concerning time course of symptom severity.

Another potential methodological problem in this study concerns the reporting of atrocities. Other investigators have suggested that participation in atrocities may be underreported in Vietnam veterans (1–6). We cannot rule out the possibility that veterans underreported their participation in war crimes, even though they were studied after engaging in treatment. Finally, because the present investigation did not study combat veterans without PTSD, it is not possible to address the question of differential risks associated with the development of a stress disorder following exposure to combat versus exposure to atrocities, as has been addressed in other studies. Nonetheless, the data support the hypothesis that exposure to atrocities plays an important role in the longitudinal course of PTSD.

# Symptoms of PTSD in 124 Survivors of the Holocaust

Klaus Kuch, M.D., and Brian J. Cox, M.A.

*Objective: Survivors of the Holocaust are expected to be at risk for posttraumatic stress disorder (PTSD), but few empirical data are available. This study investigated PTSD symptoms in Holocaust survivors with well-documented exposure to trauma. Method: The German files of 124 Jewish Holocaust survivors who were judged to be free from bipolar affective disorder, obsessive-compulsive disorder, and organic brain syndrome were selected from those of 145 applicants to West German compensation boards. The psychiatric assessments were reexamined for explicit descriptions of current PTSD symptoms according to the* DSM-III-R *diagnostic criteria. A subgroup of 20 Auschwitz survivors with tattooed identification numbers were also compared with the 45 survivors who had not been in concentration camps. Results: Sixty-three percent of the total sample had been detained in concentration camps, and an average of 78% of their first-degree relatives were reported killed in the Holocaust. Forty-six percent of the total sample met the DSM-III-R criteria for PTSD. The most common symptoms were sleep disturbance, recurrent nightmares, and intense distress over reminders. The tattooed Auschwitz survivors had significantly more symptoms and were three times more likely to meet diagnostic criteria for PTSD than the survivors who had not been in concentration camps. Conclusions: The results suggest a greater risk of chronic PTSD in survivors who were exposed to atrocities. Most survivors had not received adequate psychiatric care.*

(Am J Psychiatry 1992; 149:337–340)

Many survivors of the World War II Nazi concentration camps suffer from chronic psychiatric symptoms (1–8). However, in comparison to Vietnam war veterans, Jewish Holocaust survivors have been virtually neglected by the empirical literature on posttraumatic stress disorder (PTSD). No recent study has explored the full spectrum of their symptoms.

The purpose of this study was to describe symptoms of PTSD (*DSM-III-R*, p. 250) and related phenomena as systematically as possible in a relatively large sample of Jewish Holocaust survivors and to gain an impression of the long-term effects of the concentration camps. Documentation is important for historical reasons. A description of late effects may also contribute to our understanding of the clinical course of PTSD and to the care of other persecuted minorities.

## METHOD

The subjects for this study were 124 Jewish survivors of the Holocaust (58 male and 66 female) whose mean age was 62.0 years (SD=9.4, range=39–86). The minimum entrance criterion for the study, criterion A for PTSD in *DSM-III-R*, was having witnessed atrocities while personally at risk. The subjects were selected out of 145 applicants for German compensation. Because this study was aimed at the symptoms of PTSD, potential subjects with confirmed or suspected organic brain syndrome (N=19), bipolar affective disorder (N=1), and obsessive-compulsive disorder (N=1) were excluded. One subject was included in the total sample but excluded from consideration in the subgroups we describe because of a stay in Auschwitz of less than 1 month. The remaining 123 subjects were divided into three groups. 1) One group (N=78) had been detained in various concentration camps for 1 month or more. 2) A subgroup (N=20) of the concentration camp group had been detained in one extermination camp (Auschwitz) and had been tattooed on the volar side of their left forearms with identification numbers beginning with the letter A. This subgroup had had particularly well-documented exposure to extreme atrocities and threat of death. 3) A third group (N=45) had not been in concentration camps. These subjects had been in labor camps and ghettos or had hidden in the illegal un-

**TABLE 1. Frequency of the *DSM-III-R* Symptoms of PTSD in 124 Holocaust Survivors**

| | Total Sample (N=124) | | Concentration Camp Survivors (N=78) | | Tattooed Concentration Camp Survivors (N=20) | |
|---|---|---|---|---|---|---|
| Symptom | N | % | N | % | N | % |
| B(1) Intrusive recollections | 69 | 55.6 | 51 | 65.4 | 16 | 80.0 |
| B(2) Recurrent nightmares | 103 | 83.1 | 68 | 87.2 | 18 | 90.0 |
| B(3) Feelings of recurrence | 3 | 2.4 | 1 | 1.3 | 1 | 5.0 |
| B(4) Intense distress over reminders | 93 | 75.0 | 62 | 79.5 | 15 | 75.0 |
| C(1) Avoidance of thoughts and feelings | 48 | 38.7 | 38 | 48.7 | 9 | 45.0 |
| C(2) Avoidance of activities and situations | 62 | 50.0 | 50 | 64.1 | 14 | 70.0 |
| C(3) Psychogenic amnesia | 4 | 3.2 | 3 | 3.8 | 2 | 10.0 |
| C(4) Diminished interest | 80 | 64.5 | 52 | 66.7 | 13 | 65.0 |
| C(5) Detachment | 39 | 31.5 | 29 | 37.2 | 7 | 35.0 |
| C(6) Restricted affect | 35 | 28.2 | 26 | 33.3 | 7 | 35.0 |
| C(7) Sense of foreshortened future | 33 | 26.6 | 22 | 28.2 | 7 | 35.0 |
| D(1) Sleep disturbance | 119 | 96.0 | 77 | 98.7 | 20 | 100.0 |
| D(2) Irritability/anger | 64 | 51.6 | 40 | 51.3 | 10 | 50.0 |
| D(3) Difficulty concentrating | 83 | 66.9 | 53 | 67.9 | 15 | 75.0 |
| D(4) Hypervigilance | 66 | 53.2 | 48 | 61.5 | 14 | 70.0 |
| D(5) Exaggerated startle response | 17 | 13.7 | 11 | 14.1 | 5 | 25.0 |
| D(6) Physiologic reactivity | 75 | 60.5 | 54 | 69.2 | 15 | 75.0 |

derground. They represented a well-documented comparison group with relatively less exposure to atrocities than the tattooed concentration camp survivors. The three groups did not differ significantly in age, sex, or date of assessment.

All 124 subjects were seen by the first author for independent psychiatric examinations requested by German compensation boards. The examination included a 1–2-hour psychiatric interview and a review of the compensation board files. It had been the practice of the psychiatrist to record current symptoms with the assistance of checklists. He was directed by the guidelines of the West German compensation law (9) to examine for exposure to "abuse, characterological sensitization and chronic non-phasic depression." The compensation board files included an affidavit and other documentation of the applicant's persecution and symptoms as well as medical reports submitted by the applicant.

For this study the German-language psychiatric assessments were reviewed for the explicit presence of current PTSD symptoms listed in *DSM-III-R*. For the overall sample the mean time span between the board-ordered assessment and scoring of the record for the study was 7.5 years (SD=5.7, range=0–17). Thirty-eight percent (N=47) of the subjects had been seen within the past 3 years. The date of the psychiatric assessment had no significant effect on whether symptoms met the diagnostic criteria (r=0.14). Symptoms were scored according to the *DSM-III-R* diagnostic criteria. A minimum of one category B symptom, three category C symptoms, and two category D symptoms (table 1) were required for a *DSM-III-R* diagnosis of PTSD.

## RESULTS

The 78 concentration camp subjects (62.9%) had been detained in the camps for a mean of 14.7 months (SD=11.7, range=1–60). Sixty-seven subjects (54.0%) had been in labor camps (mean=26.5 months, SD=14.5, range=2–62); 46 (37.1%) had been in ghettos (mean=25.7 months, SD=12.7, range=2–52); and 28 (22.6%) had been in hiding (mean=16.6 months, SD=15.7, range=1–51). These figures are not exclusive, in the sense that concentration camp subjects had also spent time in ghettos and labor camps. On average, 78% of the first-degree relatives of each subject were reported killed in the Holocaust. A higher percentage of the first-degree relatives of the tattooed subjects (87.7%) than of the subjects who had not been in concentration camps (76.9%) had been killed (t=1.68, df=58, p<0.10).

The mean age of the subjects at the onset of persecution was 19.3 years (SD=6.5, range=3–51). At the time of the examination, 100 (80.6%) of the subjects were married, 14 (11.3%) were widowed, and six (4.8%) were divorced. Data on marital status were incomplete for four subjects (3.2%). One hundred three (83.1%) of the subjects had children, and 20 (16.1%) were childless. For one subject there was no information about parenthood.

All subjects had been referred by German compensation boards through consular offices and were living in the Toronto area. Eighty-six (69.4%) had migrated directly from Europe to Canada. Fifteen (12.1%) had migrated to three countries or more. The subjects were predominantly blue-collar workers. Compared to full-time work status (100%), the mean percentage of time spent at work was 61.9% (SD=26.7%, range=0%–100%).

The subjects had received a mean of 1.7 confirmed medical diagnoses (SD=1.5, range=0–6) since the Holocaust. Thirty-two (25.8%) of the subjects were taking antihypertensive medications, 13 (10.5%) were taking antidyspeptics, 66 (53.2%) were taking analgesics, and 50 (40.3%) were taking other drugs for medical conditions. There was unremitting head pain in 111 (89.5%) of the subjects, gastrointestinal pain in 41 (33.1%), generalized musculoskeletal pain in 39 (31.5%), spinal pain in 37 (29.8%), and chest pain in 14 (11.3%). Sixty-three subjects (50.8%) reported persistent dizziness.

For treatment of psychiatric symptoms, 19 (15.3%) of the subjects were taking antidepressants, 80 (64.5%) were taking benzodiazepines, eight (6.5%) were taking major tranquilizers, and two (1.6%) were taking other psychiatric medications. Twenty-two subjects (17.7%) had received psychotherapy.

The frequency of each symptom of PTSD according to *DSM-III-R* is presented in table 1 for the total sample, for all of the concentration camp survivors, and for the subgroup of tattooed Auschwitz survivors. Fifty-eight (46.8%) of the subjects in the total sample, 40 (51.3%) of the 78 concentration camp survivors, and 13 (65.0%) of the 20 tattooed survivors met the *DSM-III-R* criteria for PTSD.

The tattooed concentration camp survivors had a higher number of PTSD symptoms (mean=9.4, SD=2.4) than did the subjects who had not been in concentration camps (mean=6.7, SD=2.4). This difference was significant ($t=4.16$, df=63, $p<0.001$). Differences between the tattooed survivors and the survivors who had not been in concentration camps were significant for intrusive recollections (80.0% and 40.0%, respectively; $\chi^2=7.35$, df=1, $p<0.007$), for avoidance of activities and situations reminiscent of the trauma (70.0% and 26.7%; $\chi^2=9.10$, df=1, $p<0.003$), and for hypervigilance (70.0% and 40.0%; $\chi^2=3.86$, df=1, $p<0.05$). There was a trend toward a significant difference in physiologic reactivity (75.0% and 46.7%; $\chi^2=3.42$, df=1, $p<0.07$). Although 13 (65.0%) of the 20 tattooed subjects met the *DSM-III-R* criteria for PTSD, only 10 (22.2%) of the 45 subjects who had not been in concentration camps did—a significant difference ($\chi^2=10.46$, df=1, $p<0.002$).

## DISCUSSION

Direct exposure to the Nazi Holocaust surely qualifies as a traumatic experience, and given its magnitude, many survivors are expected to suffer from PTSD. Almost half of our sample of Holocaust survivors met the *DSM-III-R* criteria. Among these, sleep disturbances with nightmares of Holocaust-related content were almost universal. Reminders of the Holocaust evoked intense distress and associated physiologic reactivity in most survivors. Intrusive recollections, avoidance of reminders, difficulty concentrating, diminished interest in the affairs of daily living, hypervigilance, and irritability were present in a majority. Psychogenic amnesia and feelings of recurrence were uncommon (table 1). By comparison, "flashbacks" are common in Vietnam veterans. Perhaps this discrepancy is due to the apparent absence of substance abuse in our sample (10).

Twenty survivors from a notorious extermination camp (Auschwitz) had been tattooed with identification numbers and represented a subgroup with well-documented exposure to extreme atrocities. When we compared them with a group of 45 survivors who had not been in concentration camps, the tattooed Auschwitz survivors experienced more recurrent and intrusive recollections, were more hypervigilant, and made more efforts to avoid activities and situations reminiscent of the camps. The Auschwitz survivors were also three times more likely to meet the diagnostic criteria for PTSD. This difference is all the more remarkable when one considers the number of years that have passed since the Holocaust.

Prolonged exposure to atrocities may produce irreversible effects (1–8, 11). Two studies reported in the past few years also found persistent distress and sleep disturbance in Holocaust survivors (12, 13). In an authoritative paper published 30 years ago, Eitinger (1) described symptoms that resembled those of our sample. He noted that symptoms were particularly severe among prisoners with death sentences. This study presents data that support those findings.

The results of our study should be interpreted with caution. It was not a blind study and our instrument, the list of *DSM-III-R* criteria, has not had norms established to differentiate the effects of catastrophic stressors from the effects of aging. Also, our subjects had been exposed to resettlement and medical illness.

The Holocaust survivors reported a disturbing lack of psychiatric care in spite of our health care system's reputed accessibility. More than half of the subjects were taking benzodiazepines, but only in minimal doses. Less than one-fourth were taking antidepressants or had been in psychotherapy at any time after the war. The reasons for this are unclear. Perhaps survivors avoid a reminder of atrocities in the form of a detailed psychiatric history. Perhaps physicians avoid taking detailed histories of brutality and may therefore not recognize cases of PTSD (14). Perhaps it was demoralization (15) that undermined treatment attempts. Future research may investigate the utilization of health care services by severely traumatized survivors, which has implications for the provision of services and for compliance with treatment.

## Information on APA Periodicals at the 1992 Annual Meeting

*American Journal of Psychiatry* staff will be located in the APA Resource Center and the editorial office in Room 19, Level 1, Convention Center. Hours of operation: Saturday, May 2, noon–5:00 p.m.; Sunday, May 3, 10:00 a.m.–5:00 p.m.; Monday, May 4, through Thursday, May 7, 8:00 a.m.–5:00 p.m. Staff at both locations will be available to schedule office appointments with the Editor, answer authors' questions, and receive papers submitted for publication. The *Journal* publishes only original material that has not been published elsewhere in any form and that is not being considered for publication elsewhere. Five copies are required.

*Hospital and Community Psychiatry* staff will be located in the APA Resource Center. Hours of operation are the same as the Resource Center: Saturday, May 2, noon–6:00 p.m.; Sunday, May 3, 8:00 a.m.–6:00 p.m.; Monday, May 4, through Wednesday, May 6, 7:30 a.m.–6:00 p.m. Staff will be available to answer questions about *H&CP* and about writing for publication in psychiatric journals. Authors may submit papers (unpublished material) for publication. Five copies are required.

*Psychiatric News* operates its news gathering and reporting activities from Room 19, Level 1, Convention Center. Hours of operation: Sunday, May 3, 10:00 a.m.–5:00 p.m.; Monday, May 4, through Thursday, May 7, 8:00 a.m.–5:00 p.m. Persons who wish to contact editors or reporters may make arrangements for appointments here, or may leave written announcements, suggestions for articles, or letters to the editor for the newspaper's consideration.

# Mania Compared With Unipolar Depression in Old Age

Kenneth I. Shulman, M.D., S.M., Mauricio Tohen, M.D., Dr.P.H.,
Andrew Satlin, M.D., Gopinath Mallya, M.D., and Douglas Kalunian, M.D.

---

*Objective: The goal of this study was to clarify the meaning and importance of mania in old age. Method: The authors conducted a retrospective study of 50 elderly patients consecutively admitted to a private mental hospital with an index episode of mania. As a comparison group, they used 50 age- and sex-matched patients with unipolar depression. They reviewed the charts of the 100 patients for family history, clinical course, and neurological disorders. Outcome was determined by contacting patients, families, physicians, institutional settings, and vital statistics records. Survival analysis compared mortality rates. Results: The manic patients had a greater familial predisposition to affective disorder and were younger at first psychiatric hospitalization. For the 20 manic patients whose first affective episode was depression, an average of 15 years elapsed before mania became manifest. Eighteen of the manic patients, compared with only four of the depressed patients, had neurological disorders. The manic patients had a significantly higher mortality rate than the depressed patients; by the end of the follow-up, 25 of the manic patients, compared with 10 of the depressed patients, had died. Conclusions: Mania appears to have a poorer prognosis and to be a more severe form of affective illness than unipolar depression. The 18 manic patients with neurological disorders seemed to have "secondary mania." Subtle cerebral changes due to aging may have been responsible for the conversion to mania in the 20 patients who experienced a long latency from first depression to onset of mania. The low frequency of early-onset mania in this study group highlights the need to differentiate early- from late-onset mania.*

(Am J Psychiatry 1992; 149:341–345)

---

The incidence of first admissions for mania tends to increase with advancing age (1, 2), yet the meaning and importance of mania in old age remains unclear. In contrast, the prevalence of bipolar disorder in the community decreases with age from 1.4% in young adults to 0.4% in those older than 65 years (3). For many elderly manic patients, a latency period averaging as long as 17 years separates the first episode of depression and the onset of mania (4–6). Furthermore, numerous depressive episodes often occur during the latency period. Even among young patients with unipolar depression, Akiskal et al. (7) found that 20% experienced a manic episode within a 6-year follow-up. Therefore, the concept of a unipolar-bipolar dichotomy of affective disorder (8) has been challenged by spectrum and threshold theories that consider mania a more severe form of affective disorder (9, 10).

The average age at onset of affective disorder has been reported to be in the late 40s or 50s in elderly manic patients. Indeed, few elderly subjects with bipolar disorder have suffered from mania before the age of 30 (5). Age at onset may distinguish subgroups of manic patients with different clinical and biological features (11).

In both mania and depression in old age, a good deal of attention has been directed at the role of cerebral-organic factors. Retrospective studies have found an association between coarse brain disorders and mania in old age (4, 5, 12). In a recent prospective study, Broadhead and Jacoby (6) used CT scans to study elderly as well as young patients with mania. They concluded that "organic factors may play an important role in the genesis of affective disorder in old age."

Based in part on the earlier findings of Shulman and Post (4), we hypothesized that, compared with depression in old age, mania in old age 1) is a more severe form of affective disorder, 2) is associated with a preponderance of neurological disorders, and 3) has a poorer prognosis. Usually, depression in old age has

been studied separately from mania (13, 14). To our knowledge, this is the first reported study comparing elderly manic patients with age- and sex-matched patients with unipolar depression.

## METHOD

Using medical record data, we conducted a chart review of all patients discharged from a private mental hospital in 1980–1987 to identify 50 consecutive admissions of patients 65 years old or older who met *DSM-III-R* criteria for a manic episode. Since the outcome data were recorded in 1990, the minimum follow-up was 3 years and the maximum was 10 years. Subjects with medical problems or cerebral-organic disorders were *not* excluded. For each year's group of manic patients, a comparison group of age- and sex-matched patients who met *DSM-III-R* criteria for major depression were selected. In this way, 50 elderly patients with mania and 50 elderly patients with major depression were included in the study. To select a homogeneous group of depressed patients, patients suffering from bipolar depression at index episode were excluded.

Information was recorded regarding demographic data, family history of affective disorder, and previous psychiatric and neurological history. All geriatric patients at the hospital were routinely assessed by a neurologist. We recorded the presence of a neurological disorder only when the evidence was clearly documented by the clinical consultation note or by a radiologic report. When there was any uncertainty as to the presence or absence of a neurological disorder, consensus was reached by the two raters (K.I.S. and G.M.).

To assess the reliability of the information collected from medical records regarding family history of affective disorder, type of index episode, and presence of preexisting neurological disorder, we compared the ratings of 12 randomly selected patients with blind ratings of the same patients made by one of us (M.T.). For all three variables there was full agreement on the 12 patients.

The number and type of subsequent psychiatric hospitalizations were determined by contacting patients, relatives, physicians, and appropriate institutional settings. The dates of any hospitalization, institutionalization, or death occurring during the follow-up period were recorded. Institutionalization was defined as any placement in a supervised residential setting, including rest homes, homes for the aged, nursing homes, or chronic care settings. Treatment issues were not controlled in this naturalistic study.

To estimate the effects of risk factors simultaneously, logistic regression models (15) and the computerized Statistical Analysis System (SAS) (16) were used. We obtained adjusted odds ratios with 95% confidence intervals.

Survival curves based on the Kaplan-Meier method (17) were used to estimate time to psychiatric rehospitalization, institutionalization, or death. We obtained adjusted hazard ratios (18) and their 95% confidence intervals, controlling for other variables, by using the SAS (19).

## RESULTS

### *Comparison of Patients With Mania and Depression*

Each group was composed of 35 (70%) women and 15 (30%) men. The mean age at index admission of the women in the mania group was 70 years (SD=4.5, range=65–83); the mean age of the women in the depression group was also 70 (SD=4.1, range=65–79). The mean age at index admission of the men in the mania group was 74 years (SD=7.0, range=65–85); the mean age of the men in the depression group was 72 (SD=4.7, range=66–79). No significant differences existed between the subgroups of manic and depressed patients. There was no significant difference in length of follow-up between the mania and depression groups. The mean follow-up period was 5.6 years (SD=2.5, range=3–10). Outcome information regarding mortality was obtained for all 100 patients either by direct contact with patients and families or by referring to the official vital statistics records.

Eighteen (36%) of the manic patients had evidence of neurological disorders, compared with four (8%) of the depressed patients. The difference was statistically significant after adjusting for age, sex, and previous episodes (adjusted odds ratio=8.0, 95% confidence interval=2.3–27.4, p=0.001). Table 1 lists the type of neurological disorders evidenced by the 18 manic patients. Because of the retrospective nature of the study we did not attempt to establish an exact temporal relationship between first episode of mania and cerebral-organic disease.

The manic patients had a significantly higher mortality rate than the depressed patients (adjusted hazard ratio=2.4, 95% confidence interval=1.1–11.8, p=0.02) after controlling for age, sex, previous episodes, and neurological disorder. At the end of the follow-up, 25 (50%) of the manic patients were dead compared with 10 (20%) of the depressed patients. Figure 1 shows that the probability of remaining alive after 5 years of follow-up was approximately 90% for patients with unipolar major depression and 65% for patients with mania. By 10 years the probability of remaining alive for each group was 75% and 30%, respectively. With the use of survival curves we can estimate the probability of remaining alive for 10 years after being alive for 5 years; for manic patients this probability was 54% (0.35 divided by 0.65) and for depressed patients it was 82% (0.70 divided by 0.85). Only one death by suicide was reported—that of a patient with unipolar depression—in the entire study group.

The depressed patients had a shorter time to institutionalization (adjusted hazard ratio=3.6, 95% confidence interval=1.1–5.4, p=0.02) after controlling for age, sex, previous episodes, and neurological disorder. At follow-up, 18 (37%) of the 49 depressed patients were institutionalized compared with 13 (30%) of 44 manic patients. (Patients who died while institutionalized were included in this analysis.)

Twenty-six (52%) of the manic patients compared

**TABLE 1. Demographic and Clinical Data for 18 Elderly Patients With Mania and Neurological Disorders at Index Hospitalization**

| Patient | Sex | Family History of Affective Disorder | Age at Onset of Affective Disorder (years) | Age at First Manic Episode (years) | Neurological Disorder |
|---|---|---|---|---|---|
| 1 | M | Negative | 82 | 82 | Chronic alcoholism, peripheral neuropathy |
| 2 | F | Positive | 20 | 20 | Frontal lobotomy, bilateral encephalomalacia |
| 3 | F | Negative | 50 | 50 | Chronic alcoholism, dementia |
| 4 | F | Negative | 67 | 67 | Chronic alcoholism, seizures/delirium |
| 5 | M | Negative | 69 | 70 | Chronic alcoholism, blackouts/delirium |
| 6 | M | Negative | 68 | 68 | Cerebral contusions |
| 7 | F | Positive | 41 | 46 | Parkinson's disease |
| 8 | F | Negative | 39 | 43 | Right cerebral infarct |
| 9 | F | Negative | 83 | 83 | Multiple cerebral infarcts |
| 10 | F | Negative | 43 | 58 | Encephalopathy/neuroleptic malignant syndrome |
| 11 | M | Negative | 58 | 58 | Closed head injury |
| 12 | M | Negative | 80 | 80 | Recurrent cerebral contusions (boxing), lacunar infarct |
| 13 | F | Positive | 71 | 71 | Left cerebral hemorrhage 20 years before onset of affective disorder |
| 14 | F | Positive | 39 | 39 | Cerebral infarct |
| 15 | M | Positive | 84 | 85 | Dementia |
| 16 | M | Negative | 76 | 76 | Embolic cerebral infarct, mild dementia |
| 17 | F | Negative | 19 | 19 | Right capsular necrosis, cerebral vasculitis (rheumatoid) |
| 18 | F | Positive | 68 | 68 | Parkinson's disease |

with 16 (32%) of the depressed patients had a positive family history of affective disorder in a first-degree relative (odds ratio=2.3, 95% confidence interval=1.01–5.2, p=0.04).

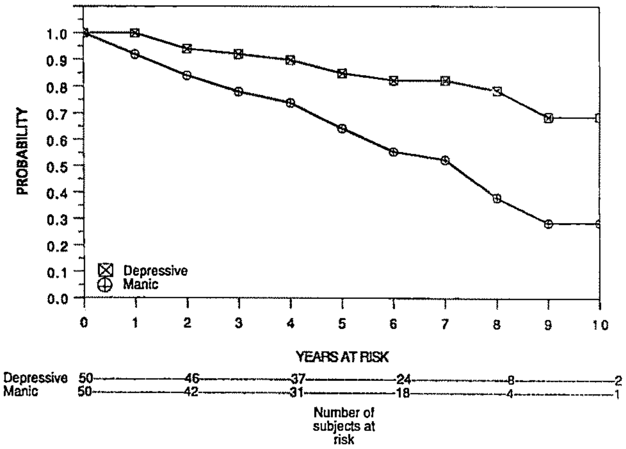
The manic patients were significantly younger at first psychiatric hospitalization than the depressed patients (two-tailed t test=2.3, df=98, p=0.02). The mean age at first psychiatric hospitalization of the depressed patients was 62.7 years (SD=11.0, range=34–79). For the manic patients the mean age at first psychiatric hospitalization was 55.5 years (SD=18.8, range=19–84).

### *Manic Patients*

Twenty-three (46%) of the manic patients were rehospitalized in a psychiatric unit at least once during the follow-up period. Having a neurological disorder at the time of the index admission was a predictor of subsequent psychiatric hospitalization (odds ratio=4.6, 95% confidence interval=1.1–19.2, p=0.05) after adjusting for sex, age, previous episodes, and age at first manic episode. Neurological disorder also predicted institutionalization (adjusted odds ratio=7.7, 95% confidence interval=1.2–48.1, p=0.03) after adjusting for age, sex, and previous episodes. Twelve (24%) of the manic patients were institutionalized during the follow-up period.

Unlike Shulman and Post (4), we found no significant sex differences between the manic and depressed patients with respect to neurological disorders. In addition, an age at onset of more than 55 years predicted a shorter time in remission until first psychiatric rehospitalization (adjusted hazard ratio=3.9, 95% confidence interval=1.2–13.5) after controlling for age, sex, neurological disorder, and previous episodes. Six (33%) of the 18 neurologically impaired manic patients had a positive family history of affective disorder in first-degree relatives (table 1), compared with 26 (52%) of all 50 manic patients ($\chi^2$=4.6, df=1, p=0.03).

**FIGURE 1. Cumulative Probability of Death for 50 Elderly Patients With Mania and 50 Elderly Patients With Unipolar Depression at Index Hospital Admission**



Twenty (40%) of the manic patients experienced depression as their first affective episode at a mean age of 47.5 years (SD=18.3, range=19–84). The mean latency from first depression to first mania in these 20 patients was 14.9 years (SD=5.1, range=1–48). There was a significant difference in mean age at first mania between men (mean=58.7, SD=16.6, range=19–83) and women (mean=68.7, SD=13.2, range=42–85) (t=2.05, df=47, p=0.04).

The clinical course of six manic patients was characterized by manic episodes but not depressive episodes before the index admission.

### *Depressed Patients*

Not surprisingly, older age predicted higher mortality in the depressed patients (adjusted hazard ratio=1.2, 95% confidence interval=1.0–1.4, p=0.02) after controlling for sex, previous episodes, and neurological disorder. Also, depressed patients who had been institutionalized before the index episode had a higher mortality (adjusted odds ratio=17.2, 95% confidence interval=1.0–287.7, p=0.05) after controlling for age and sex. In addition, nonmarried status predicted institutionalization for the depressed patients (adjusted odds ratio=4.7, 95% confidence interval=1.2–18.6, p=0.02) after controlling for age and sex.

## DISCUSSION

This study supports a number of hypotheses and findings of earlier studies of elderly manic patients (4–6). In particular, the prevalence of cerebral-organic disorder was found to be significantly higher in manic patients (36%) than depressed patients (8%). Neurological disorders were heterogeneous in nature and nonspecific with regard to brain location. As in previous studies, the prevalence of Alzheimer-type dementia was no higher than the expected proportion in the general population. Alcohol-related disorders accounted for four of the 18 cases of neurological impairment in the manic patients, and cerebrovascular disease was evident in six of the 18 patients. Despite the uncertain relationship of neurological disorder to the onset of mania, a unique pattern appears to be evident in these 18 patients. The age at first mania and age at onset of affective disorder were the same or very close temporally in these patients. They seemed to fit the category of patients with "secondary mania" described by Krauthammer and Klerman (20), associated with a relatively lower rate of genetic predisposition to affective disorder. This is in marked contrast to the long latency from first depression to manic episode for many of the elderly manic patients who did not have evidence of neurological disorder.

Manic patients experienced a poor outcome, suffering a significantly higher mortality rate. Half of the manic patients were dead after almost 6 years of follow-up, compared with 20% of the depressed patients. This high mortality rate has not been reported in follow-up studies of patients with early-onset mania (21). The higher mortality rate among manic patients may account for the relatively shorter time to institutionalization for depressed patients.

For elderly manic patients whose first psychiatric hospitalization was for depression, an average of 15 years elapsed before mania became manifest. This is suggestive of a "conversion" that may be due to factors different from those operating in patients with obvious neurological disorders. It should be emphasized that this retrospective study used coarse measures of cerebral-organic disorder. Therefore, we may have underestimated the true role of cerebral dysfunction, especially subtle cerebrovascular pathology. With newer imaging techniques such as magnetic resonance imaging, positron emission tomography, and single photon emission computed tomography, this issue can be studied more accurately.

Genetic loading may be more of a factor in elderly manic patients than in elderly depressed patients. Although genetic factors are generally considered to play a less prominent role in old age (22), mania has been associated with a higher prevalence of positive family history than has unipolar depression (23). We found a higher proportion of manic patients with a positive family history of affective disorder (52%) than has been reported in other studies (5, 6, 12). However, we applied the same assessment measures to the depression comparison group and found that only 32% had a positive family history. The manic patients had an earlier age at onset of first psychiatric hospitalization than the depressed patients. An earlier age at onset is associated with a positive family history (5, 6). Even in old age, manic patients appear to be genetically predisposed to affective disorder but perhaps less so than young manic patients (23).

Overall, age at onset of mania was late in life (mean=55.5 years), a finding that is consistent with other studies of old age (4, 5). The average age at onset of "early-onset" mania found in other studies was 29 years (23, 24). Indeed, only three of our 50 elderly manic patients had suffered from mania when they were younger than 30. A study of university clinic outpatients (25) compared elderly patients with young depressed patients and found a higher prevalence of mania in the younger patients—7.3% versus 1.4%. Does the young patient with bipolar disorder burn out (26) or is there a high mortality rate? This raises questions about fundamental differences between early-onset and late-onset mania.

Our data are consistent with the spectrum theory of Akiskal (9) and the threshold theory of Tsuang et al. (10), which consider mania a more severe form of affective disorder. Controlled studies of the treatment of mania, particularly with lithium carbonate, are needed to explore the hypothesis that mania in old age represents a manifestation of greater CNS vulnerability (27).

As a group, the 50 elderly manic patients in this study had a genetic predisposition to affective disorder that became manifest relatively late in life. This applies especially to the manic patients without coarse brain disorders. With growing interest in elderly manic patients, greater numbers of patients will be available for study. Furthermore, the advent of new technologies (28, 29) and advances in our conceptualization of affective disorders should help to clarify the special meaning and importance of mania in old age. We have highlighted two distinct subgroups of patients with mania in old age: 1) patients whose first episode of affective disorder is depression and who have a long latency period before they experience their first episode of mania and 2) those suffering from secondary mania associated with neurological disorders, whose mania is often their first affective episode or follows closely after their first episode of depression. Further studies of mania in the elderly should focus on its distinct nature compared with depression and its fundamental difference from mania that begins early in life.

# Correlates of Persistent Depressive Symptoms in Widows

Wendy S. Nuss, M.S.N., and George S. Zubenko, M.D., Ph.D.

*Objective: Delineation of factors that predict depressive symptom severity 6 or more months after the loss of a spouse may help identify individuals at risk for persistent depressive symptoms. In this study, sociodemographic and clinical correlates of depressive symptom severity were examined among widows 6 to 16 months after the deaths of their husbands. Method: The 50 subjects were identified from the Allegheny County, Penn., death records and were interviewed by telephone. The authors examined the relationship of depressive symptoms to sociodemographic variables, perceptions of sex role and quality of social supports, level of support sought for bereavement, and premorbid personal and family psychiatric history. Results: Widows with persistent depressive symptoms were less likely to have worked outside the home, had less favorable perceptions of their interpersonal support systems, were more likely to have had previous psychiatric disorders, and were likely to have sought professional help in response to their bereavement. In a multivariate model, only premorbid psychiatric history and the perception of interpersonal support system made independent contributions to the prediction of Beck Depression Inventory scores above the normal range. Conclusions: These results suggest several factors that may identify women at risk of protracted psychiatric morbidity after their husbands' deaths. They also suggest that the persistence of depressive symptoms an average of 1 year after the loss of a spouse may reflect a pathological condition rather than normal grieving.*

(Am J Psychiatry 1992; 149:346–351)

As our national population ages, spousal bereavement is becoming an increasingly important source of psychiatric morbidity. Newly bereaved individuals typically respond to their losses by exhibiting depressive symptoms that are often sufficient in number and severity to be indistinguishable from primary affective disorders (1–4). However, several lines of epidemiologic evidence suggest that bereavement-related depression may be distinct from other forms of depressive illness. Unlike major depression, depression within 1 month of the death of a spouse is not more common in women than men, does not appear to increase in frequency with advancing age, and is not associated with a previous personal or family history of depression (2). The suggestion that bereavement-related depression differs in its pathophysiology from other depressive disorders (1–4), the rarity of self-destructive or psychotic symptoms in bereaved individuals (1–4), and the encouraging observation that bereavement-related depression most often resolves spontaneously (1, 3) have led most clinicians to be conservative in their management of this condition.

Bereaved patients who have persistent depressive symptoms present a diagnostic dilemma. This diagnostic issue is addressed in *DSM-III-R,* which states that prolonged and marked functional impairment suggests the bereavement is complicated by the development of a major depression. However, recognizing the interindividual and transcultural variations in the duration of what is considered to be a normal bereavement period, *DSM-III-R* does not provide specific guidelines regarding duration. The delineation of factors that predict depressive symptom severity 6 or more months after the loss of a spouse may help to identify individuals at risk for persistent depressive symptoms and to detect and treat complicating major depression.

In the current study, we assessed the number and severity of depressive symptoms among 50 widows whose husbands had died 6 to 16 months previously. The relationships of sociodemographic and clinical variables to persistent depressive symptoms were examined with the goal of better understanding the nature of bereavement-related depressive symptoms that persist an average of 1 year after the loss of a husband.

## METHOD

### *Selection of Subjects*

An alphabetical listing by surname of widows whose husbands had died between 6 and 16 months before the study was generated from the Allegheny County, Penn., death records (Carnegie Library of Pittsburgh, Vital Statistics Department). The first 188 of these names were cross-checked against all telephone directories for Allegheny County, and current listings for 120 widows were identified. The remaining 68 were dead, had moved outside Allegheny County, or were no longer listed in the telephone directories for unknown reasons. Of these 120 widows, 72 were contacted in alphabetical order to produce a target sample of 50 widows who were fluent in English and willing to participate in the study. This 69% rate of participation was similar to rates found in previous studies of bereavement (2, 5). Written informed consent was obtained by mail, and confidentiality was maintained through the use of a data base organized according to a numerical identification system. This study was approved by the Psychosocial Institutional Review Board of the University of Pittsburgh.

### *Sociodemographic and Clinical Assessments*

Sociodemographic and clinical information was obtained from each subject through a semistructured telephone interview administered by a mental health nurse with specialized experience in geriatric psychiatry. Each interview included the administration of a sociodemographic questionnaire, the Beck Depression Inventory (6), the Interpersonal Support Evaluation List (7), and the Bem Sex Role Inventory—Short Version (8). All three instruments are self-evaluative and have been validated for use across the adult age spectrum in clinical and nonclinical populations. Each self-report item was presented verbatim in the order in which it appeared in the respective instrument. The individual telephone interviews averaged approximately 30 minutes.

Our pilot studies and a previously published methodological study of bereaved elders (9) indicated that, compared to mailed questionnaires, telephone interviews make potential subjects more comfortable with providing sensitive information and result in greater subject compliance and less likelihood of inadvertent omissions. Previously published studies of bereaved elders (5, 9, 10) did not indicate systematic differences in responses on self-report instruments designed to assess depression or other bereavement-related feelings or behaviors when the instruments were administered in person or through mailed questionnaires. Furthermore, the telephone interview provided an opportunity for a mental health professional to clarify the questions about onset of depressive symptoms and about personal and family psychiatric history. Comparisons of the quality of data obtained from community samples by telephone and by personal interviews (11–15), including information about depressive symptoms and social functioning (15), have revealed few differences between these two methods.

The sociodemographic questionnaire included age, telephone number, race, religion, highest level of education completed, work history, annual income, number of children, and date of husband's death. In addition, this questionnaire elicited information on the level of support sought in response to the loss of the subject's husband and her previous personal and family history of psychiatric disorders. The level of support sought in response to bereavement was elicited by the question, "Since your husband's death, have you talked with anyone about your feelings and/or problems?" If the response was "yes," the subject was asked whether this was best described as support from friends, family, or clergy; one contact with a mental health professional; more than one outpatient mental health contact; or inpatient psychiatric treatment. The level of support sought for bereavement was rated from 1 to 4, from the least to the most intensive. A global assessment of each subject's premorbid personal and family psychiatric history was elicited by the question, "Have you or any member of your family ever seen a doctor, nurse, counselor, social worker, or therapist for emotional, psychological, or nerve problems, before the loss of your husband?" If the answer was "yes," the subject was asked to specify the individual as herself or to state the relationship of the affected family member(s) to her. This method of determining the presence of a premorbid personal history or family history of psychiatric disorder was chosen because it is efficient and provides few false positives (16–18). Individuals identified by personal reports and those of family members as having received treatment by mental health professionals almost always have authentic psychiatric disorders (16–18). However, underreporting of episodic or less debilitating psychiatric disorders is an inherent limitation of the family history method, even when consensus diagnoses are made from information obtained from multiple informants and ancillary sources (16–18).

An assessment of the number and severity of depressive symptoms was made by using the Beck Depression Inventory. This multiple-choice inventory includes 21 items, each of which corresponds to a depressive symptom and is followed by four self-evaluative statements. The statements are weighted to indicate the severity of each symptom, from absent (0) to severe (4), and they are summed to produce a total score. In this way, the total Beck score is weighted for both the number and severity of depressive symptoms. A total score less than 10 reflects euthymia or minimal depressive severity (19). For each widow who endorsed depressive symptoms, a best assessment of the time of onset was made.

The Beck Depression Inventory served as the principal dependent variable in our study. It provided an index of the number and severity of depressive symptoms, and we used it, rather than a structured diagnostic interview, because *DSM-III-R* does not provide operationalized criteria for distinguishing "uncomplicated" bereavement from major depression. However, each of the nine *DSM-III-R* symptom criteria for major depression is addressed by at least one of the items included in the Beck inventory (depressed mood: Beck items 1, 10, 11; diminished interest or pleasure: items 4, 12; weight or appetite change: items 18, 19; sleep disturbance: item 16; psychomotor retardation: item 15; loss of energy: items 15, 17; feelings of worthlessness or guilt: items 3, 5–8; inability to concentrate or indecisiveness: item 13; suicidal ideation: item 9). Ignoring the *DSM-III-R* criteria for uncomplicated bereavement, we used these data to assess whether the criteria (five of nine symptoms) for major depression were met.

The Interpersonal Support Evaluation List consists of 40 true-false statements and assesses the perceived availability of supportive resources. The items are divided equally into 20 positive and 20 negative statements. One point is assigned for each answer indicating the availability of a particular resource, and the total score ranges from 0 to 40.

The Bem Sex Role Inventory—Short Version was designed to rate an individual's sex role orientation on a continuum from "feminine" to "masculine." It includes 20 gender-specific characteristics (10 masculine, 10 feminine) and 10 gender-neutral items. This instrument is based on the traditional concept of femininity, i.e., derivation of personal fulfillment from dedication to others, and characteristic traits include passivity, dependence, helplessness, and submissiveness. In contrast, assertiveness, dominance, self-reliance, and independence are examples of the masculine traits included in the instrument. Each description is rated on a 7-point scale to reflect the extent to which the item is considered a desirable personal trait. Raw and standard scores for both the masculinity and femininity subscores are derived from the 20 gender-specific characteristics. Single t scores are then assigned on the basis of the difference in the standardized subscores (femininity minus masculinity) and range from 12 to 88 (12–50=masculine range, 51–88=feminine range). Bem (20) suggested that women whose personalities include a combination of traditional feminine and masculine traits (lower scores) are more adaptive than those who exclusively endorse traditional feminine traits.

### *Statistical Analysis*

Mean values were compared by using two-tailed t tests, and categorical variables were compared by means of the chi-square statistic or Fisher's exact test, as appropriate. Associations of sociodemographic and psychometric characteristics with the Beck score were explored with parametric Pearson or nonparametric Spearman correlation coefficients, as appropriate.

A multivariate model predicting the severity of depressive symptoms from the sociodemographic and clinical variables included in this study was calculated by using the stepwise multiple logistic regression method. A widow was characterized as depressed if her Beck score was 10 or higher and as not depressed if her Beck score was less than 10. According to Beck et al. (19), this cutoff separates nondepressed subjects or those with minimal depression from those with at least mild depression.

## RESULTS

The mean age of the study group was 68.5 years (SD=8.7), and the mean duration of widowhood was 11.6 months (SD=2.7). Most widows were living on retirement incomes; of the 48 widows who responded to this question, 44 (91.7%) had annual incomes of $20,000 or less. A total of 38 (76.0%) had completed at least a high school education, and 46 (92.0%) of the women had worked outside of the home at some time in their lives. The group studied was almost exclusively Caucasian (two of the 50 were black), and 46 (93.9%) of 49 respondents were Catholics or Protestants. The widows in the study had given birth to an average of 2.3 children (SD=1.8). The average perceived availability of interpersonal support was reflected by a mean score on the Interpersonal Support Evaluation List of 34.8 (SD=5.2).

The study group was compared to the population data for females in Allegheny County provided by the 1980 census (21). However, the data available for comparison must be viewed as estimates because widows are not separated as a group in the census. In 1980, 88.5% of the population of Allegheny County was white, 10.3% was black, and 1.2% was composed of other racial groups. Assuming that this racial distribution exists currently and is similar for widows, 44 whites and six nonwhites would have been expected in our sample of 50 widows. Forty-eight whites and two blacks were actually included, a proportion that did not differ significantly from that expected from the census statistics (Fisher's exact test, p=0.27). According to the 1980 census, 32.0% of the women living in Allegheny County who were at least 25 years of age had less than a high school education, 44.5% had completed high school, and 11.9% had completed a college or graduate degree. The respective percentages from our sample of widows were similar: 24.0% (N=12) had not completed high school (p=0.50, Fisher's exact test), 46.0% (N=23) had graduated from high school (p=1.00, Fisher's exact test), and 6.0% (N=3) had completed college (p=0.49, Fisher's exact test). Relevant data on the employment status and annual income of widows in Allegheny County were more difficult to extract from the census and were further complicated by retirement. In 1980, 6.6% of the women living in Allegheny County who were at least 65 years of age were employed full-time, compared to 4.0% (N=2) in the study sample (p=1.00, Fisher's exact test). However, an additional 12.0% of the widows in the study (N=6) were engaged in part-time employment, and no comparative data on part-time employment were available. In addition, the average annual income in 1980 for women who were at least 65 years of age and living in Allegheny County was $13,696, and the average income of female heads

**TABLE 1. Correlations of Sociodemographic and Clinical Variables With Beck Depression Inventory Scores of 50 Widows**

| Variable | Correlation With Beck Score: Coefficient | p |
|---|---|---|
| Age | 0.143[a] | 0.16 |
| Duration of widowhood | 0.004[a] | 0.49 |
| Level of education | –0.048[b] | 0.37 |
| Employment history | –0.380[b] | 0.003 |
| Annual income | 0.010[b] | 0.47 |
| Level of support sought for bereavement | 0.402[b] | 0.002 |
| Interpersonal Support Evaluation List score | –0.396[a] | 0.002 |
| Bem Sex Role Inventory score | 0.018[a] | 0.45 |

[a] Pearson correlation coefficient.
[b] Spearman correlation coefficient.

of households (by virtue of divorce or widowhood) was $11,451. Both of these averages are in the middle of the range for the widows in the study sample. Furthermore, the mean Bem Sex Role Inventory score for the widows, 69.9 (SD=10.3), was in the middle of the femininity scale, which ranges from 51 to 88. In summary, the study sample appeared to be reasonably representative of widows in Allegheny County, to the extent that we could assess this from census information.

The mean Beck depression score for the 50 widows was 7.4 (SD=5.4, range=0–30). Twelve (24.0%) of the 50 had scores of 10 or higher, beyond the upper limit of the range for euthymia or minimal depression. The mean Beck depression score of this group of 12 widows was 14.6 (SD=5.6), whereas the mean score for the residual group was 5.1 (SD=2.7). The validity of the cutoff score for the Beck Depression Inventory was evaluated by determining the proportions of widows in the two groups who fulfilled the *DSM-III-R* symptom criteria for major depression, each of which is addressed by one or more items on the Beck scale. Ten (83.3%) of the 12 widows whose Beck scores were 10 or higher met the *DSM-III-R* symptom criteria for major depression, and the remaining two widows endorsed at least three of the five depressive symptoms required to satisfy these criteria. In contrast, only one (2.6%) of the 38 widows whose Beck scores were less than 10 met the *DSM-III-R* symptom criteria for major depression (p=0.000, Fisher's exact test). All of the widows who endorsed depressive symptoms at the time of inclusion in our study dated the onset of the symptoms to the deaths of their husbands; this finding is consistent with the results of previous prospective, longitudinal studies of spousal bereavement (1, 3).

Six (12.0%) of the 50 widows stated they had received psychiatric treatment before the loss of their spouses. Three (6.0%) of the widows had first-degree relatives who had been treated for psychiatric disorders. Twenty subjects (40.0%) sought emotional support in response to the loss of their husbands; five (10.0%) contacted mental health professionals, and two (4.0%) remained in sustained outpatient therapy. In no case did loss of a husband lead to inpatient treatment for bereavement.

**TABLE 2. Stepwise Multiple Logistic Regression Model Predicting Beck Depression Score of 10 or Higher From Sociodemographic and Clinical Variables of 50 Widows[a]**

| Variable | Odds Ratio | 95% Confidence Interval | Improvement Chi-Square (df=1) | p |
|---|---|---|---|---|
| Premorbid psychiatric history | 19.7[b] | 1.25–308 | 10.73 | 0.001[c] |
| Interpersonal Support Evaluation List score | 1.2[b] | 1.02–1.50 | 4.01 | 0.05[c] |
| Family psychiatric history | 19.9 | 0.79–504 | 3.38 | 0.07 |

[a] Stepwise multiple logistic regression was performed with 0.10 and 0.15 confidence limits for entry and removal, respectively, of premorbid psychiatric history, family psychiatric history, and the variables listed in table 1.
[b] Statistically significant odds ratio.
[c] Statistically significant contribution to goodness-of-fit of model.

Correlation coefficients describing the associations of sociodemographic and clinical characteristics with the scores on the Beck Depression Inventory are presented in table 1. A history of work outside of the home and the perceived availability of interpersonal support were significantly negatively correlated with the continuous Beck score. Not surprisingly, the level and intensity of support sought for bereavement exhibited a significant positive correlation with the Beck score. Widows who reported personal psychiatric histories before the loss of their husbands had a mean Beck score of 15.2 (SD=7.9), which is in the moderately severe range, whereas those who had no such history had a mean Beck score that was less than half of this value, 6.3 (SD=4.0) (t=4.45, df=48, p=0.000). The mean Beck depression score was not significantly higher in the subjects who had first-degree relatives with histories of psychiatric disorders (mean=10.0, SD=5.3) than among the women without such relatives (mean=7.2, SD=5.4) (t=0.87, df=48, p=0.39). However, the latter comparison was limited by the small number of widows who had family psychiatric histories (N=3).

We used stepwise multiple logistic regression to determine which of the sociodemographic and clinical variables independently contributed to the prediction of widows who had Beck scores above the normal range (10 or higher), while controlling for the other variables. A best-fitting model was calculated by using confidence units of 0.10 and 0.15 for entry and removal of variables from the stepwise procedure. A description of the resulting model is presented in table 2. The presence of a premorbid psychiatric history and the perception of inadequate social supports emerged as independent predictors of Beck scores above the normal range. Specifically, the likelihood of an abnormal Beck score an average of 1 year after the husband's death was 20 times as high among women with premorbid psychiatric histories as among widows without such histories. In addition, each 1-point increase in the score on the Interpersonal Support Evaluation List increased the likelihood of having an abnormal Beck score by 20%. The presence of a family psychiatric history tended toward an independent contribution to the goodness-of-fit of the model, although the odds ratio associated with this variable did not reach statistical significance.

## DISCUSSION

Some discussion of the dependent variable of the study seems warranted to place the findings into perspective. We chose the Beck Depression Inventory, which provides a continuous index of the number and severity of depressive symptoms, rather than a structured diagnostic instrument designed to provide a *DSM-III-R* diagnosis of major depression because previous studies of bereavement-related depression have not used the same diagnostic systems and because *DSM-III-R* does not provide clear diagnostic criteria for distinguishing this disorder from uncomplicated bereavement. With the possible exceptions of psychomotor retardation, morbid guilt, or suicidal ideation, a full range of depressive symptoms is common in the first year after the death of a spouse (1–4). Moreover, *DSM-III-R* does not provide a limit for the duration of uncomplicated bereavement.

The persistence of depressive symptoms after the death of a spouse often raises the clinical suspicion that a major depression has emerged, but there is little empirical evidence in the literature to guide the application of this commonly held view. In their prospective, longitudinal study of older bereaved widows and widowers, Bornstein et al. (3) found that the prevalence of depression defined according to the Feighner criteria (22) was 35% at 1 month and 17% at 13 months, and 13% of the subjects were depressed for the entire year. Retrospective or cross-sectional estimates of the prevalence of major depression (*DSM-III-R* symptom criteria) in bereaved widows have been 28% (23) to 32% (5) at 6 months and 27% (5) at 1 year after the death of a spouse. Although most bereaved individuals fail to fulfill diagnostic criteria for a full depressive syndrome as early as 1 month after the death of the spouse, a substantial fraction are depressed at 1 month and remain so 1 year later.

The Beck Depression Inventory is a widely used self-report instrument that has been validated as a measure of depressive symptoms in clinical and nonclinical populations across the age spectrum (6, 19). Several lines of evidence also support the use of the Beck cutoff of 10 for bereaved widows. Eleven (22.0%) of the 50 widows in our study exhibited a sufficient number of depressive symptoms to fulfill the *DSM-III-R* symptom criteria for major depression, and this rate falls within the range (17% to 27%) of previously published prevalences for depression 1 year after a spouse's death. Of these 11 widows, ten (90.9%) had Beck scores of at least 10. Furthermore, Reynolds et al. (24) recently reported that the EEG sleep recordings of bereaved subjects who met the Research Diagnostic Criteria (RDC) (25) for major depression resembled those of elderly patients with recurrent unipolar major depression, and the recordings of nondepressed bereaved subjects were similar to those of elderly comparison subjects. The mean Beck scores of the depressed and nondepressed bereaved subjects included in the sleep study, 15.2 (SD=6.2) and 5.1 (SD=4.7), were similar to those of the widows in the current study, who were categorized as depressed according to the Beck cutoff score of 10.

The principal findings of the current study were that employment history, level of support sought for bereavement, perception of social support system, and premorbid psychiatric history all exhibited significant univariate associations with the severity of persistent depressive symptoms in widows bereaved for an average of 1 year. Several of these results support the findings of previous studies. Jacobs et al. (5) found that unemployment was more common among bereaved individuals who met the *DSM-III-R* symptom criteria for major depression 6 to 12 months after the loss of their spouses than among those who were not depressed, although this observation was confounded by a gender effect that was not present in our study. Whether this association derives from a protective effect of employment or from the fact that depression may lead to the inability to work cannot be determined from our data. We found no previous studies that assessed the relationship of the level of emotional support sought for bereavement to the severity of persistent depressive symptoms. However, Raphael (26) found that supportive psychotherapy provided to widows for 3 months after the deaths of their husbands significantly reduced the level of psychiatric morbidity 13 months later. In this intervention study, the perception of nonsupportiveness in the social network was hypothesized to be a risk factor for persistent psychiatric morbidity and predicted greater response to psychotherapeutic intervention.

In previous studies that examined bereaved individuals as long as 13 months after the deaths of their spouses (1–5), premorbid psychiatric history was not associated with the clinical diagnosis of depression. However, in our study of widows whose husbands had died 6 to 16 months previously, this variable made an important contribution to the severity of persistent depressive symptoms. This difference suggests that the persistence of major depressive symptoms beyond 1 year may reflect the exacerbation of a premorbid psychiatric disorder, a criterion embodied in the differential diagnosis of bereavement and major depression in the RDC but not *DSM-III-R*.

Because it was recognized that the sociodemographic and clinical variables used in our study might not act independently in the prediction of persistent depressive symptoms, a multivariate analysis was performed to determine which variables made independent contributions to the prediction of Beck scores of at least 10. Only premorbid psychiatric history and the score on the Interpersonal Support Evaluation List, two of the four variables identified in the univariate analyses, made significant independent contributions to the goodness-of-fit of the multiple logistic regression model. As described in the Results section, both of these factors were strongly associated with persistent depression, reflected by Beck scores of at least 10, an average of 1 year after the deaths of their husbands.

Although our findings must be interpreted in the context of the limitations of the methods used and may not be generalizable to other populations, they suggest four sociodemographic and clinical variables that may identify widows who are at risk for persistent depressive symptoms after the deaths of their husbands. Furthermore, our results provide the first empirical evidence supporting the view that the persistence of major depressive symptoms beyond 1 year after the death of a spouse may reflect a pathological rather than a normative condition.

# Quantitative Assessment of the Behavior of Psychotherapy Supervisors

Stephen B. Shanfield, M.D., Paul C. Mohl, M.D.,
Kenneth L. Matthews, M.D., and Vroni Hetherly, M.D.

*Objective: The aim of this study was to explore the behavior of psychotherapy supervisors by using the Psychotherapy Supervision Inventory. Method: The authors used the Psychotherapy Supervision Inventory to rate 53 videotaped supervision sessions of 34 different supervisors. They also used the variable of the rater's perception of the excellence of the supervisor as a teacher. The data were subjected to a cluster analysis and a K-means analysis. Discriminant function analyses were applied to the comparison of the behavior of 19 supervisors with two different residents and the behavior of all 34 supervisors with residents in three different years of training. The relationship between rater-perceived excellence and Psychotherapy Supervision Inventory scores was analyzed by using stepwise multiple regression. Results: There was a high level of agreement among the four raters' judgments of supervisors' excellence. Empathy accounted for 72% of the variance in rater-perceived excellence and focus on the therapist accounted for an additional 5%. When empathy was dropped from the equation, experiential orientation accounted for 60% of the variance in ratings of excellence, clarification and interpretation accounted for an additional 16%, and depth accounted for another 3%. Conclusions: In the context of established relationships, supervisors have stable behavior patterns. Rater-perceived excellence is related to the supervisor's focusing on the resident's immediate experiences and making many synthesizing comments in depth. The Psychotherapy Supervision Inventory can be used to orient supervisors to supervision and provide feedback about their behavior.*

(Am J Psychiatry 1992; 149:352–357)

There has been little systematic research on psychotherapy supervision. Most reports of supervision are descriptions or studies of the process (1–11). Only a few used direct observational data of supervision, and these did not assess reliability adequately (12, 13). The Psychotherapy Supervisory Inventory (14) was developed to measure dimensions of the behavior of supervisors in videotaped supervision sessions. Categories of behavior were drawn from empirical observations of supervision and the therapeutic process (13–15). Previous research has established that trained observers can distinguish patterns of supervisory behavior with considerable agreement (14). The present study explores patterns of supervisory behavior using the Psychotherapy Supervision Inventory. A new variable was developed, the rater's perception of the excellence of the supervisor, to provide a measure of the supervisor's ability as a teacher and facilitator of resident learning during the videotaped session.

## METHOD

All psychotherapy supervisors at two departments of psychiatry were asked if their supervision sessions could be videotaped. Both the supervisors and residents involved were told that supervisory interaction would be assessed. Thirty-four (87%) of the 39 supervisors in the two departments participated in the study. All but three were psychiatrists; the three nonpsychiatrists were doctoral-level psychologists. Supervisors and trainees were well along in their supervisory relationship when the first supervision session was videotaped; the mean number of days from the time they were as-

signed to meet on a weekly basis at the beginning of the academic year to the time of taping was 239.2 days (SD=72.4). Videotaping was not done in the regular meeting place for supervisor and resident; usually it was done in a television studio. Most supervisors were experienced. Twenty-eight (82%) had supervised 30 or more residents. Two (6%) had supervised about 20 residents. Only four (12%) were beginner supervisors, having supervised only three to four residents. Nineteen supervisors were videotaped with two different residents. In all, 53 videotapes were rated (one for each of the 34 supervisors plus one for each of 19 supervisors with a second resident). Fourteen residents in postgraduate year two, 25 in postgraduate year three, and 14 in postgraduate year four were videotaped. The mean number of days between videotaping with two different residents was 210.3 days (SD=197.3).

Videotapes were rated independently by all four of us using the Psychotherapy Supervision Inventory. We are experienced supervisors, having supervised a mean of 64.5 residents (SD=38.7, range=22–112) on an individual basis. Three of us had also taught psychotherapy seminars to residents before making these ratings. Only supervisory sessions in which the resident had an ongoing relationship with a patient were rated. We observed the complete session on each tape before making the ratings. The average of the four raters' scores for each scale was entered into the analysis.

The Psychotherapy Supervision Inventory has 13 scales that are described in more detail elsewhere (14). Seven of the scales measure the content of the supervisor's comments: 1) therapist focus, 2) patient focus, 3) frequency of intellectually oriented and discursive comments, 4) frequency of experientially oriented comments, 5) frequency of clarificatory and interpretative comments, 6) intensity of confronting statements, and 7) peak level of depth of exploration. Six scales measure interactions between the supervisor and therapist, relatively independent of content: 8) activity level of the supervisor, 9) dominance of the supervisor, 10) dominance of the therapist, 11) peak levels of comfort, 12) peak levels of tension, and 13) the amount of empathy of the supervisor with the therapist or the patient. Each variable is rated on a scale from 1 to 7 on which 1=little and 7=extremely high.

Intraclass correlation coefficients (ICC) (16–18) ranged from 0.22 to 0.62 and were significant for all scales (14). We used the ICC to compare the variance between raters with the variance within raters (16). The ICC is sensitive to skewness and would be low if there were little variance between raters (18). To address this problem, we adopted Finn's index (18), a measure comparing the variance within raters with the variance of ratings that would be predicted by random ratings. A higher value for Finn's index than for the ICC means that there was less variability in the ratings and more agreement between raters (18). Finn's index ranged from 0.52 to 0.85 (14).

A new variable, rater-perceived excellence of the supervisor, was constructed. This is a measure of the rater's global judgment of the supervisor as a teacher and facilitator of resident learning during the videotaped session. We rated our perceptions of each supervisor during an entire videotaped session on a scale from 1 to 7 on which 1=little quality and 7=extremely high quality. We each rated 15 of the 53 videotaped sessions while blind to each other's ratings. These ratings were used to compute the ICC (16–18) and Finn's index (18). The statistical significance of the ICC was tested by using analysis of variance (16). The reliability for the mean scores of two and four raters was tested by using the Spearman-Brown coefficient. This coefficient was interpreted to mean that if another random sample of raters were to rate the same subjects, the reliability coefficient would represent the correlation between the two sets of data (16, 19). Our ratings of the excellence of the supervisors were obtained for all of the videotaped sessions, and the averages of the four ratings of each session were entered in the data analysis. A correlation matrix of the Psychotherapy Supervision Inventory variables plus the rater-perceived excellence variable was constructed, and the Bonferroni correction for the effect of multiple correlations was applied to test the significance of the correlations (20).

Cluster analysis, a multivariate statistical procedure, was done to classify the scales of the Psychotherapy Supervision Inventory and the excellence variable into homogeneous groups (21, p. 165). After the only videotaped supervision session of 15 of the supervisors and the first session of 19 of the supervisors were analyzed, the scales and the excellence variable were subjected to a hierarchical agglomerative analysis that produced a tree diagram of the variables (22, pp. 35–45). In this procedure, the variables were grouped into larger and larger clusters until all the variables were members of a single group (21, p. 189). Distance or similarity between the variables was measured by the product-moment correlation coefficient, and the average linkage method was used for combining variables (22, p. 61). The data were subjected to iterative partitioning with a K-means procedure for the number of clusters observed on the tree diagram, a procedure that assigns supervisors to a cluster (22, pp. 45–47). The variables for the two groups defined by K-means analysis were compared by using two-tailed t tests.

The behavior patterns of each of 19 of the supervisors in a videotaped supervision session with one resident were compared with their behavior patterns in a session with another resident by using discriminant function analysis. This statistical procedure identifies variables that best distinguish the groups being compared (21, p. 75). In addition, the behavior patterns of all 34 supervisors with residents in three different years of training were compared by using discriminant function analysis.

In an effort to understand the determinants of our ratings of excellence of the supervisors, we entered this as a dependent variable and the Psychotherapy Supervision Inventory scale scores as independent variables in a stepwise multiple regression analysis. This statistical procedure identifies a subset of independent vari-

ables that best predict a dependent variable, taking into account the correlations among the variables (21, p. 9). This analysis was based on the only videotaped supervision session of 15 of the supervisors and the first session of 19 of the supervisors.

## RESULTS

The measure assessing the rater's perception of the excellence of the supervisor had a high degree of interrater reliability (ICC=0.62, p=0.0001); Finn's index was 0.79, indicating less variance in the ratings and considerable agreement between raters. Moreover, with r=0.77 for two raters and r=0.87 for four raters, considerable agreement among two and four raters was found. Table 1 provides the correlation matrix of all the variables.

Cluster analysis of the 34 different supervisors resulted in a tree diagram depicting two clusters of variables at the highest level of organization (figure 1). K-means analysis for the two clusters assigned 25 supervisors to one group and nine supervisors to the other. The cluster of 25 contained supervisors who were empathic and judged to be relatively excellent in their facilitation of resident learning, who focused their comments on the trainee and somewhat more on the patient, who made many clarifications (both experiential and intellectual) in some depth, who were somewhat confronting, and who dominated the interaction but not to the exclusion of the resident's involvement. The cluster of nine included supervisors rated lower in empathy and in the degree they were perceived to facilitate resident learning. These supervisors focused more on the patient and less on the therapist and made mostly intellectual and discursive comments to the near exclusion of entering into the resident's immediate experiences. They made some clarificatory comments but were not at all confrontative or clearly in charge of the supervision. All four beginner supervisors were in this second group. Three of the supervisors in this group, however, had considerable supervision experience, having supervised more than 30 residents each.

A comparison of the two groups on each variable using two-tailed t tests revealed no significant differences on the activity, comfort, or tension variables (table 2).

Discriminant function analyses revealed no distinguishing variables between the two sessions of the 19 supervisors who had sessions with two different residents videotaped. These analyses also revealed no distinguishing variables between supervisors of residents in different years of training. Multivariate F statistics for Wilks's lambda were not significant for these two comparisons (lambda=0.51, F=1.5, df=14, 23, p<0.16, and lambda=0.77, F=0.82, df=14, 38, p<0.65, respectively).

Stepwise multiple regression analysis of the 34 supervisors revealed that for the rater's perception of excellence (the dependent variable), empathy accounted for 72% of the variance (standardized coefficient=0.63, p<0.0001) and focus on the therapist accounted for 77% of the variance (standardized coefficient=0.32, p<0.01) (F=52.18, df=2, 31, p<0.0001). In this analysis, empathy is a global indicator. Therefore, in order to look at the relationship of the raters' judgments about supervisors' excellence as teachers to more discrete patterns of supervisory behavior, empathy was dropped from the regression equation. When this was done, experiential orientation accounted for 60% of the variance of the rater-perceived excellence variable (standardized coefficient=0.46, p<0.0001), clarification and interpretation accounted for 76% of the variance (standardized coefficient=0.35, p<0.001), and depth accounted for 79% of the variance (standardized coefficient=0.27, p<0.04) (F=38.41, df=3, 30, p<0.0001).

## DISCUSSION

Within the context of an established supervisory relationship, the behavior of psychotherapy supervisors appeared not to change significantly with different psychiatry residents or across different years of resident training. These findings provide support for earlier observations of enduring and consistent styles of psychotherapy supervisors (13). About three-quarters of this group of 34 supervisors were judged to be at the higher end of excellence in facilitating resident learning and were rated higher in empathy. These supervisors provided a mix of comments directed to the therapist and the patient on intellectual as well as experiential levels and made many synthesizing comments in some depth. In contrast, one-quarter of the supervisors were rated low in the degree to which they facilitated resident learning and in empathy. Their comments were more often discursive, intellectualized statements and generalized elaborations of the material, with little attention to the specific concerns of the student. Of note, four of the nine supervisors with low ratings were inexperienced beginners, but three were senior supervisors who had supervised many residents.

The supervisors' activity levels, as well as levels of tension and comfort in the session, were not distinctive aspects of supervision when considered within the context of all other variables. In other words, the amount of talking done by supervisors was a trait that appeared to have little to do with perceptions of teacher excellence or empathy. Similarly, levels of tension and comfort had an ebb and flow in any supervision session and appeared not to have a bearing on judgments about excellence and empathy.

This research is an effort to systematize the study of supervision. Raters showed notable agreement in discerning the behavior of supervisors and in their overall judgments as to the excellence of the supervisors' facilitation of residents' learning. Our findings are in general agreement with the supervision literature as well as the current understanding of the clinical teaching process (8–11, 23, 24). Supervisors judged to be excellent were empathic and focused on the immediate concerns of the trainee. They had an experiential orientation and tailored their comments to the residents' concerns. Such supervisors emphasized the patient's or the therapist's thoughts and feelings as closely as possible to the way they were actually elaborated and stayed with the immediate material, including cognitive and affective elements. Furthermore, these supervisors frequently synthesized and reframed material for the resident and made comments in depth. They were teachers who reflected with residents on their actions as therapists and supervisees (8, 25).

There are limitations to this research. First, we studied supervisors as they appeared on videotapes. What patterns of behavior changed as a result of being videotaped is unclear. The literature on observed psychotherapy and interviews does not provide a clear guide to what specifically changes as a result of the observation process. Therapists are often conscious of being observed and experience varying levels of anxiety about the possibility of criticism from peers as to their competence. However, fulfilling the task at hand prevails, in spite of these concerns (26–33). We found relative stability of the patterns of behavior of supervisors with two different residents as measured by the Psychotherapy Supervision Inventory scales even after a considerable lapse of time between taped sessions. It is possible that some patterns of behavior could have changed consistently across sessions in response to taping, but there is no information about this. Asking residents and supervisors about this would provide a sense of which

[c] $p<0.05$.

[d] $p<0.01$.

[e] $p<0.001$.

patterns of behavior, if any, changed while taping. This question merits study.

A second limitation of this study is that ratings were based on experts' judgments of the supervisor without attention to the supervisors' or supervisees' perspectives. Knowledge of these perspectives would provide data about the transfer of learning from the supervisory session to the resident's interaction with the patient. This item also merits exploration.

Finally, a third limitation of this study is that the raters' judgments of excellence reflected their biases, likely based on a tacitly agreed upon model of teaching psychotherapy. Although the findings appear to fit with what is known about the supervisory process, they merit validation from other researchers informed about supervision who also observe videotaped sessions and rate a large number of such sessions in a systematic fashion.

How can the findings of the present study be used in psychotherapy education? The Psychotherapy Supervision Inventory can be used to orient supervisors to styles of supervision and to provide feedback about their individual patterns of behavior. Training can be done individually or in a group. Group training of supervisors has been shown to improve resident ratings of supervision (12). Such training is best done by teachers who are informed about the supervisory process by having reviewed and discussed observed supervision sessions.

# An Outcome Study of Psychotherapy for Patients With Borderline Personality Disorder

Janine Stevenson, M.B., B.S., F.R.A.N.Z.C.P.,
and Russell Meares, M.D., F.R.A.N.Z.C.P., F.R.C.Psych.

*Objective: This study evaluated the effectiveness of well-defined outpatient psychotherapy for patients with borderline personality disorder. Method: Thirty patients with borderline personality disorder diagnosed according to the* DSM-III *criteria were given twice weekly outpatient psychotherapy for 12 months by trainee therapists who were closely supervised. The treatment approach was based on a psychology of self (this term being used in its broad sense), and strong efforts were made to ensure that all therapists adhered to the treatment model. Outcome measures included frequency of use of drugs (both prescribed and illegal), number of visits to medical professionals, number of episodes of violence and self-harm, time away from work, number of hospital admissions, time spent as an inpatient, score on a self-report index of symptoms, and number of* DSM-III *criteria (weighted for frequency, severity, and duration) fulfilled. Results: The subjects showed statistically significant improvement from the initial assessment to the end of the year of follow-up on every measure. Moreover, 30% of the subjects no longer fulfilled the* DSM-III *criteria for borderline personality disorder. This improvement had persisted 1 year after the cessation of therapy. Conclusions: The results suggest that a specific form of psychotherapy is of benefit for patients with borderline personality disorder.*

(Am J Psychiatry 1992; 149:358–362)

Until comparatively recently, no treatment was available for persons with severe personality disorder. Individuals so badly damaged were considered "unanalyzable." However, over the last two decades, methods of treating borderline and narcissistic personalities have been steadily evolving. The aim of this project was to evaluate the effectiveness of an identifiable form of psychotherapy, conducted by trainee therapists working under close supervision, in the management of outpatients with borderline personality disorder. As far as we are aware, this report describes the first prospective study of this kind.

## THE STUDY

A group of patients with severe personality disorder were given psychotherapy for 12 months, at two sessions per week. Measures were taken to assess the patients before, during, and after treatment.

### *Treatment Model*

We made considerable efforts to develop a coherent, consistently applied, and identifiable treatment approach. It was based on the notion that borderline personality disorder is a consequence of a disruption in the development of the self. The principal assumption is that a certain kind of mental activity, found in reverie and underlying symbolic play, is necessary to the generation of the self. This kind of mental activity is nonlinear, associative, and affect laden. In early life its presence depends on a sense of "union" with caregivers, in which they are experienced as extensions of the developing individual's subjective life (1, p. 243). Development is disrupted through repeated "impingements" (2) of the social environment, which have an impact on the child rather like that of a loud noise. This effect arises through actual stimuli (abuse of various kinds is common in the early lives of borderline patients [3–5]), through high anxiety, and through responses that do not connect with the child's immediate reality and so seem to come from "outside."

The aim of therapy is maturational. Specifically, it is to help the patient discover, elaborate, and represent a personal reality (6), i.e., a reality that relates to an inner life

---

and that has an affective core (7). The first task is to establish the enabling atmosphere in which the generative mental activity can arise. In order to do so, the therapist must imaginatively immerse himself or herself in the embryonic inner life of the patient. Empathy, however, inevitably fails. The second main task of the therapist is to detect these failures, to focus with the patient on his or her experience at the moment of the failures, and then to allow these experiences to be the starting point of experiential explorations. Such empathic failures, or disjunctions, are indicated by 1) negative affect (e.g., deadness, anxiety), 2) linear thinking, 3) an orientation toward events and the outer world, 4) a change in self state (e.g., devaluing, grandiose), and 5) emergence of transference phenomena (8). An illustrative therapy session, which includes a further description of the treatment method, is reproduced elsewhere (9).

This therapeutic approach was influenced by Robert Hobson's work with borderline patients at the Bethlehem Royal Hospital, London, during the 1960s (10). The theoretical framework includes essential elements from the work of Kohut (11) and Winnicott (12). The model is consistent with Pine's description of the "borderline-child-to-be" (13).

Whether therapists adhere to the therapeutic model is a major problem in psychotherapy outcome research. In this project, the problem was approached in three main ways. First, all therapists were given instruction in the method by means of weekly seminars. Second, all therapy sessions were audiotaped and replayed with a supervisor once a week. In this way, the supervisor could make judgments about adherence to the model and suggest alterations of therapists' behavior. Third, in order to achieve maximum uniformity of approach, supervisors, on occasion, supervised together.

Ideally, a manual that defines therapeutic behavior is used to establish adherence, in the manner of Luborsky (14). This might be done by independent judges rating transcripts, which facilitates replication studies and also matching of outcome against the treatment model. However, in this case such a process is complex, since the therapeutic field is "intersubjective" (15). The therapeutic response cannot be judged as "correct" before it is made. Its suitability is evident only after it has been made. For example, a patient who had spent much of his early life in an orphanage and who could not remember anything before the age of 10 began a session by announcing that his girlfriend was pregnant. This appeared to be "no problem," since she would get an abortion. After a few connecting sentences, the patient, showing little affect, went on to say that he wondered whether some early memories were beginning to be recovered, since he had had "images" of himself as a terrified child being dragged from under a bed, presumably to be taken to the orphanage. The therapist then remarked that the forthcoming abortion seemed to have triggered feelings relating to his being "gotten rid of" by his own mother. The patient said, "Good point," in a rather pompous voice. He then recounted, without any apparent reason, successive incidents in which he had been physically attacked and injured; had been humiliated after revelation of an emotional state; had felt "paranoid"; and had been enraged. A disjunction was signaled by the change from inner concerns ("images") to outer events, by the affect which escalated from agitation to anger, and by the alteration in self state indicated by the pompous voice. It is apparent that the therapist's response was sensed as an intrusion (16). In one sense it was "correct," in that it was accurate; in another it was not, since it produced a disjunction. The "correct" subsequent response is to explore the effect of the first response. This requires skill, since it may be sensed as a second intrusion.

A second difficulty in rating transcripts is that the nuances of the interchange are often reflected in changes in voice, which are a matter of subjective judgment. In the incident just described, for example, the change of voice at "Good point" was not noticed by the therapist.

Despite these problems, a linguistic analysis of transcripts, based on Halliday's systemic grammar (17), is underway in order to provide data for a future manual that will address a limited range of therapeutic issues.

### *Subjects*

Patients were referred by psychiatrists, allied health professionals, community clinics, and inpatient units, and some were self-referred. Eighty-five consecutive patients were rated by three independent psychiatrists according to the *DSM-III* criteria for borderline personality disorder in a diagnostic interview that included the Diagnostic Interview for Borderline Patients (18). They were then seen by a consultant psychotherapist who made a diagnosis of borderline personality disorder on dynamic grounds. Potential subjects were also required to display persisting social dysfunction (e.g., unemployment for more than 12 months, absence of or severely dysfunctional interpersonal relationships, antisocial behavior). Sixty-seven patients fulfilled these criteria. All 67 had previously been unsuccessfully involved in other forms of therapy for a period of not less than 6 months.

Eight of these patients were considered unsuitable for psychotherapy for the following reasons: borderline intellectual retardation (N=2), language difficulty (N=2), antisocial and uncontrollable violent behavior (N=1), and failure to keep three consecutive appointments (N=3). Fifty-nine potential subjects now remained.

After the course of treatment was explained, 11 patients declined treatment or accepted but failed to keep further appointments. At this stage written consent was obtained from the remaining 48 patients, all initial assessments were performed, an appointment was made for an interview with a close friend or relative of each patient, and the patient was assigned to a therapist. After 6 months of therapy and at the conclusion of therapy, further assessments were performed. During the 12 months, eight patients dropped out of therapy, mostly in the first 3 months, before a firm relationship had been established with the therapist. This left 40 patients who completed 12 months of therapy. (Seven of these elected to continue therapy for a longer time and so were excluded from the present study. They were doing well. The decision to omit them was on the grounds that they had not terminated and that their current state might seem to inflate the value of the treatment.) It was explained to the 33 patients who completed the 12-month course of therapy that they would be contacted a year later "to see how they were doing." Of these 33 patients, three could not be contacted. Thus, of the 48 patients who accepted therapy, 37 completed all assessments. Seven continued therapy and were excluded from the present study. The remaining 30 patients are the subject of this article.

### *Therapists and Supervisors*

The 20 therapists were relatively untrained in psychotherapy, since they were trainee psychiatrists (1–3 years of psychiatry training, 1–2 years of postgraduate medical training), registered nurses, and psychologists. They were young (average age=30.6 years—close to the average age of the patients), 12 were single and eight were married, and 11 were male and nine female. Six had postgraduate qualifications.

Although the supervisors had different training experiences, they developed fairly consistent supervisory behavior. Two were trained by Robert Hobson, a third was a psychoanalyst trained in London, a fourth was oriented toward Sullivan's interpersonal psychology, and two others were oriented toward Kohut's self psychology.

## METHOD

Demographic data—age, sex, occupation, partner's occupation, marital status, education, physical health, place of residence, parent's or surrogate parent's occupation, and country of origin—were collected on all subjects. (A large number of patients had been adopted, placed in foster homes, or institutionalized early in life.)

The number of *DSM-III* criteria for borderline personality disorder fulfilled by the subject was determined. Each was weighted on the basis of frequency, severity, and duration, and the total score was recorded. (A number of patients also fulfilled the *DSM-III* criteria for other personality disorders, such as schizotypal, histrionic, narcissistic, and antisocial.) No modifications were made following publication of *DSM-III-R*, since the criteria were essentially unchanged.

The Cornell Index (19) provided a self-report rating of symptoms. An initial measure was taken to assess severity of dysfunction and as a baseline for later comparison. This index is generally used for quite disabled patients. Consequently, it was considered more suitable for our population of subjects than instruments used for neurotic patients. Measures were taken at the initial assessment, after 6 months of therapy, after 12 months of therapy, and at follow-up 12 months later.

Objective behavioral measures were collected en bloc for the entire year preceding and for the year following therapy. They included amount of time away from work (in months), use of medical facilities (number of outpatient visits to a medical facility each month), quantity of drugs (prescribed and illegal) used on a daily basis, self-destructive behavior and outwardly directed violence (number of episodes over a 12-month period), and number of hospital admissions and time spent as an inpatient (in months). Information was obtained from the patient, friends or relatives, medical records, and referral sources. Such methodology reduces errors that may be inherent in the patient's own report. All assessments were performed by the research psychiatrist (J.S.), who was not involved in the therapy process.

The MINITAB data analysis software was used to analyze results. Paired t tests were used to explore the differences between the independent variables before and after therapy, followed by post hoc Bonferroni adjustments of alpha levels.

## RESULTS

The mean age of the subjects was 29.4 years (SD=7.9). Nineteen were female and 11 male. Nine were married. Only three had not completed junior high school; six had undertaken college studies. Eight subjects had received long-term institutional or foster care. None had serious medical problems. Twenty-two (73.3%) were receiving government financial assistance (sickness benefits, invalid pension, unemployment benefits, etc.). The remaining eight worked erratically in various nonskilled (N=2), skilled (N=3), and professional (N=3) occupations. Only two owned their own homes; the remainder were renting privately, living with friends or relatives, or in government housing.

There was a significant reduction in the number of *DSM-III* criteria fulfilled at follow-up (mean=10.50) compared with pretreatment (mean=17.40) (table 1). The most frequently observed changes were reductions in impulsivity, affective instability, anger, and suicidal behavior. It is also noteworthy that at follow-up, only 70% (N=21) of the 30 subjects fulfilled the *DSM-III* criteria for borderline personality disorder, compared with 100% before treatment.

There was a marked and statistically significant improvement on all seven objective behavioral measures over the 12 months following therapy compared with the 12 months before therapy when pretreatment scores were compared with follow-up scores (table 1); for example, medical office visits dropped to only one-seventh of pretreatment rates (3.50 to 0.47 per patient per month), and self-harm and drug use dropped to one-fourth of pretreatment rates.

Cornell Index scores had dropped significantly 12 months after treatment when compared with pretreatment levels (table 1); the rate of change over the 2 years was approximately linear (mean scores at 0, 6, 12, and 24 months were 42.63, 41.00, 33.60, and 28.63).

**TABLE 1. Scores of 30 Patients on Behavioral Measures, the Cornell Index, and *DSM-III* Criteria for Borderline Personality Disorder for the 12 Months Preceding and Following Psychotherapy**

| Measure | One Year Before Therapy Mean | One Year Before Therapy SD | One Year After Therapy Mean | One Year After Therapy SD | Paired t Test t (df=29) | Paired t Test p |
|---|---|---|---|---|---|---|
| Violent behavior (episodes per year) | 2.70 | 4.05 | 0.80 | 1.80 | 3.69 | <0.001 |
| Drugs used (number per day) | 3.80 | 3.42 | 0.63 | 0.80 | 5.05 | <0.001 |
| Medical visits (number per month) | 3.50 | 2.75 | 0.47 | 0.57 | 6.16 | <0.001 |
| Self-harm (episodes per year) | 3.77 | 4.66 | 0.83 | 1.18 | 3.82 | <0.001 |
| Time away from work (months per year) | 4.47 | 4.10 | 1.37 | 2.57 | 4.90 | <0.001 |

[b] Number of criteria for borderline personality disorder (weighted for frequency, severity, and duration) fulfilled by subject.

## DISCUSSION

Thirty patients with the diagnosis of borderline personality disorder were treated for 12 months. They showed significant symptomatic and behavioral improvement. Moreover, 30% no longer fulfilled the *DSM-III* criteria for borderline personality disorder. Improvement was maintained at follow-up 12 months later. These findings suggest that a specific form of therapy, supervised in a focused and coherent way, is helpful to a group of people who, most studies report, "do not fare well at follow-up" (20).

Studies of the management of borderline personality disorder have been criticized on the grounds that diagnostic criteria are not clear, outcome measures are relatively subjective, designs are retrospective rather than prospective, and there are no control measures (21). In this study we attempted to overcome these problems. The patients were carefully diagnosed according to *DSM-III,* the outcome measures were objective, and the study was prospective. The principal difficulty, however, concerned the method of control; we used control measures rather than control subjects.

No sensible or ethical solution to the problem of control subjects was evident to us. Ideally, a "placebo" therapy would be compared with the treatment model, in the manner of pharmacotherapy studies. The control subjects would spend the same amount of time as the other patients in sessions with a therapist. The therapist, however, blind to these circumstances, would be instructed by a supervisor to make interventions likely to have no therapeutic effect. Such a design seemed unacceptable from several points of view, including the communal. The clinic is the only one of its kind. The expectation of referral sources was that their patients, who had usually already received extensive and various treatments including drugs and ECT, would receive a "different" therapy, specially geared toward patients with severe personality disorders. Attempts to assign patients to treatments they had previously encountered resulted in these patients' dropping out. An alternative, the use of patients on the waiting list as control subjects, is impracticable with such an unstable population. On the other hand, since personality disorder is relatively enduring, comparisons between different periods of the patients' lives offer a suitable means of obtaining a control. Thus, 1 year of the patients' lives before treatment was compared with 1 year after.

This study cannot be compared with most others in this area, since they usually concern inpatients and are retrospective. Tucker et al. (20), however, reported on a prospective study of inpatients, the results of which, over 2 years, were favorable.

Of particular interest in the present study is the finding that patients were able to terminate treatment and maintain their improvement. Alternative explanations for the good outcome did not seem plausible. Those that were considered included spontaneous remission, a ceiling effect, selective attrition, and intercurrent therapy.

Spontaneous remission seemed an unlikely explanation for the results. In a previous study of psychotherapy outcome, a period of 6 months with continuous symptoms was used to differentiate patients with chronic illness from those whose illness remitted (H. Brodaty, unpublished doctoral thesis, 1985). All patients in our trial had continuous symptoms for 12 months, the majority for many years.

A second possible explanation for the improvement of our patients might be a so-called ceiling effect. Put another way, were the patients so disturbed that they could deteriorate no further? The histories of our patients did not support this possibility. For example, many had had inpatient treatment, but no patient entered the trial at one of these periods of crisis.

The possibility that selective patient attrition distorted the results of this study was not supported. There was no evidence that the more disturbed patients had dropped out. Comparisons were made between trial subjects and dropouts on demographic data (age, sex, occupation, social class, etc.), Cornell Index scores, fulfillment of *DSM-III* criteria, and behavioral measures. No significant differences were found on any measure. There was a tendency for the dropouts to live farther from the treatment center, although this difference did not reach statistical significance. Furthermore, the dropout rate was low—16%—compared with the rates in previous studies (22, 23).

Finally, any intercurrent treatments were carefully monitored in this study. On entering the trial, all patients had their medications gradually withdrawn. Hypnotics and minor tranquilizers were given to a minority of patients on occasion and to patients who needed hospitalization. Those few patients who needed hospital admission during therapy, usually during a crisis, continued to receive psychotherapy, while the ward provided a supportive, containing environment, but no other "treatment" was given. At each assessment interview interviewers asked about intercurrent treatment, appointments with other doctors, and alternative therapies. Little evidence of these was found. One patient who continued to see a previous therapist and who received medications from him eventually dropped out. Most patients had more or less exhausted other treatment options before referral into our trial.

In conclusion, this report suggests that a specific form of psychotherapy is of benefit for borderline patients. All patients will be followed up at 5 and 10 years. The cost effectiveness of treatment and aspects of the therapeutic process that are related to change are the basis for subsequent reports.

---

*Objective:* *Clomipramine, a serotonin reuptake blocker that has unique antiobsessional properties, was hypothesized to have a different effect from that of desipramine, a tricyclic antidepressant with selective adrenergic effects, for the stereotyped, repetitive behaviors in autism.* *Method:* *Seven subjects, ages 6–18 years, with autistic disorder completed a 10-week double-blind, crossover trial of clomipramine and desipramine following a 2-week single-blind, placebo phase.* *Results:* *Clomipramine was superior to desipramine and placebo, as indicated by standardized ratings of autism and anger as well as ratings of repetitive and compulsive behaviors. Clomipramine and desipramine were equally superior to placebo for ratings of hyperactivity. Parents of all seven subjects elected to have their children continue to take clomipramine after the study.* *Conclusions:* *Clomipramine and desipramine are differentially effective in treating the obsessive-compulsive and core symptoms in autistic disorder. Biological links between compulsions and stereotyped, repetitive behaviors in autistic disorder should be explored.*

(Am J Psychiatry 1992; 149:363–366)

---

Autistic disorder is a pervasive developmental disorder characterized by impairments in reciprocal social interaction, communication skills, and imaginative activity (*DSM-III-R*, pp. 33–39). Since Kanner's classic description (1), repetitive, stereotyped, and ritualistic behaviors have been considered an integral part of the syndrome. Ritualized body movements, repeated touching and sniffing of objects, ritualistic ordering, checking, and collecting, and insistence on precisely following routines are commonly present. Neurochemical investigation has consistently revealed elevated levels of whole blood or platelet serotonin in more than 25% of autistic subjects (2).

Clomipramine, a tricyclic antidepressant with potent serotonin reuptake blocking action, has been shown to be more effective than desipramine, a primarily noradrenergic agent, in treating obsessive-compulsive disorder (3) as well as unwanted repetitive behaviors such as trichotillomania (hair pulling) (4) and onychophagia (nail biting) (5). These studies raise the question of what additional abnormal ritualistic behaviors may be responsive to clomipramine. We hypothesized that the compulsive and stereotyped behaviors seen in autism would be differentially responsive to clomipramine relative to desipramine.

## METHOD

Seven subjects (five male and two female), between 6 and 18 years of age (mean=9.6 years, SD=4.4), who fulfilled the *DSM-III-R* and Autism Diagnostic Interview (6) criteria for autistic disorder were obtained through self-referral and referral by health care professionals. The severity of mental retardation and obsessive-compulsive symptoms for each subject is shown in table 1. All of the subjects were free of significant medical problems, including seizures, by history and by physical examination, and no subject's autism had a diagnosed organic cause. The subjects had been free of psychoactive medications for at least 3 months before the study. The study was approved by the National Institute of Mental Health (NIMH) institutional review board. Informed consent was obtained from the parents of all of the subjects before the start of the study, and the subject's assent was obtained when possible, depending upon his or her intellectual level.

The subjects underwent a 10-week double-blind, randomized, crossover trial of clomipramine (mean dose at week 5, 129 mg/day [SD=39], or 4.3 mg/kg/day [SD=0.8]) and desipramine (mean dose at week 5, 111 mg/day [SD=40], or 3.8 mg/kg/day [SD=1.2]) following a 2-week single-blind, placebo phase. Randomization was per-

formed by the National Institutes of Health pharmacy with a random number table. All medication was administered orally by parents twice a day. The initial dose was 25 mg/day, and the dose was increased every 4–5 days until positive effects or side effects were noted or a maximum of 250 mg/day, or 5 mg/kg/day, was reached. The maximum dose was usually reached between weeks 2 and 3, so that the subjects were maintained on their maximum doses for 2–3 weeks. After 5 weeks, the first-phase medicine was tapered over approximately 1 week concurrent with a gradual increase of the second-phase medicine, which was also given for 5 weeks. Plasma drug levels were ascertained during week 5 of each medication phase by high-performance liquid chromatography.

Weekly physician ratings included the Children's Psychiatric Rating Scale (7), the Clinical Global Impression (CGI) (8), a modified version of the obsessive-compulsive subscale of the Comprehensive Psychopathological Rating Scale (9), a modified version of the NIMH Obsessive-Compulsive Rating Scale (10), and modified versions of the NIMH Global Obsessive-Compulsive and Anxiety scales (11). The obsessive-compulsive rating scales were modified to make them more relevant for relatively nonverbal subjects. Intraclass correlation coefficients for two physicians who independently rated 10 autistic subjects from a separate sample with the modified obsessive-compulsive rating scales were 0.72 for the obsessive-compulsive subscale of the Comprehensive Psychopathological Rating Scale, 0.88 for the NIMH Obsessive-Compulsive Rating Scale, 0.94 for the NIMH Global Obsessive-Compulsive Scale, and 0.67 for the NIMH Global Anxiety Scale. Data were analyzed by repeated measures analysis of variance, with Bonferroni-corrected post hoc t tests (two-tailed), comparing ratings for baseline, placebo, week 5 of clomipramine treatment, and week 5 of desipramine treatment.

## RESULTS

Two subjects discontinued taking desipramine after 3 weeks during the second phase because of uncharacteristic and severe irritability and temper outbursts. For these subjects, ratings for week 3 of desipramine treatment were analyzed in place of week 5 ratings.

Clomipramine had a selectively beneficial effect, as measured by the 14-item autism-relevant subscale of the Children's Psychiatric Rating Scale (table 2). These 14 items have been found to represent four factors: autism (individual items measure withdrawal, rhythmic motions, abnormal object relations, unspontaneous relation to the examiner, and underproductive speech), anger/uncooperativeness, speech deviance, and hyperactivity (12). The percent change from baseline scores for each of these factors during placebo, week 5 of clomipramine, and week 5 of desipramine is shown in figure 1. Statistically significant improvement in the autism and anger factors and a trend toward improvement in the speech deviance factor were seen. For hyperactivity, both drugs were rated superior to placebo but not significantly different from each other.

As predicted, there was significant improvement in obsessive-compulsive symptoms with clomipramine but not desipramine, as measured by the modified NIMH Obsessive-Compulsive Rating Scale (table 2). All of these results contributed to the substantial superiority of clomipramine on the efficacy index of the CGI ($F=42.98$, $df=2, 12$, $p=0.0001$).

Additional ratings (modified obsessive-compulsive subscale of the Comprehensive Psychopathological Rating Scale and modified NIMH Global Obsessive-Compulsive and Anxiety scales) all showed significant ($p<0.05$, two-tailed t tests) improvement during clomipramine treatment as compared to baseline, placebo, and desipramine. The superiority of clomipramine over desipramine was not an artifact of behavioral deterioration when subjects were taking desipramine. No measure showed significant worsening in the desipramine phase as compared to baseline or placebo.

For the most part, side effects were minor and did not differ significantly between drugs. They included mild sleep disturbance, dry mouth, constipation, and, in one subject, a mild tremor when taking clomipramine. There were no serious cardiac or CNS side effects. As previously noted, two subjects discontinued desipramine after 3 weeks because of adverse behavioral effects.

As expected, plasma drug levels varied widely; at week 5, the mean clomipramine level was 159 ng/ml (range=56–301), the mean desmethylclomipramine level was 345 ng/ml (range=182–448), and the mean desipramine level was 325 ng/ml (range=75–291, except that one subject had a level of 839 ng/ml). There was no significant correlation between plasma drug levels and clinical ratings or side effects. (The subject with the desipramine level of 839 ng/ml had no side effects.)

The parents of all seven subjects elected, before the blind was broken, to have their children continue to take clomipramine after the study.

## DISCUSSION

This was the first controlled trial of a serotonin reuptake blocking agent for autistic disorder. In this double-blind comparison, clomipramine, a potent serotonin re-

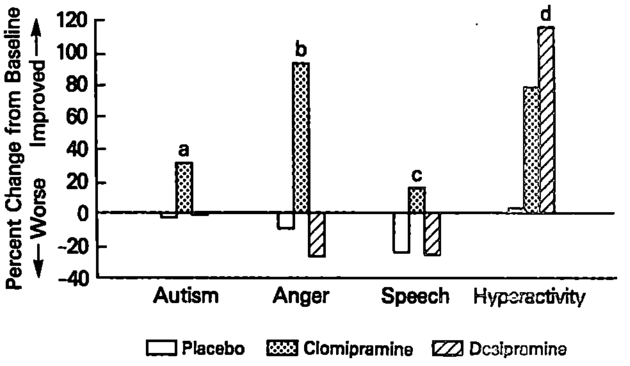
uptake blocker, was differentially effective in treating autistic disorder compared with the primarily noradrenergic tricyclic desipramine. Obsessive-compulsive symptoms improved, as had been hypothesized given the differential response of these behaviors to serotonin reuptake blockers in obsessive-compulsive disorder. In addition—and unexpectedly—core autistic symptoms, as measured by the autism factor of the Children's Psychiatric Rating Scale, were improved differentially by clomipramine. The results of this study are consistent with a previous single case report of fluoxetine treatment of a 26-year-old autistic woman in which improvement in ritualistic behavior and other autistic symptoms was described (13). These findings have important clinical and theoretical implications.

Pharmacologic trials in autism to date have yielded relatively disappointing results. The most studied and consistently useful agent has been haloperidol (14), although it has been debated whether the type and magnitude of improvement shown in research is clinically significant (15), and side effects including tardive dyskinesia are problematic (16). Even though the sample size was small in our study, the consistency of the positive clinical effects of clomipramine was striking. Furthermore, the parents of all seven subjects chose to have their children continue taking clomipramine after completion of the study, indicating that the statistically significant improvements on the rating scales were clinically significant.

Worsening of behavior was reported in one-half of a group of 10 autistic and schizophrenic children during an open trial of imipramine, and this was cited as evidence for the detrimental effect of serotonin reuptake inhibition (17). The deterioration in behavior may have been due to reuptake inhibition of norepinephrine or other pharmacologic effects of imipramine. The clomipramine-induced improvement in our study was relative to both placebo and desipramine and not an artifact of behavioral deterioration during treatment with desipramine, the major metabolite of imipramine.

**FIGURE 1. Percent Change From Baseline in Scores of Seven Autistic Subjects on the Autism-Relevant Subscale Factors of the Children's Psychiatric Rating Scale in a Comparison of Clomipramine and Desipramine Treatment**



[a] $F=10.26$, $df=3, 15$, $p=0.02$.
[b] $F=5.03$, $df=3, 12$, $p=0.05$.
[c] $F=2.78$, $df=3, 15$, $p=0.12$.
[d] $F=4.62$, $df=3, 15$, $p=0.05$.

It is intriguing to speculate on the relation between clomipramine's serotonergic effects and its efficacy in autism. Reduced central serotonergic responsivity has been reported in autistic disorder (18), and clomipramine might enhance central serotonergic transmission, thereby improving clinical features of autism. However the effects of clomipramine on central serotonergic function remain unclear (19), and the serotonin-releasing agent fenfluramine has been extensively studied in autism (20) with equivocal results. The relation between clomipramine-induced improvement and platelet serotonin in our sample is presently under investigation.

Similarities in phenomenology and differential response to serotonin reuptake blocking drugs in obsessive-compulsive disorder, trichotillomania, onychophagia, and autistic disorder suggest similarities in underlying pathophysiology. Central serotonergic dysfunction might be related to impulsive, ritualistic behavior in general, independent of diagnostic categories.

Behavioral symptom patterns in autism are often cyclic, potentially complicating the findings derived from relatively brief medication trials. It is common for transient clinical improvements to occur shortly after the introduction of a new medication. However, this seems unlikely to have occurred in this study, since desipramine treatment did not result in similar benefit.

These preliminary results need to be extended with a larger sample and a longer-term clomipramine treatment period, as well as with short-term, double-blind placebo comparisons. Such studies are presently underway.

# Serum Prolactin Levels in Homosexual and Bisexual Men With HIV Infection

Jack M. Gorman, M.D., Patricia A. Warne, Ph.D., Melissa D. Begg, Sc.D.,
Thomas B. Cooper, M.A., Hana Novacenko, M.S., Janet B.W. Williams, D.S.W.,
Judith Rabkin, Ph.D., Yaakov Stern, Ph.D., and Anke A. Ehrhardt, Ph.D.

*Objective: Prolactin is a neurohormone that may be secreted in response to stress and also has regulatory effects on the immune system. Some, but not all, studies suggest that prolactin levels are higher than normal in persons with HIV infection. The authors measured prolactin levels in HIV-positive and HIV-negative homosexual and bisexual men to assess possible differences in levels and then examined relationships between prolactin level and measures of medical status, anxiety, depression, stress, and neuropsychological test performance. Method: Blood for prolactin level determination was obtained from 121 HIV-seropositive and 79 HIV-seronegative homosexual and bisexual men enrolled in a longitudinal study. The men also underwent a daylong assessment that included medical, immunological, psychiatric, psychosocial, psychosexual, and neuropsychological evaluations. Results: There was no statistically significant difference in serum prolactin level among the seronegative men, the seropositive men with no or minimal physical symptoms, and the seropositive men with significant physical symptoms of HIV infection. Furthermore, within the HIV-seropositive group, the correlations between serum prolactin level and measures of depression, anxiety, stress, and neuropsychological test performance were all nonsignificant. Conclusions: Serum prolactin level does not seem to respond to HIV infection or to be related to stress or psychiatric symptoms in HIV-infected men. As none of the subjects had AIDS, the possibility cannot be ruled out that prolactin level increases in very late stages of HIV infection.*

(Am J Psychiatry 1992; 149:367–370)

The human immunodeficiency virus (HIV) produces disruption in almost every aspect of immune function, ultimately leading to an inability to contain opportunistic infection and neoplastic cell growth. It is clear, however, that a variety of responses are mounted against HIV by the infected host and, at least in early stages, contain the virus's ability to create immunological collapse. Neuroendocrine factors are known to have a role in regulating immune function, and recent work has examined possible ways in which the hypothalamus and pituitary gland may respond to HIV infection.

Prolactin is one hormone of particular interest because it is believed to have significant interaction with immune function (1–4) and may also be released during stress (5–8). High prolactin levels have also been implicated in panic disorder (9), psychosis (10), and alcoholism with psychosis (11). In all cases, the differences in prolactin level are modest.

A few studies have examined prolactin levels in patients with HIV infection. Croxson et al. (12) measured the prolactin levels of 85 homosexual men. The mean prolactin levels of patients with AIDS and patients with AIDS-related complex were significantly higher than that of seronegative men. The difference in prolactin level between asymptomatic HIV-positive and HIV-negative men was not significant. Nelson et al. (13) also found a higher mean prolactin level in a group of 48 HIV-infected men than in either a group of 13 HIV-negative homosexual men or a group of 14 men described by them as "normal heterosexuals." Three small studies (14–16) showed no relationship between prolactin level and HIV infection.

The literature therefore suggests that prolactin level may increase with increasing severity of HIV infection, and there are theoretical reasons to believe that prolac-

tin level may increase with stress or psychiatric illness and play a role in immune function. As part of a longitudinal, multidisciplinary study of patients with HIV infection, we obtained blood for prolactin level determination from HIV-seropositive and HIV-seronegative homosexual and bisexual men during a baseline evaluation that included medical, immunological, psychiatric, psychosexual, and neuropsychological assessments. In our relatively large study group we looked for differences in prolactin level among groups stratified for degree of illness severity. Furthermore, we analyzed the data to determine relationships between prolactin level and measures of illness severity, stress, and psychiatric symptoms.

## METHOD

### *Subjects*

The subjects of this report are all enrolled in an ongoing study of HIV infection and are described in more detail elsewhere (17). When the study was initiated in 1988, the cohort of homosexual and bisexual men included 123 HIV-seropositive and 84 HIV-seronegative subjects. One HIV-seropositive subject previously included in the cohort actually had AIDS at the baseline assessment according to information subsequently received and has therefore not been included here. The subjects are seen every 6 months for a daylong evaluation that includes medical history and physical examination, neurological examination, neuropsychological testing, and psychiatric and psychosexual interviews. Blood is obtained for lymphocyte subset analysis, serum p24 antigen level determination, and confirmatory HIV testing. Serum from every subject is then frozen. Urine is also obtained for 24 hours to determine urinary free cortisol level. All subjects signed informed consent statements before testing.

To be included in the study, a subject was required to have known his HIV status for at least 1 month and to have not used intravenous drugs more than 10 times since 1981. HIV-seropositive subjects at all stages of the illness were enrolled, but subjects who already had histories or evidence of opportunistic infection or secondary tumors that met the CDC National Surveillance Criteria for AIDS (18) were excluded.

Of the 123 HIV-seropositive and 84 HIV-seronegative men assessed at baseline, serum samples sufficient for prolactin level determination were available for 121 and 79, respectively. The mean ages of the two groups were not significantly different: 38.4 years (SD=8.2) versus 37.5 years (SD=8.7) ($t=-0.71$, $df=198$, $p=0.48$).

### *Procedure*

The medical history was obtained from each subject by a research nurse who was not blind to HIV status and used a structured interview focusing on HIV-related symptoms. Although the physician who performed the physical examination followed a semistructured format that also focused on HIV-related signs, the physician was blind to the subject's HIV status. The stage of HIV infection was rated according to standard CDC criteria (19).

The numbers of $CD4^+$ and $CD8^+$ T lymphocytes in peripheral blood were determined with a fluorescent activated cell sorter on mononuclear cell populations.

Psychiatric examination was performed by a trained mental health professional who was not blind to HIV status. This assessment included the Structured Clinical Interview for DSM-III-R (SCID) (20) and a battery of rating scales. Here we report results on the Hamilton Rating Scales for Depression and for Anxiety (21), a demoralization scale from the Psychiatric Epidemiology Research Interview (PERI) of Dohrenwend (22), the Beck Hopelessness Scale (23), and a modified version of the Faschingbauer et al. Texas Revised Inventory of Grief (24). Further details on our use of these scales can be found elsewhere (25, 26).

Neuropsychological testing was performed by a trained technician blind to HIV status and included a battery of tests described in detail elsewhere (27). Performance on each test was compared to the norm for an age- and education-matched population and then rated as normal, borderline (at least one standard deviation below expected mean), or defective (at least two standard deviations below the expected mean). A clinical impression of neuropsychological performance (normal, borderline, or abnormal) was based on the consensus of two experienced neuropsychologists who reviewed the test scores independently and were blind to HIV status.

Serum prolactin levels were determined from stored frozen serum. The protocol called for blood to be obtained from each subject between 8:30 and 11:00 a.m. Occasionally, for technical and scheduling reasons, a blood sample was obtained from a subject later in the day, but no record of this was kept. The nurses responsible for phlebotomy reported that in more than 90% of the cases blood samples from this cohort were obtained in the morning and that any breaches in the protocol occurred at random with respect to the subjects' HIV status.

Serum prolactin was measured with double antibody radioimmunoassay (28). The prolactin standard (hPR1-RP-1) and the primary antiserum were donated by the National Pituitary Agency (National Institute of Arthritis, Metabolism and Digestive Diseases). The $^{125}$I-labeled PR1 was repurified before use on a G-100 Sephadex column. Anti-rabbit-globulin serum was used to separate the bound and free fractions. The samples were assayed in duplicate. The intra- and interassay coefficients of variance were 6.37% and 6.86% at 3.8 ng/ml, 3.83% and 5.72% at 27.0 ng/ml, and 2.01% and 3.49% at 46.3 ng/ml.

To test for differences in serum prolactin level, we divided the subjects into three groups: HIV seronegative, HIV seropositive with no symptoms or only enlarged lymph nodes (CDC stages II and III), and HIV seropositive with more serious symptoms (CDC stages

IVa, IVb, IVc-2, and IVe). A three-group analysis of variance (ANOVA) was performed.

To test for a relationship between serum prolactin level and severity of HIV infection, we computed Pearson correlation coefficients within the HIV-positive group for the correlations between prolactin level and both number of $CD4^+$ T lymphocytes and ratio of $CD4^+$ to $CD8^+$ T lymphocytes (CD4/CD8).

To test for a relationship between psychological state and prolactin level, we computed Pearson correlation coefficients for the relationship between prolactin level and scores on the Hamilton depression scale, Hamilton anxiety scale, PERI demoralization scale, Beck Hopelessness Scale, and Texas Revised Inventory of Grief within the HIV-positive group. Finally, we determined the correlation between prolactin level and score on the neuropsychologists' impression within the HIV-seropositive group.

All p values are two-tailed. The number of subjects varies among measures because of missing data.

## RESULTS

Table 1 indicates that the HIV-positive patients had significantly fewer $CD4^+$ T cells, significantly more $CD8^+$ T cells, and a significantly lower CD4/CD8 ratio. The HIV-positive subjects had significantly higher demoralization and hopelessness scores and nearly significantly higher anxiety and depression scores than the HIV-negative subjects. The clinical neuropsychological impression and grief scores were not significantly different.

Only six (5%) of the HIV-positive subjects were taking zidovudine at the time of the baseline assessment, and we did not observe any relationship between zidovudine use and prolactin level in this small subgroup. Of other medications taken by the subjects in the study, only the antipsychotic drugs have, to our knowledge, a known effect on prolactin level. However, only two of the 121 HIV-positive men and one of the 79 HIV-negative men were taking these drugs.

Forty-seven (39%) of the seropositive men were in CDC stage II (asymptomatic), 28 (23%) were in CDC stage III (enlarged lymph nodes), and 46 (38%) were in CDC stage IVa, IVb, IVc-2, or IVe. The subjects were divided into three groups: 1) HIV-seronegative, 2) HIV-seropositive—asymptomatic/lymphadenopathy, and 3) HIV-seropositive—symptomatic. Three-group ANOVA of serum prolactin level revealed no significant difference among these groups; the mean levels were 9.2 (SD=3.2), 10.2 (SD=3.4), and 9.9 (SD=3.9) ng/ml, respectively (F=1.47, df=2, 197, p=0.23).

**TABLE 2. Correlation of Prolactin Level With T Cell Concentrations and Test Scores for 12 HIV-Positive Homosexual and Bisexual Men**

| | Correlation With Prolactin Level | | |
|---|---|---|---|
| Variable | r | df | p |
| T cell concentrations | | | |
| $CD4^+$ | –0.07 | 118 | 0.42 |
| CD4/CD8 ratio | –0.15 | 118 | 0.11 |
| Test scores | | | |
| Hamilton depression scale | –0.07 | 118 | 0.44 |
| Hamilton anxiety scale | –0.08 | 102 | 0.41 |
| PERI demoralization scale | –0.06 | 115 | 0.54 |
| Beck Hopelessness Scale | –0.07 | 114 | 0.47 |
| Texas grief inventory | –0.01 | 106 | 0.88 |
| Neuropsychologists' impression | 0.10 | 119 | 0.26 |

Table 2 indicates that within the HIV-positive group the correlations between serum prolactin level and number of $CD4^+$ T cells, CD4/CD8 ratio, anxiety, depression, demoralization, hopelessness, grief, and neuropsychological performance were all nonsignificant.

## DISCUSSION

We did not find higher than normal prolactin levels or a significant correlation between severity of infection and prolactin level in our HIV-seropositive men. Furthermore, we did not observe any relationship between prolactin level and measures of anxiety, depression, or neuropsychological test performance.

Like other groups of subjects (26), our group of HIV-positive subjects was relatively free of psychiatric illness at baseline, and none had AIDS. Without severely anxious, depressed, or medically ill individuals, we may have been limited in our ability to detect a relationship between psychological or medical state and prolactin level.

In an earlier report involving the same subjects (29), we found no significant difference between HIV-positive and HIV-negative homosexual and bisexual men in the level of 24-hour urinary free cortisol. The present findings on prolactin level are similar and, despite the cautions mentioned, suggest that prolactin level, like urinary cortisol level, is not altered in the earlier stages of HIV infection. Nevertheless, it is still conceivable that HIV, because it infects both the immune and the nervous systems, may disrupt normal relationships between neurohormones and immune function, as noted elsewhere (30). Future studies of prolactin's role in the immune response of HIV-infected patients should focus on more advanced stages of illness, functional measures of immune response (such as mitogen stimulation studies), and patient groups other than homosexual men.

# Prevalence of Cocaine Use Among Residents of New York City Who Committed Suicide During a One-Year Period

Peter M. Marzuk, M.D., Kenneth Tardiff, M.D., M.P.H., Andrew C. Leon, Ph.D.,
Marina Stajic, Ph.D., Edward B. Morgan, M.P.H., and J. John Mann, M.D.

*Objective: In the mid-1980s the form of cocaine called "crack" became widely available in New York City. The authors sought to determine the prevalence of cocaine metabolites detected at autopsy in persons who committed suicide in New York City during this period. Method: Individual reviews of the autopsy and toxicological records of all persons under the age of 61 who had committed suicide in the city during a 1-year period were conducted to determine demographic characteristics, suicide methods, and cocaine and alcohol use at the time of death. Results: In one of every five cases studied, the person who committed suicide had used cocaine within days of his or her death. The prevalence of cocaine use among young Hispanic males who committed suicide was 45%. Persons who were young, black, or Hispanic and who had used alcohol immediately before the fatal injury were most likely to have been recent cocaine users. After controlling for demographic variables and ethanol use, the investigators found that individuals who committed suicide with firearms were twice as likely to have used cocaine as those who used other methods. Conclusions: In contrast to the results of regional and household surveys during this period, which suggested that the current prevalence of cocaine use in New York City was 3%–5%, these results suggest a high prevalence of cocaine use in the days immediately preceding death by young persons who commit suicide. Additional studies are needed to determine how cocaine may act as a risk factor for suicide.*

(Am J Psychiatry 1992; 149:371–375)

Much recent attention has been properly focused on the association between cocaine use and rising homicide rates. However, the link between cocaine use and suicide has not been adequately investigated. Several studies have shown that chronic cocaine users experience intense suicidal ideation, particularly in the withdrawal phase, which can last for several days immediately following a cocaine binge (1–3). In addition, alcohol abuse, a major risk factor for suicide, is common among cocaine users (2).

Evaluation of the role of cocaine in suicide assumes added urgency in view of both the large proportion of polysubstance abusers among young persons who commit suicide and the rising suicide rate in the 1960s and 1970s among young males (4). The San Diego Suicide Study, conducted in the early 1980s, found that 30% of the persons under age 30 who committed suicide had histories of cocaine use, but it did not estimate the prevalence of cocaine use either at autopsy or in the general community (4). In 1986, 7% of all cocaine-positive deaths in New York City were suicides (5).

By 1985 a new, potent, inexpensive, smokable alkaloidal form of cocaine called "crack" had become widely available in New York City. The purpose of this study was to determine the prevalence of cocaine use among persons who committed suicide and the demographic characteristics of this group during this crack epidemic.

## METHOD

All cases certified as suicides by the New York City medical examiner that occurred among city residents during the calendar year 1985 were eligible for the study. This year was chosen because it corresponded to the latest full calendar year immediately before the most recent regional survey of cocaine use among the general

population of New York City. A list of all suicides classified according to *ICD-9* codes E950 through E959 was provided by the Office of Biostatistics of the New York City Health Department. Cases of individuals who were not residents of New York City but committed suicide within its geographic boundaries and cases of residents whose suicides were certified in other jurisdictions were not eligible for the study. In addition, cases in which the manner of death was certified as "undetermined" (*ICD-9* codes E980–E989) were ineligible. The medical examiner's records were individually reviewed in their entirety at the Office of the Chief Medical Examiner of New York City to ascertain demographic data; time, date, and location of injury, death, and autopsy; results of police and medical examiner investigations; previous hospital records if available; and toxicological findings.

For the purpose of determining the demographic characteristics related to cocaine use and suicide, we confined our analysis to persons aged 60 years or less who had been screened for cocaine at autopsy and who had died within 48 hours after a self-inflicted injury. Previous studies have shown that the prevalence of cocaine metabolites detected at autopsy in persons older than 60 is negligible (5, 6).

Survival time, defined as the period from self-inflicted injury to death, was also determined for all individuals who had received medical care prior to their deaths. A survival time in excess of 48 hours prohibits inferences about cocaine use at the time of lethal injury. A number of studies have shown that little cocaine metabolite is detectable in urine, by homogeneous enzyme assay at detection limits of 0.3 mg/liter, beyond 48 hours (7–9). Other studies suggest that metabolites can be detected in heavy users up to 120 hours or more after use (10, 11). In practice, this discrepancy in detection time had little appreciable effect on this sample of suicides, as the vast majority of individuals died within 48 hours after injury. The small group that had prolonged survival times survived for longer than 120 hours. In some cases, the lethal injury was accomplished in secret, and the dead person was discovered hours to days following the injury. For these individuals who did not receive medical care after the injury, survival time was indeterminate but was presumed to be less than 48 hours.

Urine and blood specimens obtained at autopsy were stored at 4 °C until assay. The principal metabolite of cocaine, benzoylecgonine, was screened in urine samples by means of a homogeneous enzyme immunoassay. A sample was considered positive if benzoylecgonine was detected at a concentration of 0.3 mg/liter or more. Analysis was repeated on all positive urine specimens. In addition, substantiation of positive results in urine specimens was obtained by radioimmunoassay for cocaine and/or metabolites in blood.

In some cases in which urine was not readily available at autopsy, blood was screened by radioimmunoassay. Results were considered positive by radioimmunoassay if cocaine and/or benzoylecgonine were detected at concentrations greater than 0.1 mg/liter. Blood specimens considered positive by radioimmunoassay were, in addition, analyzed for cocaine by gas chromatography.

Head space gas chromatography was used to perform ethanol analysis. Specimens were considered positive if the blood ethanol concentration was 2 mmol/liter or more. In cases in which blood alcohol concentrations were 7 mmol/liter or more, gas chromatography was done to assess brain concentrations.

Data were analyzed with the SPSS and BMDP Statistical Software. Differences in proportions were assessed with chi-square tests, and analyses of variance were used to compare group means. A logistic regression analysis was done to examine the association of hypothesized predictors (sociodemographic characteristics and methods of suicide) and cocaine use. The logistic regression model was used to estimate the risk of cocaine use associated with each level of a given predictor, controlling for all other predictors. Statistical significance was defined as a two-tailed probability of less than 0.05.

## RESULTS

There were 749 cases of suicide among New York City residents in the study year, of which 570 involved persons aged 60 years or less. In this sample of 570 cases, 482 persons had survival times under 48 hours and were screened for cocaine. In the remaining 88 cases, excluded from this study, most persons had survival times that exceeded 48 hours, and in a few, toxicology screens were not available because of family objections to autopsy. Both the mean age and the racial composition of the smaller, excluded group (N=88) differed significantly from those of the study group (N=482): the excluded group was older (mean ages=41.7 years [SD=12.8] and 35.4 years [SD=10.8], respectively; F=24.21, df=1, 568, $p<0.0001$) and had more white and Asian persons ($\chi^2=19.9$, df=3, p=0.0002). There were no sex differences between these groups.

Cocaine metabolites were detected in 105 (21.8%) of the 482 persons who were 60 years of age or younger (95% confidence interval=18.1%–25.5%). By assuming that the excluded cases had negative toxicological findings for cocaine and/or benzoylecgonine, the minimum and most conservative prevalence estimate of recent cocaine use for the total sample under age 61 (N=570) was 18.4%, and for the total sample of all ages (N=749), it was 14.0%.

The demographic characteristics of the 482 persons who survived 48 hours or less after injury, grouped according to cocaine toxicology results, are shown in table 1. Ethanol was detected conjointly with cocaine in approximately half of the cases consistently across all demographic categories.

A logistic regression analysis was performed to test the effects of age, sex, race/ethnicity, suicide method, and alcohol use on the likelihood of recent cocaine use. Of these, age, race, use of firearms, and positive ethanol toxicology results were significant, but sex was not (table 2). When age, sex, alcohol use, and suicide method

were controlled, Hispanic and black persons were 3.3 and 1.9 times as likely, respectively, as white persons to have used cocaine immediately before committing suicide (table 2). It is particularly noteworthy that when age, race/ethnicity, sex, and alcohol use were controlled, persons who used firearms to commit suicide were twice as likely to have used cocaine as individuals who used other methods. As shown in table 3, the prevalence of cocaine use rose with age across sex and racial/ethnic groups, peaking at ages 18–30, then fell dramatically after age 50. The highest prevalence of use (45.7%) was detected in Hispanic males aged 18–30 (table 3).

## DISCUSSION

The principal finding of this study is that in the mid-1980s, approximately one in five persons aged 60 years or less who resided in New York City and who committed suicide had used cocaine in the days prior to death. It has been hypothesized that the 150% increase in the suicide rate among young adults from 1960 to 1980 is explained in part by the high prevalence of drug use among young persons (4). Previous studies have found a relative risk of suicide among substance abusers ranging from five to 20 times that of the general population (12–14). Other studies suggest that the lifetime prevalence of suicide attempts among drug abusers ranges from 17% to 30% of cases, but whether suicide attempters and those who succeed in committing suicide constitute distinct or overlapping populations remains controversial (14–16). Most studies investigated the role of alcohol, sedative hypnotics, or opiates. However, this is the first study, to our knowledge, that has specifically investigated the use of cocaine immediately prior to suicide.

Our finding that the prevalence of cocaine use was greatest among individuals in their 20s and 30s is consistent with the results of other studies (17). Compared with "pure" alcoholics, cocaine users, like other substance abusers, commit suicide both at an earlier age and in a shorter time after initial drug use (4).

There were no significant sex differences in the prevalence of cocaine detected at autopsy. While this finding contrasts with those of other studies which show a higher proportion of drug use among males who commit suicide, we also found no sex difference in cocaine use among motor vehicle fatalities in New York City (6).

The high prevalence of cocaine use among black and Hispanic persons who committed suicide is interesting. Black males have traditionally had much lower suicide rates than white males, although in recent years this difference has been narrowing, particularly in younger age groups (18). Some observers have implicated drug use in these trends. It is uncertain why Hispanic individuals appear to be particularly vulnerable. One study found that almost two-thirds of suicide attempters of Puerto Rican descent had diagnoses of substance or alcohol abuse (19). That study and others of this population suggest that many young Hispanic persons attempt or commit suicide following arguments with their spouses or parents (20, 21). Whether a drug such as cocaine, with its potential for inducing irritability and paranoia, is more likely to set the stage for suicide in some cultural groups has not been determined.

The high conjoint prevalence of cocaine and alcohol use among persons who committed suicide (alcohol was detected in one-half of all the cocaine users at autopsy) is not surprising. In the San Diego study (4), 84% of substance users also used alcohol regularly. In addition, most studies suggest that drug-abusing individuals likely to commit suicide are polysubstance

abusers (17). The role of other drugs used conjointly with cocaine in enhancing suicide risk remains to be elucidated.

The association of cocaine-related suicides with firearms is striking. Firearms accounted for 39% of all suicides by cocaine-positive individuals but only 20% of all suicides in New York City. Similarly, 35.7% of all firearm suicides in New York were by cocaine-positive persons. It is possible that cocaine users are more likely than others both to own guns and to commit suicide.

How does the prevalence of cocaine use among persons who commit suicide compare with the prevalence of its use in New York City? A household telephone survey of drug abuse conducted for the Division of Substance Abuse Services included 6,368 respondents aged 18 years or older who were residents of the state (22). The sample, stratified by state region, included an oversample of Hispanic and young residents (groups at particular risk for substance abuse) as well as subsets of undergraduate college students, transients in shelters, and persons without telephones. Prevalences for current (the past 30 days), recent (the past 6 months), and lifetime cocaine use were 3%, 5%, and 13%, respectively. However, the survey relied on self-reported drug use, unlike this study of actual post-mortem toxicology results. Nevertheless, comparing the findings of that survey with our data suggests that cocaine use is considerably more common among individuals who commit suicide than in the general population of New York City.

The mechanism by which use of cocaine enhances suicide risk is unknown. However, any hypothesis must account for the marked comorbidity between drug use and psychiatric disorders such as depression, schizophrenia, and anxiety disorders, which are independently associated with suicide (23). Since the increased availability of cocaine in New York City in the mid-1980s has not been paralleled by marked contemporaneous increases in the overall suicide rate, it is likely that many persons using cocaine are already predisposed to suicide on the basis of other factors. Some authors suggest that predisposition to drug abuse and certain personality disorder symptoms (e.g., affective lability or impulsivity) may share a common biological or psychological substrate (24). Others argue that cocaine users are "self-medicating" underlying mental syndromes (25).

Any attempt to explain mechanisms will also need to elucidate both the timing of drug use in relation to the suicidal act and the presence of a dose-response effect. It is uncertain, for example, whether cocaine users are at highest risk in the intoxicated phase or in the withdrawal phase. Similarly, it is uncertain whether a heavy pattern of cocaine use is associated with an increased propensity to commit suicide.

Clinical reports suggest that those who may be at greatest risk are chronic, heavier users who experience withdrawal syndromes (2). These individuals report feeling edgy and dysphoric and may experience intense suicidal ideation. Prolonged use of cocaine results in marked depletion of neurotransmitters, including serotonin (26). A number of studies have found decreased concentrations of 5-hydroxyindoleacetic acid, the principal serotonin metabolite, in the CSF of suicide attempters who use violent means of self-destruction (27). Other psychostimulants, particularly amphetamines, that have pharmacologic actions similar to that of cocaine have also been linked to suicide (28). This suggests the intriguing but unproven hypothesis that psychostimulants may enhance suicide risk directly by changing brain neurochemistry. Substance abusers are also subject to intense psychosocial stressors, including deteriorating physical health, marital discord, legal and financial difficulties, and unemployment, all of which have been identified as potentiators of suicide (23).

There are several methodological issues that warrant comment. First, this study provided information about prevalence of cocaine use at one point in time at one location. American cities may differ significantly in the prevalence of illicit drug use over time (29). Our results may be substantiated in other urban centers where crack cocaine is widely available, but they may not apply to more rural areas.

In this study a person who committed suicide was considered cocaine positive on the basis of metabolite screening at autopsy. Metabolite assays establish use only within several days of death and provide no information about dosage, frequency of use, lifetime pattern of use, or recency of use. Assays alone do not establish the diagnosis of cocaine abuse or dependency. Presumably, a number of the cocaine-negative suicide cases in fact involved current, recent, or lifetime users of the drug.

Although not all persons who committed suicide were screened for cocaine or had survival times that allow inferences about cocaine use at the time of lethal injury, it is unlikely that artifacts of cocaine surveillance significantly affected our estimate of prevalence, since the conservative assumption that all excluded cases were cocaine negative would still result in a prevalence as high as 18%.

Finally, ascertainment bias, which refers to the criteria used to establish a diagnosis of suicide, is particularly important in studies of drug-abusing populations. We chose to examine only certified suicides. Many cocaine users die in "accidents" or with self-inflicted injuries of unknown intent, or the circumstances of death are indeterminable. These individuals and those who died of overdoses of illicit drugs (i.e., chronic or acute narcotism) were not included in this study.

We believe that there are several clinical implications of our study. First, cocaine users should be presumed to be at increased risk of suicide, and careful suicide histories should be taken. Since obtaining the drug is both illegal and dangerous, many users and dealers own firearms. The strong connection among firearms, suicide, and cocaine use underscores the need for clinicians to inquire about access to guns and make efforts for their removal.

It is likely that suicidal behavior represents only one type of self-destructive, violent behavior associated with cocaine use along a spectrum that includes accidents, criminal activities, and homicide. The probability of suicide among cocaine users needs to be assessed in terms of comorbid psychiatric diagnoses, patterns of use, dosage, and concurrent psychosocial stressors. Identification of those at greatest risk for suicidal ideation is essential before specific treatment interventions can be designed and implemented.

# High Cholesterol Levels in Patients With Panic Disorder

Waheed K. Bajwa, M.D., Gregory M. Asnis, M.D., William C. Sanderson, Ph.D.,
Ahmad Irfan, M.D., and Herman M. van Praag, M.D.

---

*Objective: This study was undertaken to help clarify whether the higher cholesterol levels found in patients with panic disorder are a complication of panic disorder only or are associated with any psychiatric disorder. Method: The subjects of the study were 30 patients with panic disorder and 30 patients with major depression, diagnosed according to the Structured Interview for DSM-III-R, and 30 normal control subjects. The three groups were matched for sex and age, and none of the subjects had alcohol/drug abuse, abnormal ECGs, or unstable medical conditions. Blood samples were drawn at random times, and serum cholesterol levels were determined. Results: The patients with panic disorder had significantly higher serum cholesterol levels than did the patients with major depression and the normal control subjects. Among the patients with major depression, histories (current or past) of anxiety disorders were associated with significant elevation of serum cholesterol levels. The presence of stable medical conditions was not associated with higher cholesterol levels in any of the three groups of subjects. Conclusions: Higher cholesterol levels were particularly associated with panic disorder in comparison with major depression. Higher levels of cholesterol in panic disorder are hypothesized to be a result of increased noradrenergic activity, which may be the underlying biological/neurochemical mechanism for symptoms of panic disorder, including anticipatory anxiety.*

(Am J Psychiatry 1992; 149:376–378)

---

Hayward et al. (1) reported that a higher than expected number of female patients with panic disorder had cholesterol levels that exceeded the 75th percentile of national reference values. A high cholesterol level is a risk factor for coronary heart disease; therefore, that finding has significant medical implications and requires further study. Since panic disorder was the only psychiatric diagnosis that was investigated in the Hayward et al. study, it is unclear whether a higher cholesterol level is a complication of panic disorder or an artifact associated with any psychiatric diagnosis. To clarify this issue, we compared the serum cholesterol levels of patients with panic disorder to those of age- and sex-matched patients with major depression and normal control subjects.

## METHOD

The patients with major depression and the patients with panic disorder in this study came for outpatient treatment at a hospital psychiatry department. The normal control subjects were recruited through a newspaper advertisement soliciting volunteers for research studies. The two groups of patients received diagnoses according to the Structured Clinical Interview for DSM-III-R—Patient Edition (2). They had been drug free for a period of 3 weeks. The normal control subjects were screened for the presence of psychiatric disorders by mental health professionals. The patients and the control subjects were given ECGs and routine blood tests (CBC, SMA-18, VDRL, and thyroid function tests). Cholesterol levels were assessed as part of routine screening on admission. The blood samples for determining cholesterol levels were drawn at random between 10:00 a.m. and 5:00 p.m. The subjects were not given any instructions to change their usual dietary habits. Although it is desirable to obtain blood for cholesterol assessment after a 12-hour fast, it has been reported that mean plasma cholesterol concentration is unchanged after a fat-rich meal (3). Cholesterol levels were assessed with a TECHNICON SMAC 3 system

**TABLE 1. Characteristics of Patients With Panic Disorder, Patients With Major Depression, and Normal Control Subjects[a] in a Study of Cholesterol Levels**

| | Patients With Panic Disorder (N=30) | | Patients With Major Depression (N=30) | | Normal Control Subjects (N=30) | | Analysis | | |
|---|---|---|---|---|---|---|---|---|---|
| Variable | Mean | SD | Mean | SD | Mean | SD | F | df | p |
| Age (years) | 37.7 | 10.6 | 38.2 | 10.7 | 36.2 | 12.1 | 0.26 | 2, 87 | <0.77 |
| Weight (lb) | 159.5 | 37.1 | 156.4 | 39.6 | 153.2 | 24.1 | 0.24 | 2, 87 | <0.78 |
| Height (inches) | 66.1 | 4.2 | 65.8 | 4.3 | 67.8 | 4.1 | 1.88 | 2, 87 | <0.16 |
| Body mass index | 2.3 | 0.4 | 2.4 | 0.5 | 2.4 | 0.5 | 0.94 | 2, 87 | <0.40 |
| Duration of illness (months) | 17.1 | 19.6 | 19.3 | 32.1 | | | 0.09 | 1, 58 | <0.77 |
| Cholesterol level (mg/dl) | 224.7[b] | 43.5 | 189.8 | 32.8 | 183.6 | 37.7 | 10.10 | 2, 87 | <0.001 |

[a] In the group with panic disorder, 18 were white, nine Hispanic, one black, and two Asian/other; in the group with major depression, 12 were white, 11 Hispanic, three black, and four Asian/other; in the group of normal control subjects, 16 were white, four Hispanic, seven black, and three Asian/other; for race/ethnicity, $\chi^2$=14.9, df=8, p<0.06.

[b] Significantly different from the patients with major depression and the normal control subjects (each p<0.002, Tukey's honestly significant difference).

(sensitivity=0.00103 absorbance unit/unit of concentration mg/dl).

The exclusion criteria for potential patient subjects and normal control subjects were alcohol/drug abuse or dependence within the past 6 months, abnormal ECG, and unstable medical conditions such as hypertension, diabetes mellitus, and asthma. The three study groups contained 30 subjects each.

## RESULTS

Table 1 presents the characteristics of the three groups. They were age- and sex-matched (17 male and 13 female subjects in each group) and similar in height, weight, body mass index (i.e., weight in pounds divided by height in inches), and duration of illness. None of the patients with major depression and none of the normal control subjects was using oral contraceptives; one woman in the panic disorder group was using oral contraceptive pills. As can be seen in table 1, the pretreatment cholesterol levels in the three groups were significantly different. Follow-up multiple comparisons (Tukey's honestly significant difference) revealed that the panic disorder patients' mean cholesterol level was significantly greater than that of the patients with major depression and that of the normal control subjects. The cholesterol levels of the patients with major depression were not significantly different from those of the normal control subjects.

Patients with major depression who had histories (current or past) of anxiety disorders (N=9, five of whom were female; three with generalized anxiety disorder, two with simple phobia, and four with panic disorder) had higher cholesterol levels than did patients with major depression without histories of anxiety disorders (N=21, eight of them female) (214.1 mg/dl and 179.3 mg/dl, respectively; t=2.99, df=28, p<0.006). The sex ratio between groups was not significantly different ($\chi^2$=0.78, df=1, p<0.38). Since age was a significant covariate with cholesterol (F=31.3, df=1, 86, p<0.0001), and patients with major depression who had histories of anxiety disorders were older than those without such histories (mean=45.7 years, SD=13.9, and mean=34.9 years, SD=7.2, respectively), an analysis of covariance was conducted to adjust for the effect of age on cholesterol. When the effect of age was covaried out, patients with major depression and histories of anxiety disorders still had a significantly higher mean cholesterol level than patients without such histories (F=4.85, df=1, 27, p<0.04).

Thirteen of the patients with panic disorder had stable medical conditions (e.g., mitral valve prolapse, bronchial asthma, hypertension, or gout), and 10 of the patients with major depression had stable medical conditions (hypertension, diabetes mellitus, peptic ulcer, or migraine). The cholesterol levels of the patients with medical diagnoses did not differ from those of the patients without medical conditions (206.7 mg/dl and 207.2 mg/dl, respectively; F=0.006, df=1, 58, p<0.94). When patients with medical conditions were excluded from the analysis, the cholesterol levels of the patients with panic disorder remained significantly higher than those of the patients with major depression (224.5 mg/dl and 193.1 mg/dl, respectively; t=2.43, df=35, p<0.02), even after covarying out the effect of age (F=6.35, df=1, 34, p<0.02).

To ensure that a comorbid medical disorder was not responsible for the elevated cholesterol levels of the patients with panic disorder, analyses were conducted with only healthy patients (i.e., those without medical diagnoses) and their age- and sex-matched normal control subjects. The cholesterol levels of the healthy patients with panic disorder (N=17) were significantly higher than those of the control subjects (224.5 mg/dl and 179.8 mg/dl, respectively; t=3.00, df=32, p<0.01). The cholesterol levels of the healthy depressed patients (N=20) were significantly higher than those of their age- and sex-matched control subjects (193.1 mg/dl and 170.0 mg/dl, respectively; t=2.38, df=38, p<0.05). Since comorbid anxiety disorders were significantly related to cholesterol levels in the patients with depression, analyses were conducted excluding the depressed patients with histories of anxiety disorders. There was no significant difference between the healthy depressed patients (N=16) and their age- and sex-matched control subjects (183.1 mg/dl and 167.1 mg/dl, respectively; t=1.56, df=30, $p<0.13$). Healthy depressed patients with histories of anxiety disorders (N=4) had significantly higher cholesterol levels than depressed patients without such histories (N=16) (233.3 mg/dl and 183.1 mg/dl, respectively; t=3.49, df=18, $p<0.01$). To ensure that this effect was not due to age, an analysis of variance with age as a covariate was conducted. The difference remained statistically significant (F=10.29, df=1, 17, $p<0.01$).

## DISCUSSION

Our results support findings of an earlier study by Hayward et al. (1) which demonstrated that patients with panic disorder have higher cholesterol levels than age- and sex-matched normal control subjects. In addition, our study found that higher cholesterol levels were particularly associated with panic disorder in comparison to major depression. Interestingly, histories of anxiety disorders in patients with major depression were associated with higher cholesterol levels. There are two possible explanations that may account for these findings. First, anticipatory anxiety may be responsible for the elevations in cholesterol levels of patients with panic disorder. These patients experience substantial anticipatory anxiety related to the stressful experience of panic attacks. Previous research has demonstrated that natural and experimentally induced stress results in a significant increase in cholesterol (4–7). This hypothesis would suggest that the presence of anxiety per se may increase the risk of coronary heart disease. Second, there have been several studies demonstrating increased noradrenergic activity in panic disorder (8, 9). It may be that higher cholesterol levels in patients with panic disorder are a result of induction of lipoprotein lipase by norepinephrine (1).

It should be noted that in this study, the cholesterol levels of the patients with panic disorder as a group remained within the normal range (150–250 mg/dl). In addition, we did not measure high-density lipoprotein (HDL) or low-density lipoprotein (LDL) cholesterol levels, which are considered to be more specifically correlated with risk of coronary heart disease. Whether a mildly elevated cholesterol level is a prodrome or is directly related to morbidity and mortality from cardiovascular diseases is unknown. There is some evidence of high cardiovascular mortality among patients with panic disorder at long-term follow-up (10, 11). Further research is necessary to investigate the potential negative impact of elevated cholesterol levels in patients with panic disorder by measuring both LDL and HDL cholesterol levels and to examine whether the cholesterol level decreases after the disorder goes into remission with adequate treatment.

# Racial/Ethnic Identity and Amount and Type of Psychiatric Treatment

Jacquelyn H. Flaskerud, R.N., Ph.D., and Li-tze Hu, Ph.D.

Objective: *The purpose of this study was to examine the relationship of racial/ethnic identity to the amount and type of psychiatric treatment received by white, black, Latino, and Asian patients in the Los Angeles County mental health system.* Method: *The patients studied (N=19,400) consisted of all adult inpatients and outpatients seen in all county mental health facilities between January 1983 and August 1988. Multiple regression analysis was used to test the relationship between race/ethnicity and four measures of treatment received: number of treatment sessions, treatment modality, treatment setting, and therapist's discipline. The covariates included in the analyses were age, sex, socioeconomic status, primary language, diagnosis, and measures of treatment when these were logical predictors and were not acting as dependent variables.* Results: *Race/ethnicity did not have a consistent significant relationship to the treatment variables studied. However, diagnosis had a consistent and highly significant relationship to all four measures of treatment. A psychotic diagnosis was related to receiving more treatment sessions, greater use of medication, greater use of inpatient treatment, and less treatment by a professional therapist. Socioeconomic status and primary language also had consistent and significant relationships to three of the treatment variables.* Conclusions: *In considering modifications to the service delivery system, clinicians must evaluate whether the type of treatment provided to psychotic patients is the treatment of choice in terms of effectiveness and efficiency or whether it involves bias in service delivery. Similarly, the issue of bias in treatment of lower socioeconomic patients must be addressed.*

(Am J Psychiatry 1992; 149:379–384)

The question of whether there is a relationship between racial/ethnic group identity and the amount and type of psychiatric treatment received is approached from several perspectives in the clinical and research literature. One issue raised frequently is discrimination in the assignment of treatment. In a follow-up study of an earlier finding, Mollica and Milic (1) reported that lower-class patients received low-intervention treatments from nonprofessional staff. More than half of lower-class patients who sought treatment were discharged without a treatment assignment. Conversely, Lindsey and Paul (2) contended that black patients are overrepresented among admissions to public institutions and that this is related to their lower socioeconomic status and to institutional racial bias in assigning treatment. Supporting their argument, an examination of black and white patients admitted to a psychiatric hospital by the police found that more black than white patients were admitted (3). Black patients were more likely than white patients to receive neuroleptics, compulsory orders, outpatient appointments, and a diagnosis of schizophrenia and drug-induced psychosis. The differences found in clinical management were partially accounted for by differences in diagnosis.

Armstrong et al. (4) reported opposite findings. They found black patients to be less impaired than white patients, to be underrepresented, to terminate treatment earlier, and to receive equal services. However, they found that more black than white patients were referred by the criminal justice system. Finally, Robinson and Johnson (5) noted that the effect of deinstitutionalization in the black community has been a significant increase in penal incarcerations.

Underutilization of mental health service—defined as a failure to seek treatment—has been noted for black, Latino, and Asian populations. Despite similar rates of psychosocial dysfunction, Mexican Americans have been reported to use mental health services proportionately less than Anglos (6–8). Sue and Sue (9) observed

that Asians do not seek psychiatric treatment until their illness is severe. Several investigators (10–12) have reported that blacks in the United States do not use mental health services at the same rate as whites for similar psychiatric problems. Underutilization defined in terms of retention of patients in treatment according to therapists' recommendations for therapy has also been noted for black, Latino, and Asian patients, who have been observed to terminate treatment earlier than whites (4, 9, 13, 14).

The issue of the relationship of race/ethnicity to the amount and type of psychiatric treatment received is complex, involving not only the patient's race/ethnicity but also the patient's diagnosis, socioeconomic status, and other personal characteristics as well as several characteristics of treatment. In a further attempt to clarify the relationship of race/ethnicity to the type and amount of psychiatric treatment received, we examined white, black, Latino, and Asian patients in the Los Angeles County mental health system and four measures of psychiatric treatment: number of treatment sessions, treatment modality, treatment setting, and therapist's discipline. The relationships of age, sex, socioeconomic status, primary language, and diagnosis to the four measures of treatment were also examined.

## METHOD

Race/ethnicity was designated by each patient as non-Hispanic white, non-Hispanic black, Latino/Hispanic, and Asian/Pacific Islander. These groups were classified for analysis as white, black, Latino, and Asian.

The sample consisted of adult (18 years old and older) outpatients and inpatients seen in Los Angeles County mental health facilities between January 1983 and August 1988. Approximately equal numbers of white, black, Latino, and Asian patients were included in the total sample, which comprised all Asian patients seen during this time period and a random sample of equal numbers of Latino, white, and black patients. (Patients were included only if they had completed treatment; no patients were counted twice.) The total sample included 19,400 patients; 12,889 (66.6%) of these were outpatients and 6,511 (33.4%) were inpatients. For the entire Los Angeles County mental health system, 43.0% of the patients seen during the 5-year period were white, 20.5% were black, 25.5% were Latino, and 3.1% were Asian. According to 1985 census data, the population of Los Angeles County was 44.2% white, 12.8% black, 33.7% Latino, 8.7% Asian, and 0.6% all others.

The mean age of our entire sample was 33.5 years (SD=12.0). For whites, the mean age was 35 (SD=12.7), for blacks, 32.7 (SD=11.2), for Latinos, 32.3 (SD=11.9), and for Asians, 33.8 (SD=12.1). Tukey's honestly significant difference test was used to determine significant differences in age among the racial/ethnic groups. All pairwise comparisons were significant ($p \le 0.05$) except between blacks and Latinos. In the entire sample, 9,655 (49.8%) of the subjects were women and 9,745 (50.2%) were men. Among the white patients, 2,768 (51.7%) were women, among the black patients, 2,372 (44.5%), among the Latinos, 1,959 (49.8%), and among the Asians, 2,556 (53.5%). Comparisons of the racial/ethnic groups with one another on all other characteristics were made by using tests of proportions. For these analyses, the Bonferroni-adjusted alpha level of 0.008 was used to control for the simultaneous error rate that occurs when multiple comparisons are made. Black patients differed significantly from all of the other groups in sex; Latinos and Asians differed significantly from each other in sex.

Our measure of socioeconomic status of the subjects was based on the MediCal eligibility index. The MediCal index is determined by monthly family income and by number of dependents. We sorted the patients by whether they were eligible for MediCal (low income) or not: 15,157 (78.1%) of the patients were eligible for MediCal, and 4,243 (21.9%) were not. Among the whites, 3,991 (74.6%) were eligible, among blacks, 4,476 (84.0%), among Latinos, 3,169 (80.8%), and among Asians, 3,521 (73.8%). Tests of proportions revealed significant differences between all of the possible pairwise comparisons except between whites and Asians.

The primary language of each patient was categorized as English or other. For this variable, data were missing for 3,736 (19.3%) of the patients; the missing data were distributed proportionately among the racial/ethnic groups. There were 15,664 patients with complete information on this variable. The primary language was English for 4,426 (98.7%) of the whites, for 3,956 (97.5%) of the blacks, for 1,764 (56.7%) of the Latinos, and for 1,639 (40.9%) of the Asians. There were significant differences between all the possible pairings except between whites and blacks.

Diagnoses were made on standardized admission interview forms by therapists who were trained in the use of *DSM-III* diagnostic criteria. Diagnoses are routinely categorized three different ways in the Los Angeles County data system: 1) into multiple specific diagnostic categories, 2) into nine compressed categories, and 3) into dichotomized categories of psychotic and nonpsychotic. Psychotic diagnoses include schizophrenic disorders, paranoid disorders, psychotic affective disorders, and other psychotic disorders. For this analysis the dichotomized categories of psychotic and nonpsychotic were used. Of the entire sample, 11,216 (57.8%) were diagnosed as psychotic and 8,184 (42.2%) were diagnosed as nonpsychotic. Among whites, 2,942 (55.1%) were diagnosed as psychotic, among blacks, 3,348 (62.9%), among Latinos, 1,883 (47.9%), and among Asians, 3,043 (63.8%). Significant differences occurred in all the possible pairings except between blacks and Asians.

Data for the study originated from the Automated Information System currently in use by the Los Angeles County Department of Mental Health. The Automated Information System provides data for management information, revenue collection, clinical management, and monitoring with the potential for research. Data are collected routinely on each patient who contacts the county mental health system. Patient information is collected on standardized forms by the therapist and then transferred to a computerized file by a clerk. Patient files include information on demographics, clinical course, type and extent of services used, and agency or service provider.

The validity of the Automated Information System data is controlled through a variety of mechanisms. First, all data are entered into the Automated Information System through a fixed format screen. Second, values that are out of a given range as well as certain logical and substantive inconsistencies cannot be entered. Third, both the state and the county conduct program audits and program evaluations. Finally, the Los Angeles County Department of Mental Health monitors and reviews Automated Information System operations and data entry. Variables of interest to this study are routinely monitored through these means.

The reliability of the Automated Information System data has not been assessed systematically by the Los Angeles County Department of Mental Health. The reliability of some of the variables included in this study are of concern. For example, the reliability of diagnosis has been discussed in the literature (15, 16). Both the stability of diagnosis over time and the variability of diagnosis related to its use have been addressed. It is possible that reliability may be lower in clinical than in experimental settings. However, in this study, the treatment measures examined were dichotomized in the analysis; reliability would be expected to be higher in this situation.

## RESULTS

Least squares regression analysis was used to test the relationship of race/ethnicity to the amount and type of psychiatric treatment received for continuous variables, and logistic regression analysis was used for categorical variables. Four measures of psychiatric treatment served as dependent variables: number of sessions with the primary therapist, treatment modality, setting of treatment, and therapist's discipline. The covariates included in the analyses were age, sex, socioeconomic status, diagnosis, and treatment measures that might be considered logical predictors when they were not acting as the dependent variable in each regression model. For the regression analyses, the patients included were those with complete information on all the study variables (notably, primary language).

Least squares regression analysis was used to test the relationship of race/ethnicity and seven covariates to the number of sessions with the primary therapist. The distribution of this variable was positively skewed; therefore, log transformations were performed on the actual number of sessions with the primary therapist. However, the estimated relationship between predictors and the number of sessions was expressed in the original units by taking antilogs of the regression coefficients. The primary therapist was defined as the therapist who had the greatest number of sessions with the patient. For this variable, patients who were seen for assessment purposes only were excluded from the analysis (N=54). Additionally, since the primary therapist was not designated for the inpatients, the analysis included only outpatients.

The relationships of race/ethnicity, age, sex, socioeconomic status, primary language, diagnosis, therapist's discipline, and treatment modality to number of treatment sessions for the outpatients are displayed in table 1. The table shows that, compared with white patients, Asian patients had significantly more sessions, black patients had significantly fewer sessions, and Latino patients had close to the same number of sessions with the primary therapist.

Sex, socioeconomic status, primary language, diagnosis, therapist's discipline, and treatment modality were significantly related to number of sessions. Being female, having a professional therapist, and receiving medication were significantly related to a greater number of sessions with the primary therapist. Lower socioeconomic status, English as the primary language, and a psychotic diagnosis were significantly related to fewer sessions with the primary therapist.

Tukey's honestly significant difference test ($p \leq 0.05$) was used to provide a more detailed description of the relationship between the number of sessions with the primary therapist and each dependent variable. Test results for all the categorical variables supported the regression analysis. For this analysis, age was further categorized as younger (18–30 years), middle (31–50), older (51–64), and senior (65 and older). The middle and older age groups had significantly more sessions than either the younger or senior age groups.

Logistic regression analysis was used to test the relationship of race/ethnicity and the covariates to the other three dependent variables. The second dependent variable examined was treatment modality. This variable was categorized as therapy with medication or therapy without medication. Therapy with medication included medication plus talking therapy or medication therapy alone. Talking therapy alone was designated as therapy without medication. This analysis also included only the outpatients and excluded patients seen for assessment purposes only. Table 1 displays the relationship of race/ethnicity and six covariates to treatment modality. Black patients were significantly more likely to have medication prescribed than were white patients. Asian race/ethnicity and Latino race/ethnicity were not significantly related to treatment modality.

Socioeconomic status, primary language, diagnosis, and therapist's discipline were significantly related to treatment modality; age and sex were not. Lower socioeconomic status and English as the primary language were significantly related to not receiving medication therapy, and having a professional therapist was related to receiving medication therapy. Having a psychotic diagnosis was most strongly related to receiving medication therapy.

**TABLE 1. Relationship of Demographic and Clinical Variables to Treatment Characteristics for Patients in the Los Angeles County Mental Health System**

[i] N=3,992 for analysis of setting.

Bivariate analyses based on a larger sample (N=12,889) provided a more detailed description of the relationships between treatment modality and the other variables. To show the significance and magnitude of the association, we used both chi-square and Cramer's V. These analyses supported the regression analysis. All of the other racial/ethnic groups received more treatment that included medication than did whites: 1,430 (39.6%) of the white patients, 1,607 (49.2%) of the black patients, 1,228 (43.4%) of the Latino patients, and 1,447 (45.5%) of the Asian patients received medication ($\chi^2$=66.42, df=3, p=0.000, Cramer's V=0.07). Fewer patients in the lower socioeconomic classification (N=1,356 [43.8%]) than in the higher classification (N=4,348 [46.0%]) received medication. Fewer patients whose primary language was English (N=3,468 [44.3%]) than patients whose primary language was not English (N=1,395 [50.0%]) received medication. More psychotic patients (N=3,261 [57.4%]) than nonpsychotic patients (N=2,450 [34.0%]) received medication.

The third treatment variable studied was the setting of treatment, categorized as inpatient or outpatient. Table 1 displays the relationships of race/ethnicity and five covariates to the setting of treatment. Asian patients were significantly more likely than white patients to be treated in an outpatient setting. Similarly, Latinos were significantly more likely to be treated as outpatients than whites. The relationship of black race/ethnicity to treatment setting was not significant.

Age, sex, and diagnosis had significant relationships to treatment setting; socioeconomic status and primary language did not. Older age and female sex significantly increased the odds of outpatient treatment. Diagnosis had the greatest relationship to treatment setting.

The results of the bivariate analyses of 12,889 outpatients and 6,511 inpatients are described briefly here to provide more detail. More of the blacks (N=2,065 [38.7%]) and fewer of the Latinos (N=1,109 [28.1%]) than whites (N=1,739 [32.5%]) were treated as inpatients ($\chi^2$=117.74, df=3, p=0.000, Cramer's V=0.08). Inpatients were younger than outpatients: 3,653 (56.1%) of the inpatients were in the younger age group (18–30 years), compared with 5,948 (46.1%) of the outpatients ($\chi^2$=213.79, df=3, p=0.000, Cramer's V=0.11). A significantly greater percentage of inpatients (N=3,607 [55.4%]) than outpatients (N=6,138 [47.6%]) were men ($\chi^2$=104.64, df=1, p=0.000, Cramer's V=–0.07). The difference between inpatients and outpatients was greatest when psychotic diagnosis was considered: 5,533 (85.5%) of the inpatients and 5,683 (44.1%) of the outpatients had psychotic diagnoses ($\chi^2$=3024.47, df=1, p=0.000, Cramer's V=–0.40).

The final measure of treatment examined was the therapist's discipline. This variable was categorized as professional or nonprofessional. Therapists in professional disciplines included psychiatrists, psychiatric nurses, psychologists, and social workers. Therapists in nonprofessional disciplines included all other licensed and unlicensed technicians and mental health workers. The relationship of race/ethnicity and five covariates to therapist's discipline are displayed in table 1. Race/ethnicity was not significantly related to the therapist's discipline for any of the racial/ethnic groups. Age and sex were also not significantly related to the therapist's discipline. Socioeconomic status, primary language, and

**TABLE 1 (continued)**

| Relationship to Therapist's Discipline (N=10,599)[a] | | |
|---|---|---|
| Effect[d] | p | 95% Confidence Interval |
| 1.00[f] | | |
| 0.86 | 0.06 | 0.72–1.01 |
| 1.14 | 0.09 | 0.98–1.33 |
| 1.06 | 0.47 | 0.90–1.26 |
| 1.00 | 0.70 | 0.99–1.00 |
| 1.09 | 0.17 | 0.97–1.20 |
| 0.88 | 0.05 | 0.78–1.00 |
| 0.81 | 0.006 | 0.69–0.94 |
| 0.68 | 0.0000 | 0.61–0.76 |

diagnosis were significantly related: patients of low socioeconomic status, whose primary language was English, and whose diagnosis was psychotic were more likely to see nonprofessional therapists. Again, the magnitude of the relationship was greatest for psychotic diagnosis.

For the bivariate analyses, the therapist's discipline was further categorized as psychiatric nurse, psychiatrist, psychologist, social worker, licensed psychiatric technician, unlicensed mental health worker, and others. Most patients (N=10,978 [85%]) were seen by therapists in disciplines designated as professional. Of the patients seen by professionals, social workers saw about 40%, psychiatrists saw about 30%, and psychiatric nurses and psychologists each saw about 15%. These percentages probably reflect the numbers of each of these disciplines working in the Los Angeles County mental health system. The relationship between race/ethnicity and the therapist's discipline was significant ($\chi^2$=393.65, df=18, p=0.000, Cramer's V=0.10). However, the majority of patients in all racial/ethnic groups were seen by social workers and psychiatrists (in that order): 2,070 (57.4%) of the whites, 1,938 (59.3%) of the blacks, 1,831 (57.6%) of the Asians, and 1,856 (65.6%) of the Latinos.

Bivariate analysis revealed that more patients in the higher socioeconomic classification (N=1,670 [56.7%]) were seen by social workers and psychologists and that more patients in the lower socioeconomic classification (N=3,695 [37.2%]) were seen by psychiatrists and licensed psychiatric technicians ($\chi^2$=213.11, df=6, p=0.000, Cramer's V=0.13). The other discipline categories were similar for patients in the two socioeconomic categories. More patients whose primary language was English (N=1,835 [23.4%]) were seen by psychiatric nurses and licensed psychiatric technicians, and more patients whose primary language was not English (N=1,357 [48.6%]) were seen by social workers and unlicensed mental health workers ($\chi^2$=303.97, df=6, p=0.000, Cramer's V=0.17). Finally, more of the psychotic patients (N=3,014 [53.1%]) were seen by psychiatric nurses, psychiatrists, and licensed psychiatric technicians ($\chi^2$=222.49, df=6, p=0.000, Cramer's V=0.13). More nonpsychotic patients (N=3,699 [51.3%]) were seen by psychologists and social workers.

## DISCUSSION

Racial/ethnic group identity was not consistently and significantly related to the four measures of psychiatric treatment examined. However, diagnosis was significantly and consistently related to all four measures of treatment. Furthermore, the magnitude of the relationship of diagnosis to each of the treatment measures was always greater than the relationship of any of the other variables considered in the regression model. In addition, socioeconomic status and primary language each had significant and consistent relationships with the same three treatment measures.

There were significant relationships between racial/ethnic group and some treatment measures. Black race/ethnicity was significantly related to two treatment measures: number of sessions with the primary therapist and treatment modality. Compared with white patients, black patients had fewer sessions with their primary therapist and more treatment with medication. This latter finding is similar to the findings of Dunn and Fahy (3) that blacks were more likely to receive neuroleptics than whites. They related this finding partially to diagnosis, noting that blacks received more diagnoses of schizophrenia than whites.

Asian race/ethnicity was significantly related to two measures of treatment: number of sessions with the primary therapist and setting of treatment. Compared with whites, Asians had more sessions with the primary therapist and were more often treated as outpatients.

Latino race/ethnicity in the present study was significantly related to only one measure of treatment: setting. Latinos were more often treated as outpatients than were whites.

The issue of diagnosis appears to be an important one in the consideration of treatment. In this study, diagnosis had a consistent and highly significant relationship to all measures of treatment. A psychotic diagnosis was significantly related to fewer sessions with the primary therapist, a greater likelihood of being treated with medication, less of a chance of being treated as an outpatient, and less of a chance of being treated by a professional therapist. Although inpatient treatment and medication use might be considered intensive treatments, it might also be said that a diagnosis of psychosis was related to less treatment—fewer sessions with a nonprofessional therapist. Interestingly, low socioeconomic status was also related to fewer sessions with the primary therapist and to being treated by a nonprofessional therapist. Low socioeconomic status was related to less use of treatment with medication as well. These findings might be cautiously interpreted as meaning that patients of lower socioeconomic status received less treatment overall. This interpretation would be consistent with the findings of Mollica and Milic (1), who reported that lower socioeconomic groups received low-intervention treatment from nonprofessionals.

Finally, in the present study, the patient's primary language was significantly related to number of sessions with the primary therapist, treatment modality, and therapist's discipline. Patients whose primary language was English had fewer sessions with their primary therapist, less treatment with medication, and less treatment by a professional therapist. Over 95% of white and black patients spoke English as their primary language, but about half of the Latino patients and 40% of the Asian patients did so.

The findings of this study are limited by its retrospective design and the use of data collected more for clinical than research purposes. However, generalizability is enhanced by the large sample size, the natural setting, and the collection of data over several years from all county mental health facilities. Conclusions and recommendations should be made cautiously.

Two groups of patients were receiving less overall treatment: patients in the lower socioeconomic classification and psychotic patients. An important question for clinicians and researchers to consider in any modification of the service delivery system would be whether the treatment provided to psychotic patients is the treatment of choice in terms of effectiveness. Might services be improved by more contact with the primary therapist and with a professional therapist? The mental health service system needs to find out why there seems to be a bias against the treatment of patients in lower socioeconomic classifications. The relationships of diagnosis and socioeconomic status to treatment demand further study if only to document treatment standards and to raise for discussion how services might be improved.

A second issue for consideration in any modification of the service delivery system has to do with underutilization of services and retention in treatment. Both Asians and Latinos have been reported to underutilize services (7, 9). Blacks have been reported to both underutilize and overutilize services (2, 10). Based on their 1985 proportions in the general population of Los Angeles County and their proportions in the mental health care system, it might be said that blacks (12.8% versus 20.5%) were overutilizing Los Angeles County mental health services, that Latinos (33.7% versus 25.5%) and Asians (8.7% versus 3.1%) were underutilizing services, and that whites (44.2% versus 43.0%) were using services in proportion to their numbers in the general population. Of course, these figures do not take into account the need for services or the use or availability of other service systems.

Blacks, Latinos, and Asians have all been reported to terminate treatment earlier than whites (4, 12, 17). In the present study, 2,855 (93.5%) of the whites, 2,272 (91.0%) of the blacks, 2,206 (95.1%) of the Latinos, and 2,582 (94.6%) of the Asians had two or fewer sessions with their primary therapist. A serious issue that needs to be addressed is education of the community in the use of the service delivery system. A question for further research is whether some racial/ethnic groups are using alternative, informal systems of care.

# The Relationship Between Community Resources and State Hospital Recidivism

William H. Fisher, Ph.D., Jeffrey L. Geller, M.D., M.P.H.,
Fred Altaffer, Ph.D., and Mona B. Bennett, M.D.

*Objective: The authors examined the propositions that a revolving state hospital door is an inevitable consequence of deinstitutionalization and that enhancing resources for community-based care can limit this phenomenon. Method: They analyzed the recidivism patterns of state hospital patients in a region of Massachusetts where, because of a federal court consent decree, the level of funding for community programs was more than twice as high as it was in other regions in the state and compared the pattern of recidivism in this region with that observed in the other areas of the state. Results: Despite the fact that the average daily state hospital census in the resource-rich region was only half that of the other regions, longitudinal data on hospital use showed that the readmission patterns were similar in all state regions. Conclusions: The authors suggest that attributes of serious and persistent mental illness may have more effect on hospital readmission patterns than service system variables.*

(Am J Psychiatry 1992; 149:385–390)

It has been said that efforts at mental health reform often resolve one set of problems at the expense of bringing about new ones (1). Over the past three decades the reforms embodied in the process of deinstitutionalization have led to dramatic decreases in the populations of state hospitals. In Massachusetts, for example, this period has seen a reduction in the average daily census of state hospitals by a factor of 10, from roughly 25,500 patients in 1955 to approximately 2,500 in 1985. This time period has also seen the growth of a population of "chronic recidivists" or "revolving door" patients (2–4), whose lifetime admissions may in some cases number more than 100 (unpublished 1990 paper of J.L. Geller).

State hospital recidivists have substituted multiple short hospitalizations for the prolonged inpatient care that was the much-criticized hallmark of institutional psychiatry in the first half of this century (5). However, the "roller coaster" of inpatient treatment, discharge, decompensation in the community, and readmission is of questionable clinical value and may frustrate patients, clinicians, and families in their mutual attempts to achieve effective treatment and stable community placements for individuals with serious and persistent mental illness. Moreover, the intensive use of services by these patients makes them particularly costly to serve (6, 7).

Factors alleged to contribute to the persistence of state hospital recidivism are myriad. Prominent among these are the demographic characteristics of the population, which currently includes large numbers of young patients who are in the most active phase of their serious mental disorders (8), and the inadequacy of most service systems designed to support discharged patients in the community. These inadequacies include insufficient resources for the provision of residential care, day treatment, outpatient therapy, crisis intervention, and case management and the resulting, overwhelming failure to achieve continuity of care (9, 10).

The evolution of deinstitutionalization has spawned two important propositions regarding state hospital recidivism. The first is that striving to serve most individuals with serious and persistent mental illness in the community inevitably triggers a "revolving door" pattern of hospital utilization as a function of the shift in locus of services. The second is that the extent of chronic recidivism in a population is inversely related to the amount of community mental health resources available to that population. Neither proposition has been put to an adequate empirical test.

In this paper we report the outcome of such a test. Our study takes advantage of a natural experiment in deinstitionalization afforded by the consequences of a

legal intervention in western Massachusetts, the Northampton Consent Decree (11), which came about as the resolution in the lawsuit *Brewster v. Dukakis* (12).

## BACKGROUND

The *Brewster v. Dukakis* suit charged that the right of patients at Northampton State Hospital to be treated in the least restrictive environment was compromised because community services that would facilitate their discharge and their community tenure had not been developed. Under the terms of the Northampton Consent Decree (11) the Commonwealth of Massachusetts was obligated to reduce the census at Northampton State Hospital through the creation of a well-funded and integrated system of community services, including residential programs, day treatment, emergency services, and case management. Compliance with the Northampton Consent Decree has resulted in substantial expenditure of funds for community-based programs in one region of the Massachusetts Department of Mental Health (Region I) over the past 10 years. The other regions of the state, which were not part of the Northampton Consent Decree, have been funded at much lower levels.

It is important to note that the service system created in Region I under the Northampton Consent Decree was not simply the result of increased funding. Its development was the product of a comprehensive planning effort that assessed the needs of patients in Region I and designed specialized residential and support services targeted to meet those needs. In addition, because keeping patients out of the state hospital was a major, if not *the* major focus of the Northampton Consent Decree, resources were committed to the continuum of admission diversion services, including crisis intervention, prescreening, and respite care. These services facilitated short-term intervention in a supervised setting outside of the hospital.

The regional differences in resources arising from the Northampton Consent Decree have been striking. The data in table 1 show *actual* per capita expenditures (as opposed to budgetary projections) for a range of community services across five regions of the Massachusetts Department of Mental Health averaged for fiscal years 1986, 1987, and 1989 as well as the average, weighted by population, of expenditures in Regions II, III, IV, and V. (An additional region, Region VI, which includes the metropolitan Boston area, has been omitted from the analysis because the structure of its service delivery system and the context in which services are delivered are considerably different from all of the other regions.) The data given in table 1 indicate that the average for total community resources in Region I was 148% greater than the average in Regions II, III, IV, and V. It also shows that in the categories of residential programs, vocational training, and case management the differences between Region I and the other regions approached or exceeded 250%. Also noteworthy is the fact that the difference in per capita expenditures for total community resources between the best and the least well-funded regions other than Region I—Regions II and V, respectively—was only 22%. This relative homogeneity across Regions II–V with regard to funding supports their use as comparison groups for Region I, both individually and as a group.

In terms of actual services delivered, these differences mean, for example, that Region I had 109 intensively staffed residential placements, while the adjacent region, Region II, had none. Likewise, Region I had a larger complement of case managers, which means that the caseload per worker (16.5 patients) was 32% below the statewide average.

It is important to note that these extreme differences in resource levels were not observed across all service categories. In particular, the difference between Region I and the other regions in expenditures for outpatient care was relatively small given the difference in the sizes of the deinstitutionalized populations across regions (table 1).

The effects of this unequal distribution of resources on different aspects of the state hospital have been previously reported in the *Journal* (13, 14). However, because these utilization patterns provide an important backdrop for the assessment of recidivism, we briefly summarize them here.

During the first 8 years the Northampton Consent Decree was in effect, the average daily census at Northampton State Hospital declined by 46%, compared with only a 16% decline in the remainder of the system. Likewise, rates of first and total admissions to Northampton State Hospital dropped by 46% and 40%, respectively, but actually increased elsewhere in Massachusetts. These trends suggest that the enhancement of the community system did make a substantial contribution to reducing the use of the state hospital, although not as great as envisioned in the original Northampton Consent Decree plan. Closer analysis of the nature of this decline, however, shows that the reduction in census was not uniform across the spectrum of patients. A comparison of the characteristics of the inpatient populations at Northampton State Hospital with a another state hospital (Worcester State Hospital) serving a similar contiguous region on sample days in 1977 (before the Northampton Consent Decree's effective date of December 7, 1978) and 1986 showed that the major differences between these two hospitals on the latter date lay in their long-stay populations. The acutely ill patients at Northampton State Hospital (those who had been hospitalized for 90 days or less on the day of assessment) were less affected by the Northampton Consent Decree and, although fewer in number, did not differ in terms of their diagnostic or demographic characteristics from the acutely ill patients at Worcester State Hospital (13).

Northampton State Hospital continues to be used far less than other state hospitals in Massachusetts. In 1989, the average daily census at Northampton State Hospital was 0.21 per 1,000 persons over age 19, less than half the statewide average of 0.51. Moreover, analysis of regional patterns of utilization of all forms of psychiatric inpatient care indicates that the use of general hospital and private psychiatric hospital services was no higher in Region I than in other regions (15), although access to such providers for the Region I population is roughly equivalent to that in the rest of the state.

These data indicate that, on any given day, a larger proportion of the seriously mentally ill population in Region I is being served outside of a hospital setting than is the case elsewhere. This, together with the nearly 150% difference in community resources between Region I and the other regions, affords us the opportunity to examine questions regarding community placement, resource levels, and recidivism in a quasi-experimental framework (16) in which Region I serves as the principal study group and Regions II–V serve as comparison groups.

## METHOD

Using the quasi-experimental design described we implemented two types of analysis. The first was survival analysis, a technique that has been shown to be useful in longitudinal studies of hospital readmission patterns in which some subset of the patients under study are likely not to be readmitted during the observation period (17). Using the survival functions generated by this method, we compared the community tenure (defined for our purposes as the length of time between discharge from and readmission to a state inpatient facility) of patients discharged from Northampton State Hospital in Region I between July 1, 1985, and June 30, 1986, with patients discharged from state inpatient facilities in Regions II, III, IV, and V over the same time period. The endpoint of the observation period was June 30, 1989. The null hypothesis that the survival functions would be equivalent across regions was tested by using the Lee-Desu statistic (18).

Survival analysis is useful in showing the probabilities associated with community tenures of varying length and in allowing these probabilities to be compared across regions. However, it does not fully capture the intensity with which inpatient care is used. To address this facet of the recidivism phenomenon we conducted a second analysis that drew on the utilization patterns of the patients using state inpatient facilities in the five areas over the period 1986–1989. Using these data, we compared the proportion of patients experiencing one, two, three, or more admissions over the 4-year period in each region. We should clarify that these data are based on the utilization patterns of all patients admitted to Massachusetts state hospitals in Regions I–V over a 4-year period. Patients admitted in the second, third, and fourth years would not have been "at risk" for as many admissions during the observation period as those admitted in the first year, however, and our estimates of the prevalence of chronic recidivism, therefore, may be low. This factor does not, of course, affect our between-region comparisons because the same measurement procedures were used for all patients.

## RESULTS

The survival functions estimated for each of the regions are shown in table 2. The values of these functions represent the probability of remaining in the community (i.e., outside of the state hospital) for a length of time equal to the interval specified (e.g., 30 days, 90 days). These data indicate that the likelihood of prompt readmission in all regions was substantial. Across the five regions the probability of readmission within 30 days was between 11% and 20%; the probability of readmission within 60 days was between 16% and 26%. The majority of patients experienced prolonged tenure, however; in all but one region (Region II), the probability of remaining outside a state facility for 4 years after discharge was about 50%.

To test the hypothesis that the community tenure of Region I patients was different from that of patients in the other four regions, we compared survival functions across regions. A comparison of the survival function

| | Probability of Remaining in the Community | | | | |
|---|---|---|---|---|---|
| Number of Days After Discharge | Region I (N=624) | Region II (N=889) | Region III (N=1,121) | Region IV (N=1,732) | Region V (N=1,244) |
| 30 | 0.89 | 0.80 | 0.89 | 0.89 | 0.87 |
| 60 | 0.84 | 0.74 | 0.83 | 0.83 | 0.83 |
| 90 | 0.81 | 0.70 | 0.80 | 0.80 | 0.80 |
| 180 | 0.73 | 0.63 | 0.72 | 0.72 | 0.73 |
| 270 | 0.68 | 0.58 | 0.66 | 0.67 | 0.68 |
| 360 | 0.64 | 0.54 | 0.63 | 0.64 | 0.65 |
| 540 | 0.58 | 0.51 | 0.58 | 0.61 | 0.60 |
| 720 | 0.54 | 0.47 | 0.55 | 0.58 | 0.56 |
| 1,080 | 0.51 | 0.44 | 0.51 | 0.56 | 0.52 |
| 1,440 | 0.48 | 0.41 | 0.49 | 0.54 | 0.51 |

in Region I with those calculated for each of the other regions showed that only one region, Region II, had significantly different community tenure (Lee-Desu statistic=16.84, df=4, p=0.0000). In fact, Region II patients had significantly lower community tenure probabilities than those in all other regions. No other comparisons with Region I were statistically significant, and when Regions II–V were combined and the survival function for the combined group was compared with that for Region I the difference was not statistically significant (Lee-Desu statistic=0.21, df=1, p=0.65).

The impression that the regions differed little with regard to community tenure and, therefore, in the extent of chronic recidivism, was reinforced when we compared the distribution of the number of admissions experienced by all Northampton State Hospital patients and all those using Massachusetts Department of Mental Health facilities in the four comparison regions (N=14,522) between 1986 and 1989. As shown in figure 1, the distribution of admissions across regions was virtually identical. In fact, the proportion of patients exhibiting the most intense hospital utilization over this period—those with seven or more admissions—actually varied relatively little across regions but was slightly higher in Region I (3.3%) than the average for all of the other regions (2.4%).

## DISCUSSION

The findings reported here, obtained from two perspectives on hospital readmission patterns, reveal little difference between Region I and the four comparison regions with regard to recidivism patterns. This finding occurred despite the nearly 100% difference in the extent of deinstitutionalization and the 148% difference in levels of community resources between Region I and Regions II, III, IV, and V.

Findings that two groups did not differ significantly are often regarded as uninteresting and/or not worth reporting. However, outcomes that are clearly inconsistent with policy objectives warrant attention and discussion. These data indicate that a difference of more than 100% in the proportion of the population served in the community did not lead to an accelerated revolving door in Region I because, we might assume, more than twice as many community resources were available and delivered here than in the other regions. At the same time, the availability of these resources did not eliminate the "revolving door" population: these patients made up similar percentages of the hospital-using populations in Regions I, II, III, IV, and V.

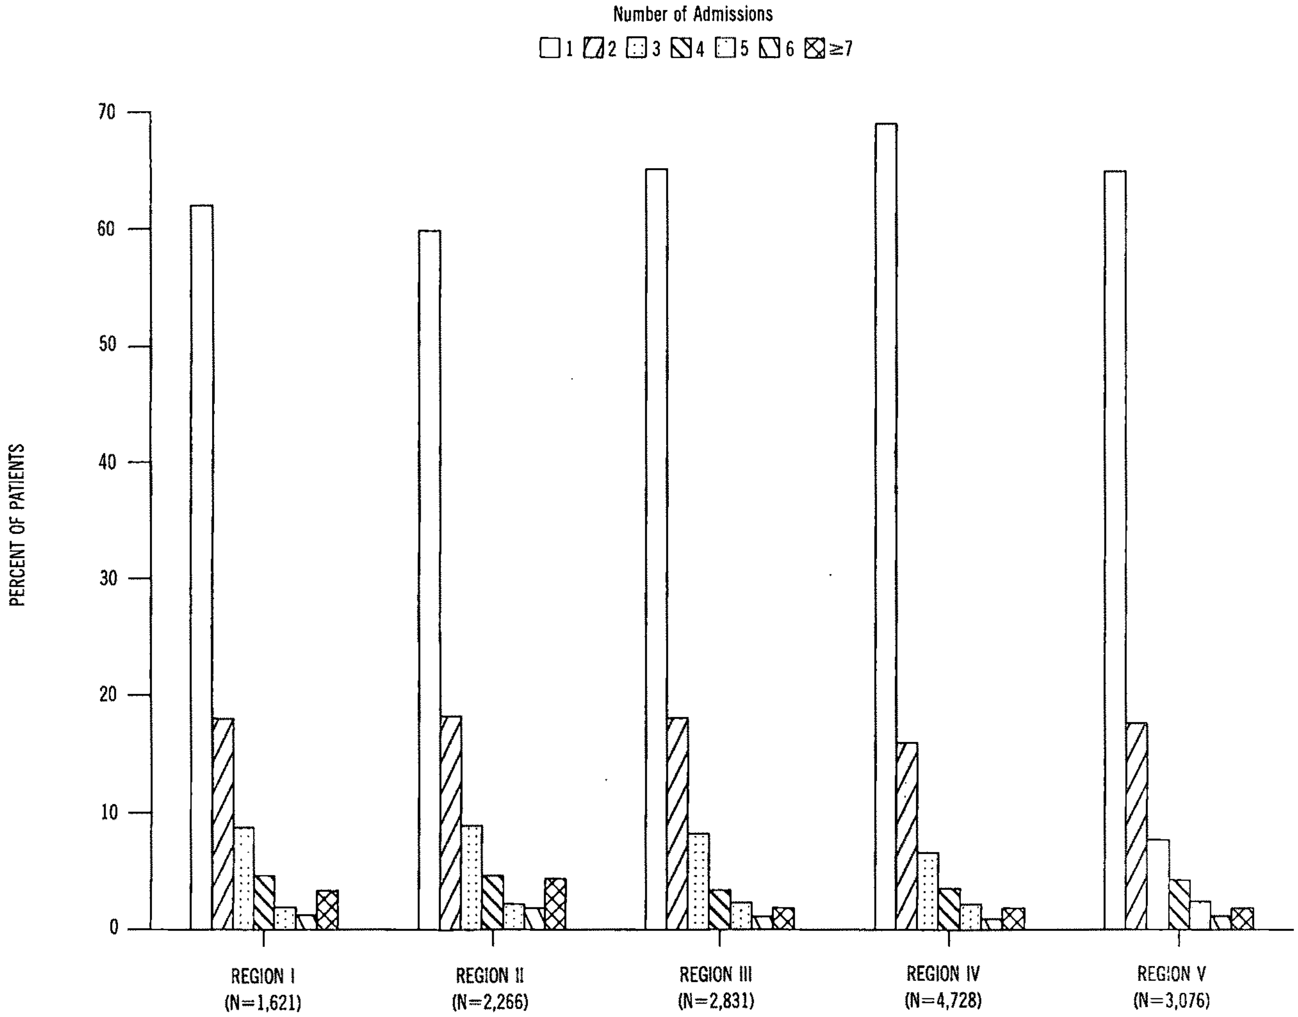
These data argue that large numbers of individuals with serious and persistent mental illness can be served in the community without developing a disproportionately large chronically readmitted population if a comprehensive array of services is made available to them. The data also indicate, however, that the problem and pattern of chronic recidivism is similar in catchment areas with comprehensive services and in catchment areas where services are not so plentiful.

Why is this the case? Our data do not allow us to answer this question directly, but generating some hypotheses should be useful for guiding further investigation.

One possible explanation is that the design of the community service system in Region I is flawed. The infusion of resources for residential programs in Region I has shifted where people live—from the hospital to the community. The emphasis on housing and the relative lack of emphasis on assertive community treatment, however, a pattern seen all too often in community service systems (10), has not prevented hospitalization and rehospitalization for some patients with serious mental disorders. The service system in Region I has been highly effective in reducing the size of Northampton State Hospital's long-stay population and has eliminated some groups of patients (e.g., psychogeriatric patients) from the hospital altogether (19). But a model so heavily focused on the residential resources required for community placement may be ill-equipped to cope with the exacerbations of acute illness and the treatment needs of chronic illness. Indeed, the low level of funding for outpatient treatment in Region I relative to that for other types of service may be indicative of this problem.

A second hypothesis is that the allocation of resources across the community service system is sound but the execution is flawed. We have neither empirical nor anecdotal data to support this proposition, how-

FIGURE 1. Number of Hospital Admissions per Patient in Five Regions of the Massachusetts Department of Mental Health, July 1, 1986–June 30, 1989



ever. Whether different organizational and administrative arrangements, such as an effective central mental health authority (20), would promote more effective service delivery remains to be tested. Also worthy of consideration is the impact of outpatient commitment in this type of resource-rich environment. Although Massachusetts has not statutorily defined outpatient commitment, variants of this intervention have been used in Massachusetts by applying the emergency detention provision of the commitment law (21) and probate court substituted-judgment decisions (22). It is noteworthy that these procedures have been used much more extensively in Region I than elsewhere in the state. How involuntary community treatment and community expenditures for services interact has been discussed (23, 24) but not yet systematically studied.

A third hypothesis postulates the existence of a population of patients in all regions who need inpatient treatment at different times. In Region I these individuals experience trials of community placement as well as frequent readmissions, but their counterparts in other regions are hospitalized for longer periods of time, experiencing fewer trials in the community because of the absence of community programs to support them. Longer stays in the hospital with fewer trials in the community result in fewer state hospital admissions but more hospital days. This would explain the slightly higher rate of recidivist admissions in Region I than in some of the other regions. On the other hand, the level of recidivism reported here may inadequately reflect the true recidivism pattern due to the considerable availability of admission-diversion beds in Region I and the relative lack of these resources in other regions.

This hypothesis focuses on the nature of serious and persistent mental illness per se. We may be observing relapse patterns that have more to do with variations in the clinical course of serious mental disorders than with the nature of the services patients receive. To the extent that this is the case, this needs to be explicitly recognized in any service system design. This view also shifts the basis for clinical care and treatment back to the nature of the illness itself and away from the alleged pervasive effects of institutionalism (25, 26).

A fourth hypothesis focuses on case finding. It may be that comprehensive community service systems, where most patients have case managers and many live in some form of residential program, identify patients in need of hospitalization more quickly and more often than do those in which patients are less carefully followed. If this is the case, it might be that fewer of the repeat admissions in Region I than in Regions II–V were what some providers call "inappropriate admissions." This would be consistent with arguments claiming that many state hospital admissions are clinically justifiable and not indicative of programmatic failure (27).

The data presented here were derived from comparisons involving one model of delivering community-based care—one that strongly emphasizes residential programming. There are others in place around the United States that emphasize alternative approaches, such as intensive case management or assertive community treatment (28). A great deal can be learned about the fundamental suppositions of community mental health through examining and comparing the experiences, clinical status, and quality of life of individuals functioning within these different models of care and treatment. Such comparisons, drawing on "experiments" in service delivery, court-ordered service expansion, "model programs," and other interventions leading to major alterations in service systems, should help us better understand what patients, families, and providers can and cannot expect from different approaches to serving the seriously and persistently mentally ill in the community.

# Vitamin E in the Treatment of Tardive Dyskinesia: A Double-Blind Placebo-Controlled Study

Christian L. Shriqui, M.D., M.Sc., Jacques Bradwejn, M.D.,
Lawrence Annable, B.Sc., Dip.Stat., and Barry D. Jones, M.D.

*The authors compared vitamin E with placebo in a double-blind randomized crossover study of 27 patients with tardive dyskinesia. Each treatment period lasted for 6 weeks. Vitamin E showed no differences from placebo in the treatment of tardive dyskinesia.*

(Am J Psychiatry 1992; 149:391–393)

A rationale for using antioxidants, such as vitamin E, in the treatment of tardive dyskinesia has been put forth (1–3), and two clinical trials have found vitamin E to be effective in decreasing the severity of tardive dyskinesia (1, 3). Our aim in this study was to replicate the short-term effectiveness of vitamin E in the treatment of tardive dyskinesia in a larger group of patients.

## METHOD

Twenty-seven outpatients (17 women and 10 men), 18 to 70 years old, were included in the study. These patients met Research Diagnostic Criteria for at least mild tardive dyskinesia (4), had stable psychopathology, and had been on a stable psychotropic drug regimen for at least 2 months before study entry. Twenty-two of the patients met *DSM-III-R* criteria for schizophrenia, and five met *DSM-III-R* criteria for bipolar disorder. All subjects provided signed informed consent.

The mean age of the patients was 42.9 years (SD=12.6, range=19–69). Twenty-one were receiving injectable neuroleptics, five were receiving oral neuroleptics, and one was not receiving any neuroleptic. Twenty (74%) of the patients had been ill for longer than 10 years and had been receiving neuroleptic drug therapy for a similar period.

The study design was double-blind and placebo-controlled and included a randomized crossover of two 6-week treatment periods with either vitamin E or placebo. The first treatment period was followed by a 2- or 3-week placebo washout period depending on the length of each subject's depot neuroleptic interval.

During treatment periods, vitamin E or placebo was administered on a fixed dosage schedule of one capsule of 400 IU of vitamin E or a placebo of identical appearance three times a day. During the placebo washout period, a placebo capsule was administered three times a day. To monitor compliance, capsule count was verified at each visit. Doses of all psychotropic medication were kept unchanged throughout the study.

All patients were assessed by the same investigator (C.L.S.), who used the Abnormal Involuntary Movement Scale (AIMS) (5) and the Extrapyramidal Symp-

[a] Least squares estimate from analysis of variance for two-period crossover design. The least squares estimate is adjusted for the fact that the number of patients beginning treatment with vitamin E differed from the number beginning treatment with placebo.
[b] Two-tailed.

tom Rating Scale (6) at baseline and every 2 or 3 weeks thereafter (depending on the injection schedule of each patient receiving depot neuroleptics) until the completion of the study. Placebo-drug differences were examined with repeated-measures analysis of variance (ANOVA) for a two-period crossover design as described by Fleiss (7).

## RESULTS

Repeated-measures ANOVA for the two-period crossover design revealed no significant differences ($p<0.05$, two-tailed) or trends ($p<0.10$) between vitamin E and placebo treatment with respect to the endpoint mean scores for the Extrapyramidal Symptom Rating Scale subscales or the AIMS total score, as shown in table 1. Similarly, analysis of the individual items of the Extrapyramidal Symptom Rating Scale dyskinetic movements subscale revealed no significant differences ($p<0.05$) or trends ($p<0.10$) between the treatments, ruling out effects on specific body areas. On the AIMS total score there were statistically significant but clinically modest reductions from baseline mean scores following both vitamin E and placebo treatment (table 1).

Statistical power calculations (8) revealed that the number of patients studied (N=27) provided 80% power to detect a true difference between treatment and placebo of 22.5% in AIMS total scores and 29.5% in the Extrapyramidal Symptom Rating Scale dyskinetic movements subscale scores ($p<0.05$, two-tailed).

## DISCUSSION

The results of this study suggest that the short-term use of 400 IU of vitamin E three times a day conferred no advantage over placebo in the treatment of tardive dyskinesia in this group of patients, the majority of whom had been treated with neuroleptic drugs for more than 10 years. The modest reductions from baseline in dyskinetic movements that occurred at the end of treatment with both vitamin E and placebo may have been related to decreased stress levels that occurred when patients became more familiar with the experimental procedures. It is well-known that tardive dyskinesia can be exacerbated by stress.

Our finding may represent differences between our patients and the subjects of two previous studies in which vitamin E showed a significant effect over placebo (1, 3). First, our patients had a long exposure to neuroleptics and had had tardive dyskinesia for several years. This factor could have reduced the effectiveness of vitamin E because patients without a lengthy exposure to neuroleptics and a relatively short onset of tardive dyskinesia (e.g., less than 2 years) may be the patients most likely to benefit from antioxidative therapy. Second, most of the patients in our study were receiving injectable neuroleptics and were regularly assessed just before their next neuroleptic injection. The timing of assessments of tardive dyskinesia may have added a withdrawal-emergent component for which vitamin E is of little or no benefit. Third, a possible drug interaction between vitamin E and injectable neuroleptics, which undergo a different hepatic metabolism from oral neuroleptics, was not examined in the context of this study. Finally, the placebo effect observed has been reported in other studies of tardive dyskinesia (9), suggesting that psychological and nonspecific factors may affect the course of a controlled clinical trial.

# Alcohol Abuse, Depression, and Suicidal Behavior in Schizophrenia

Stephen J. Bartels, M.D., Robert E. Drake, M.D., Ph.D., and Gregory J. McHugo, Ph.D.

*Alcohol use was correlated with depression and suicidal behavior in two independent studies of schizophrenic outpatients. Depression alone accounted for over 80% of the explained variance in suicidal behavior in both studies; alcohol use alone and the correlation between depression and alcohol use accounted for only small amounts of variance.*

(Am J Psychiatry 1992; 149:394–395)

People with primary alcohol use disorders are highly likely to suffer from depression and suicidal behavior (1, 2). Alcohol appears to induce suicidal behavior through both its depressant and its disinhibitory effects. Schizophrenic patients also have high rates of alcohol abuse (3, 4), depression (5), and suicidal behavior (6). The relationship between depression and suicide in schizophrenia is well documented (6, 7), but, to our knowledge, no one has examined the relationship between alcohol use and depression and suicide in schizophrenic patients. We have therefore addressed this question by examining the data derived from earlier studies of an urban group and a rural group of outpatients with schizophrenia.

## METHOD

Subjects in the study of urban patients with schizophrenia were outpatients of a teaching hospital in Cambridge, Mass. (3). Of the 133 patients in this study, 115 had a *DSM-III* diagnosis of schizophrenia and 18 had a *DSM-III* diagnosis of schizoaffective disorder. Their mean age was 38.3 years (SD=11.4). Seventy-eight (59%) were men and 55 (41%) were women. Subjects in the study of rural patients with schizophrenia were outpatients treated in a community mental health center in rural New England (4). These patients were evaluated extensively for alcohol use disorder. Of the 75 patients in this study, 67 had a *DSM-III-R* diagnosis of schizophrenia and eight had a *DSM-III-R* diagnosis of schizoaffective disorder. Their mean age was 43.6 years (SD=14.3). Thirty-six (48%) were men and 39 (52%) were women.

In both studies, primary clinicians rated depression and suicidal behavior (suicidal ideation or suicide attempts) on 5-point scales on which 1=not present, 2=mild, 3=moderate, 4=severe, and 5=extremely severe. Descriptive anchor points for this scale were based on assessments of symptoms over the preceding 6 months (3). For example, moderate depression was defined by pervasive despondency of mood and moderate suicidal behavior was defined by substantial preoccupation or attempts. Interrater agreement on 18 patients from the urban study, determined by comparing ratings of the clinician and the medication group psychiatrist, were 0.61 for depression and 0.82 for suicidal behavior (Cohen's kappa).

In both studies (3, 4), primary clinicians rated alcohol use over the preceding 6 months on the basis of separate 5-point scales. The clinicians' ratings of current alcohol use, based on longitudinal observations of behavior as well as collateral reports and self-reports, correlated highly with *DSM-III-R* diagnoses of alcohol use disorder made by using structured interviews (4). Interrater reliabilities for the clinicians' ratings in the two studies, determined by comparing ratings of the primary clinicians and medication group psychiatrists, were 0.80 for the urban group and 0.88 for the rural group (Cohen's kappa) (3).

## RESULTS

Current alcohol use disorders (abuse or dependency, determined by a rating of 3 or greater on the clinicians' rating scale) were present in the same proportion (24%) of both the urban and rural studies (32 of the 133 urban patients and 18 of the 75 rural patients). Almost half (47% [N=63]) of the patients in the urban study and almost one-third (32% [N=24]) of the patients in the rural study were rated by clinicians as moderately to extremely depressed. Thirty percent (N=40) of the patients in the urban study and 8% (N=6) of the patients in the rural study were rated by clinicians as moderately to extremely suicidal. There were no completed suicides at the time of evaluation.

In both studies, alcohol use was correlated with depression (for the urban patients, r=0.19, N=133, p=0.01; for the rural patients, r=0.20, N=75, p<0.05) and with suicidal behavior (urban, r=0.18, p<0.05; rural, r=0.22, p<0.05). Correlations between depression and suicidal behavior were much stronger: r=0.43 (p<0.001) for the urban patients and r=0.51 (p<0.001) for the rural patients.

Commonality analysis was used to determine the relative contribution of depression and alcohol use in explaining the variability in suicidal behavior in both studies. This procedure partitions the explained variance ($R^2$) in the criterion variable (suicidal behavior) into those proportions due uniquely to each predictor variable (depression and alcohol use) and due to the common variance in the predictor variables (8). Table 1 shows that 19% of the variance in suicidal behavior in the study of urban patients and 28% of the variance in suicidal behavior in the study of rural patients was explained by depression and alcohol abuse. For both studies, more than 80% of the explained variance in ratings of suicidal behavior (for the urban group, 84% [0.16 divided by 0.19], for the rural group, 82% [0.23 divided by 0.28]) was accounted for by depression. A considerably smaller percentage (for the urban group, 11% [0.02 divided by 0.19], for the rural group, 14% [0.04 divided by 0.28]) of the explained variance was due to the correlation between ratings of depression and alcohol use, and alcohol use alone accounted for only 5% of the explained variation in ratings of suicidal behavior (for the urban group, 5% [0.01 divided by 0.19], for the rural group, 4% [0.01 divided by 0.28]).

**TABLE 1. Commonality Analysis of the Proportion of Variance in Suicidal Behavior Explained by Depression and Alcohol Use for Outpatients With Schizophrenia in Urban and Rural Settings**

| | Proportion of Total Variance | |
|---|---|---|
| Variance Component | Urban Patients (N=133) | Rural Patients (N=75) |
| Depression | 0.16 | 0.23 |
| Alcohol use | 0.01 | 0.01 |
| Depression and alcohol use | 0.02 | 0.04 |
| Total explained variance ($R^2$) | 0.19 | 0.28 |

## DISCUSSION

These findings indicate that clinicians' ratings of alcohol use in schizophrenic patients have little value in accounting for suicidal behavior beyond that due to depression ratings. In both an urban and a rural group of outpatients with schizophrenia, alcohol use was significantly related to depression and suicidal behavior, but the correlations were small. Most of the explained variance in suicidal behavior was due to depression; only small amounts were explained by alcohol use alone and by the variance common to depression and alcohol use. However, since alcohol use and depression together accounted for only 19% of the total variation in clinicians' ratings of suicidal behavior for the urban patients and only 28% for the rural patients, other factors such as hopelessness may be of greater importance (9, 10).

In interpreting the data, several caveats are in order. First, the two studies used small study groups and the results are therefore tentative, although their consistency across independent rural and urban groups suggests validity. Second, the clinicians' ratings were not independent but had the advantage of characterizing behaviors and symptoms by aggregating observations over time and setting (4). Third, the results are limited by the lack of a comparison study group, but data for nonschizophrenic patients (2) indicate that patients with co-occurring alcohol abuse and depressed mood have an exceptionally high risk for suicide. Fourth, depression in these studies referred to persistent depressed mood rather than major depressive episode. Finally, suicidal behavior in these studies referred only to ideation and attempts. However, our previous study of schizophrenic patients who completed suicide (7) also found a strong relationship between depression and suicide and a weak relationship between substance abuse and suicide.

A strong relationship between alcohol use and suicidal behavior in schizophrenia was not supported by the data. One possible explanation is that because schizophrenic patients often develop alcohol-related problems with less alcohol use than patients with primary alcoholism, alcohol use by schizophrenic patients may be less likely to induce depression and suicidal behavior (4). Clinicians monitoring primary risk factors for suicidal behavior in schizophrenic patients should focus on depression and other clinical correlates that substantially outweigh any contribution of alcohol abuse.

# Suicidality and HIV Status

F. Patrick McKegney, M.D., and Mary Alice O'Dowd, M.D.

*Among psychiatric consultation patients, 322 AIDS patients were significantly less suicidal than 82 other HIV-positive patients and were comparable in suicidality to 1,086 patients with negative or unknown HIV status. AIDS patients had significantly more organic mental disorders. Organicity, denial, acceptance, and/or preoccupation with a fatal illness may reduce suicidality in AIDS patients.*

(Am J Psychiatry 1992; 149:396–398)

The prevalence of suicidality associated with HIV infection and with progression of HIV-related diseases has been variously reported. Some studies (1, 2) have shown the suicide risk of patients with HIV infection to be 35 to 40 times as high as that of HIV-negative persons. Others (3–5) have reported much lower risk rates, comparable to those found in non-HIV-infected populations. These large discrepancies may be due to differences in the risk groups studied, the stage of HIV-related illnesses, socioeconomic factors, or other sampling biases.

Some research (3, 6) has suggested differences among HIV-infected populations; AIDS patients have shown less emotional distress and suicidality than asymptomatic and symptomatic HIV-positive patients, i.e., those with Centers for Disease Control (CDC) stages I to IVa. We undertook the present study to examine the relationship between suicidality and HIV infection in its various stages; these results have been summarized elsewhere (7).

## METHOD

Data on all patients seen in psychiatric consultation in an 800-bed general hospital were gathered prospectively. The data used in the analysis were for all adult patients aged 55 and under who were seen in three years, 1988–1990. This age limit encompassed all HIV-positive patients and provided a comparably aged group of patients who were either HIV negative or, for the vast majority of patients, of unknown HIV status. It was not possible to assess patients not referred for consultation, but approximately 17% of the AIDS patients admitted were seen in consultation.

Three groups of patients were defined: 1) patients clinically diagnosed as having AIDS (CDC stages IVb to IVe), 2) other HIV-positive patients (CDC stages I to IVa), with or without symptoms, and 3) patients who were known to be HIV negative or whose HIV status was unknown.

As shown in table 1, the AIDS patients and other HIV-positive patients did not differ significantly in sex distribution or racial/ethnic makeup. Both groups were predominately male and Hispanic and significantly different from the group with negative or unknown HIV status. The mean ages of the three groups were 36.5 (SD=8.2), 34.3 (SD=7.1), and 33.9 (SD=13.5) years, respectively; the difference was not statistically significant.

The AIDS patients were significantly sicker than the other two groups; the mean Karnofsky scores of the AIDS patients, other HIV-positive patients, and patients with negative or unknown HIV status were 4.7 (SD=1.9), 5.8 (SD=2.3), and 5.6 (SD=2.2) (ANOVA; F=19.1, df=1, 337, $p<0.001$). (On the Karnofsky scale, 10=well, 0=death; 4.0="Disabled; requires special care and assistance," 5.0="Requires considerable assistance and frequent medical care.")

The 322 AIDS patients were primarily hospitalized for serious complications of AIDS, usually infectious or neurological. Almost one-half of the 82 non-AIDS HIV-positive patients were admitted for bacterial pneumonias, and the remainder were hospitalized for a wide range of non-HIV-related conditions. The admitting diseases of the 1,086 patients with negative or unknown HIV status were cardiovascular (25%), neurological (22%), pulmonary (20%), cancer (18%), gastrointestinal (8%), and renal (12%) (some patients were admitted for more than one disease).

Suicidality was determined on the basis of semistructured clinical interviews, and the same criteria for suicidality were applied to all patients seen in consultation. Virtually all patients were seen by and had their charts

---

Presented at the VI International Conference on AIDS, San Francisco, June 20–24, 1990. Received April 8, 1991; revision received July 24, 1991; accepted Aug. 29, 1991. From the Department of Psychiatry, Albert Einstein College of Medicine/Montefiore Medical Center. reviewed by senior attending psychiatrists (F.P.M., M.A.O.).

Comparisons of the three HIV groups in terms of psychiatric diagnoses and suicidality were made by analysis of variance or chi-square analysis.

## RESULTS

As shown in table 2, the percentage of patients who were considered suicidal by the referring physicians was significantly higher for the HIV-positive patients who had not yet developed AIDS than for the other two groups. The percentage of patients who were determined to be suicidal by psychiatrists was also significantly higher for this group than for the other two groups.

A significantly higher proportion of AIDS patients than patients in the two age-matched comparison groups had delirium and dementia. No significant differences were found in other major psychiatric diagnoses, including affective disorders, except for a lower frequency of substance abuse in the group with negative or unknown HIV status.

## DISCUSSION

These results confirm data gathered in a similar group of subjects (6), who were predominantly intravenous drug users and their sex partners. These data indicate a lower frequency of suicidality and other manifestations of psychological distress in patients with AIDS than in HIV-positive non-AIDS patients. However, the factors contributing to these differences are not clear. The strikingly greater prevalence of delirium and dementia due to HIV, opportunistic infections, and other systemic illnesses suggests that organicity may enhance the use of denial, an association which has been reported over several decades (8).

Another factor contributing to less psychological distress in AIDS patients may be the phenomenon Yalom and Greaves (9) called "cancer cures psychoneuroses." Describing patients who become aware of having cancer or other progressively terminal illnesses, these authors suggested that "facing and mastering some of their fear of death dissolves many other fears . . . . As one's focus turns from the trivial diversions of life, a fuller appreciation of the elemental factors in existence may emerge" (9). In addition, the certainty of an AIDS diagnosis may lead to the development of an attitude of "acceptance" (10), which may reduce psychological distress and suicidality.

Our experience with AIDS and other HIV patients is only beginning, and much more needs to be learned about the presentation of psychological symptoms over the course of the illness. This pilot survey needs replication and amplification.

# Blood Levels and Acute Response to Bupropion

Paul J. Goodnick, M.D.

*Twenty-three patients with major depressive disorder were treated with bupropion in an open-design protocol. Fifteen (65.2%) of the 23 responded with a more than 50% decrease in scores on the Beck Depression Inventory. Patients with trough blood levels of 10–29 ng/ml had a significantly better response than those with trough levels of 30 ng/ml or more. This preliminary result warrants further, double-blind evaluation.*

(Am J Psychiatry 1992; 149:399–400)

The use of blood levels of antidepressants to maximize efficacy of treatment has long been established (1). Bupropion is a recently released antidepressant whose mechanism of action is unknown, but it may block dopamine re-uptake and act as a partial dopamine agonist (2). It appears to be particularly effective in hypersomniac, hyperphagic unipolar depression and in bipolar depressions (3). Little research has been conducted concerning the application or blood levels of bupropion and clinical response. Preskorn (4) reported that trough levels in the range of 25–100 ng/ml produced maximal clinical response. Golden et al. (5) found that responders with a mean trough level of 21.7 ng/ml (SD=3.1) had lower trough levels than nonresponders (mean=41.2 ng/ml, SD=17.1); however, this result was not significant because of the small sample size. The peak bupropion blood level of any responder was approximately 30 ng/ml.

On the basis of these results, it was hypothesized that in a preliminary open study, patients who responded to bupropion would have trough blood levels in the range of 10–29 ng/ml and nonresponders, levels of 30 ng/ml or more.

## METHOD

Twenty-three patients who met *DSM-III-R* criteria for major depressive disorder were administered bupropion on an open basis. The patients consisted of seven men and 16 women with a mean age of 47.6 years (SD=14.3); there were eight bipolar and 15 unipolar depressed patients. All patients gave informed consent after the procedure was fully explained.

Bupropion treatment was initiated with a dose of 75 mg t.i.d.; the dose was increased by 75 mg every third day until response or a maximum dose of 450 mg/day was achieved. Trough blood levels were obtained 12 hours following the previous dose after at least 7–10 days of stabilization of the final dose; this occurred usually between 3 and 4 weeks after treatment was begun.

Patients returned for follow-up appointments after 2, 4, 6, and 8 weeks of treatment. At each visit, the Beck Depression Inventory was completed; patients were specifically queried regarding time to onset of improvement and presence of and change in side effects.

Statistical evaluation included one-way analysis of variance (ANOVA) with t tests to contrast responders (defined as patients who had at least a 50% decrease in Beck Depression Inventory scores) and nonresponders in terms of dose and trough blood levels and one-way ANOVA with t tests to contrast patients with blood levels of 10–29 ng/ml to others with blood levels of 30 ng/ml or more in terms of change in Beck Depression Inventory scores. Finally, time to onset of significant response was contrasted to time of onset and time of conclusion of side effects.

## RESULTS

Fifteen (65.2%) of 23 patients showed significant response to bupropion. The mean Beck Depression Inventory scores of responders improved from 24.7 (SD=8.2) to 6.1 (SD=4.3). Responders did not differ significantly from nonresponders in terms of mean age, diagnosis, bupropion dose, or baseline Beck Depression Inventory scores. Mean dose for responders was 423.3 mg/day (SD=77.6); mean dose for nonresponders was 450.0 mg/day (SD=0). Dose did not cor-

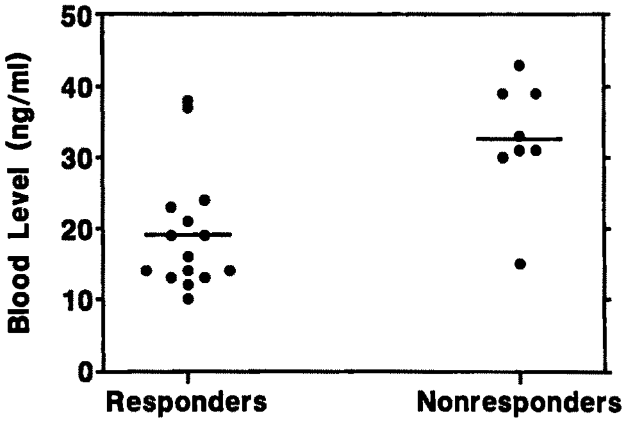
**FIGURE 1. Trough Blood Levels of Depressed Patients Who Responded (N=15) or Did Not Respond (N=8) to Bupropion**



relate significantly with blood level (r=0.26). However, responders did have a significantly lower trough blood level (mean=19.1 ng/ml, SD=8.6) than did nonresponders (mean=32.6 ng/ml, SD=8.6) (t=3.61, df=21, p=0.002). Figure 1 presents data on the bupropion blood levels of responders and nonresponders. The blood levels of responders were 10–38 ng/ml; the blood levels of nonresponders were 15–43 ng/ml. As would similarly be expected, patients with blood levels in the range of 10–29 ng/ml had significantly greater change in Beck Depression Inventory scores than those with blood levels of 30 ng/ml or more (mean=19.4, SD=6.8 versus mean=–0.8, SD=8.4; t=6.79, df=21, p<0.001) and proportionately more patients with a significant response (13 [92.9%] of 14 versus two [22.2%] of nine; $\chi^2$=12.05, df=1, p=0.0009). Mean response to bupropion was at 4.6 weeks (SD=2.6). Further information on rate of response, side effects, and long-term use of bupropion has been reported elsewhere (6).

## DISCUSSION

In this preliminary study, patients with trough levels of bupropion in the range of 10–29 ng/ml showed significantly greater response than those with levels of 30 ng/ml or more. This result may have been affected by the open design, since bupropion dose was continually increased by lack of response, to produce higher blood levels in nonresponders. Although this possibility certainly does exist, the fact that responders did not differ significantly from nonresponders in bupropion dose somewhat mitigates this argument.

Furthermore, these findings of improved response to trough levels in the range of 10–29 ng/mg certainly are consistent with the suggestion of Golden et al. (5). The relationship found by Golden et al. (5), that hydroxybupropion levels were better related to response than bupropion levels alone, could not be replicated in the present study because of lack of availability of these measures. Obviously, more double-blind studies with larger sample sizes are needed. It should also be noted that bupropion was well tolerated, with a 93% response in the suggested blood level range.

MIND AND BRAIN

**The Remembered Present: A Biological Theory of Consciousness,** *by Gerald M. Edelman. New York, Basic Books, 1990, 336 pp., $32.95.*

A curious phenomenon: just when psychiatry has beaten a wholesale retreat from overarching theory to a not always finely targeted empiricism, neuroscience has swung in the converse direction—to admit the paraphernalia of cognitive science and artificial intelligence and even consciousness, that elusive but incendiary taboo construct. Consciousness used to be systematically cold-shouldered, but even quite respectable investigators now dedicate their efforts to discovering where it lurks and how it works. No one has done this more strenuously or with more perseverance than the author of *The Remembered Present.*

A convenient windmill to tilt at always makes a good start. Long dominant, hierarchical theories of brain organization have taken a beating of late. Parallel processing and reciprocal circuitry are in. Edelman joins the growing group of theorists who have realized that problems of cognition are not solved but only kicked upstairs by shuttling information to higher and yet higher centers. Instead, the neural network must have a repertoire of states that correspond to the set of experiences. How is this correspondence accomplished?

Edelman takes advantage of the well-known property of cerebral organization by which cortico-cortical connections are reciprocal (not unidirectional, aft-to-fore, as previously supposed). His analysis relies on such "reentrant" circuitry, and he demonstrates some neat tricks that it can play. Such simulation is, of course, the cognitive science approach, and had the simulations been more numerous and more profound one would have taken the theory more seriously. Edelman, however, goes it alone, stomping imaginary opponents in cognitive science, artificial intelligence, and functionalism on his way, although they are the most likely source of help that his ideas so desperately need.

*The Remembered Present* is a dense, intense text and exhibits a voracious and eclectic intellect, but its speculations so greatly outstrip their data base that little may be lost if one defers reading it, pending the next, expanded edition, which presumably will incorporate enough compatible fact to sustain the reader's interest in the ideas.

MARCEL KINSBOURNE, M.D.
*Waltham, Mass.*

**The Science of the Mind, 2nd ed.** *by Owen Flanagan. Cambridge, Mass., MIT Press, 1991, 424 pp., $27.50; $14.50 (paper).*

It is not an uncommon assumption among psychiatrists and psychologists that they can do quite nicely without philosophy thank you very much. Yet the paradox is that it is impossible not to take a philosophical stance of some kind, and psychiatrists and psychologists are effectively logical positivists or pragmatists and not very good ones at that.

Psychology and psychiatry are built on a complex network of usually unsuspected and unexamined metaphysical and epistemological assumptions. Different psychological schools start from different assumptions and, of course, reach different conclusions.

These schools then battle, sometimes for decades, as in the case of psychoanalysis and behaviorism, over their conclusions. Unless the combatants recognize and address their underlying assumptions, such battles are probably doomed to be fruitless, inconclusive, and unending. Add to this the fact that all too often proponents of one school have only a superficial knowledge and understanding of the proponents of the other schools and the prospects for the resolution of differences obviously become very bleak.

It would be extremely helpful to have a book that lays out the philosophical grounds and assumptions of different psychologies, and this is just what Owen Flanagan's book does. Flanagan carefully examines the claims of different schools of psychology and approaches to the mind, including those of Descartes, William James, Sigmund Freud, B.F. Skinner, Piaget, and Lawrence Kohlberg. He also examines cognitive psychology, artificial intelligence, sociobiology, and the nature of consciousness. He explores the underlying assumptions and logic as well as the validity and scope of each school's claims.

Flanagan has done his homework well. He has a deep knowledge of both psychology and philosophy, has carefully studied the different schools and their related research, acknowledges his own biases, and is scrupulously fair. I found only one very small dubious area, which involved a critique of Kohlberg's suggested seventh stage of moral development. Flanagan dismisses this as the product of "a weak mystical moment," but his dismissal appears to reflect a misunderstanding of mysticism, which, in addition to being the subject of much popular nonsense, has also been the focus of some of the world's greatest philosophers—Plato, Plotinus, Shankara, Chuang Tzu, and Ibn El-Arabi to name only as many as can be counted on one hand. This is a very minor fault in an otherwise excellent work. I know of no other that provides such careful and penetrating introductions to the philosophical assumptions and implications of major psychological theories.

ROGER WALSH, M.D., PH.D.
*Irvine, Calif.*

**Body Images: Development, Deviance, and Change,** *edited by Thomas F. Cash and Thomas Pruzinsky. New York, Guilford Press, 1990, 361 pp., $39.95.*

This very interesting book covers an important area to which psychiatry has not given adequate attention. The editors, together with 15 other contributors, have undertaken the subject of the psychological and social aspects of body images. In doing this, they tell us that they will answer the following questions: What are the meaningful components of the construct of body image and how are they best measured? What are the physical, developmental, social, and cultural determinants of body image? How do gender and objective attributes of appearance influence the subjective experience of the body? What are the roles of body images in development, change in personality, and psychopathology? How do deleterious changes and physical appearance and physical competence affect body images? How can one promote adaptive change in body image through the self-management of physical aesthetics, through medical-surgical procedures, and through psychotherapeutic and somatopsychic interventions?

The book starts with Seymour Fisher's learned outline of the history of the evolution of psychological concepts of the body. Fisher pays particular attention to the contributions of Paul Schilder and of psychoanalysis. The second part of the book, which I found its most interesting section, is devoted to the development of body images. Here Thomas Cash devotes a chapter to the psychology of physical appearance. The effects of stereotyping are described in the statement, "What is beautiful is good and what is ugly is bad." People do assume that those who are good-looking possess socially desirable personalities and are happier and smarter than those who are less attractive. Cash discusses the social and psychological consequences of this and other stereotyping; he notes that several studies have shown that more attractive men and women are favored over those who are equally qualified but less attractive in a variety of employment situations. There are many other social spinoffs of this phenomenon; for example, in the criminal justice system those who are less attractive tend to receive harsher treatment.

April Fallon discusses the changing concepts of beauty. She points out that women in our society are expected to be thinner today than before; for men the standard continues to be moderate mesomorphy. Beauty has been associated with wealth throughout history and in different cultures. Fallon points out that upper-class aristocratic women were once expected to be fat, then thin and delicate, and now firm and fit. She also notes that beauty practices of other cultures, such as scarification of the cheeks, changes in the skull and neck, and ornamentation of the mouth and lip, are considered deformations by Westerners. In the United States, she says, there has been a change in desirability of breast size: the introduction of silicone implants in 1962 led to the popularity of breast augmentation; however, by the late 1970s this demand had leveled off, and plastic surgeons reported that the trend in the East Coast was toward breast reduction.

Norman Bernstein, who is an expert on the care of patients who have been facially burned, contributes a chapter that contains several interesting case discussions providing insight into the patients' methods of coping with such disfigurement. Thomas Pruzinsky devotes a chapter to psychopathology of body images; he discusses hypochondria, body dysmorphic disorder, somatic delusions, gender identity disorders, depression, sexual dysfunction, and schizophrenia in terms of bodily experiences. The association between body image and eating disorders is well discussed by James Rosen. The book also deals with change in body image through reconstructive surgery and through psychological change. In the last section, the two editors present an integrative approach to the development, deviance, and change of body images.

This is a comprehensive undertaking in an area of importance and great interest to psychiatrists. The editors have selected authors who write well and who make important contributions that should be of interest to psychiatrists and others involved in behavioral sciences.

## PERSONALITY AND ITS DISORDERS

**Cognitive Therapy of Personality Disorders,** *by Aaron T. Beck and Arthur Freeman. New York, Guilford Press, 1990, 396 pp., $35.00.*

Designed for the treatment of depression and extended to the treatment of anxiety disorders, cognitive therapy stakes a claim with this volume to treatment of the personality disorders (1, 2). Along with interpersonal therapy (3), cognitive therapy is one of the most popular therapies in clinical trials today, and the inclusion of another diagnostic domain under its purview is an event that merits notice.

The book is divided into two parts. In the first, the authors review the history, theory, and research bearing on cognitive therapy. In the second, they devote chapters to each of the types of character disorder. Cognitive theory holds that an individual's genetic proclivities interact with his or her family environment in the development of stable cognitive structures, or "schemas." The schemas guide the person's moment-to-moment thoughts, feelings, and interpretations in reaction to life, although the person is unaware of them. The schemas are learned, not developed as conflict-resolving structures, not repressed, and not actively resisting awareness.

As outlined in the first part of the book, cognitive therapy's techniques include "guided discovery" to recognize dysfunctional patterns of interpretation, "labeling of inaccurate inferences" to help the patient become aware of his or her automatic biases, "noting automatic thoughts" that potentially signify such biases, "collaborating" with the patient to test the validity of the patient's interpretations (e.g., how the patient tends to explain other people's behavior), "scaling extreme interpretations" (from 1 to 10) to counteract tendencies to all-or-none thinking, "reattribution" or reassigning responsibility according to the corrected view generated by these techniques, and "maintaining a diary" of tendentious misinterpretations and success in efforts to deal with them. Reference is frequently made to more detailed instruction available in earlier books, especially the original texts of Beck et al.

Although all of these techniques are generically useful, certain additional measures are of special importance in work with patients with character disorders. The authors use quotation marks around the word "transference" suggesting that it means something other than it does traditionally, but they use it to mean anger, disappointment, or frustration that grows out of distorted interpretations in the treatment relationship and can interfere with collaboration if not explored, which seems quite traditional. They also describe a technique called "reliving childhood experiences," which they note is not crucial in acute depression or anxiety but is emphasized for work with patients with character disorders. This technique involves a review of childhood experiences aimed at understanding the origins of nonadaptive patterns. In addition to simple recollection, role playing and reverse role playing of key interactions enhance this technique in changing core beliefs and reconceptualizing important figures of the past. The authors stress the particular importance of the therapist's scrutinizing his or her own automatic thoughts about patients during or outside of sessions. This is because patients with character disorders are often adroit in evoking feelings and behaviors that justify and confirm their own maladaptive reactions and schemas.

The second section of the book demonstrates the theory and techniques of cognitive therapy in relation to specific categories of character disorder. The authors describe the schemas that characterize each disorder and demonstrate with case vignettes and dialogue how particular techniques are applied. Schemas typical of avoidant personality disorder, for example, include, "I am socially inept and undesirable." "Others are potentially critical or rejecting." and "I cannot tolerate unpleasant feelings." Typical of obsessive-compulsive personality disorder are, "I am fully responsible . . . others tend to be too casual." "Any flaw may lead to catastrophe." "If I can't have systems, everything will fall apart." Those of antisocial personality disorder include, "People will get me if I don't get them first." "Cheating is okay as long as you don't get caught." and "What others think of me doesn't matter."

Cognitions subserving these organizing constructs are also illustrated. For example, typical of antisocial personality disorder are justification ("Wanting justifies action."), feelings make facts ("I'm right because I feel right about what I do."), and low-impact consequences ("What's undesirable won't occur or doesn't matter."). In a vignette on borderline personality disorder, the authors diagram the stages in impulse control: identify the impulse before action, inhibit automatic action, identify alternatives, select a response. Each stage is a place for possible and particular therapeutic intervention. For narcissistic personality disorder, the authors outline beliefs alternative to those typifying the disorder that can be tried on and reached for by the patient; for example, "Be ordinary. Ordinary things can be pleasurable." and "Others have needs and opinions that matter too." A diagram may also be helpful for the patient with obsessive-compulsive personality disorder. Recognition that the basic schema of this disorder ("No matter what I do, it won't be acceptable.") generates cognitions that cause avoidance and self-defeating meticulousness, which reaffirm the underlying sense of failure and unacceptability, can give the patient a cognitive handle for change.

The strengths of the book—and of the method—are several. The book lays down in elegant simplicity the fantasies that organize and guide people's behavior, and it links and labels fantasies that are typical and prominent in particular disorders of character. The book also names and defines the particular mental activities that impose dysfunctional ideas on a differing reality, such as dichotomous thinking, negative or personal attribution, catastrophyzing, and idiosyncratic meaning; thinking is believing. These are, in another parlance, the engines driving defenses. Labeling them can help therapists to recognize their enactment and thus to reflect them to patients, who can in turn recognize them and then grapple toward change. The book's illustrations show the slow, step-by-step, and delicate yet direct confrontation required to help patients grasp and alter their distorted thinking. Finally, the book provides an organized approach to active intervention and an overall treatment plan, sometimes including (without acknowledgment) the analysis of defense (for example, "Let's examine together what you just felt and thought in reaction to what I said.").

From another perspective, the book's and the method's attributes are also its limitations. Clarity and simplicity become oversimplification and naiveté in several instances. Suggestions that the therapist make a point of proving his or her trustworthiness to the patient with paranoid personality disorder because "it takes time to establish trust with most paranoid individuals" might bring a smile to therapists burned and spurned after having made such efforts. The idea that 50 weekly sessions could change a person with antisocial personality disorder seems similarly naive. (I thought that the patient described as having paranoid disorder was actually obsessive and dependent with paranoid features and that the patient described as having antisocial personality disorder—who showed a clear desire to please and be liked by the therapist—appeared not to have the pure form of this disorder.)

Perhaps the most costly virtue of the cognitive method is its base in learning theory. According to the book, for example, a bullied child becomes a bully by imitative learning. Such a view neglects the transmuting role and importance of emotions. No mention is made of the idea that the bullied child feels rage and helplessness and that he bullies later as an expression of chronic anger at those who are or were stronger and those whose weakness reminds him of his own. There is more to the development of such qualities, and all of character, than learning alone.

Despite these limits, the book is an excellent text, well worth a read. It can provide helpful tools to recognize and organize cognitive mechanisms, and it can both guide and permit activity for the therapist schooled in psychoanalytic or other therapies. It is also a major contribution to the growing literature on cognitive therapy. To an old analyst, though, it is of interest to see that this volume stresses transference and explorations of the past, re-introduces countertransference, and notes that treatment of patients with character disorders can require more frequent than weekly visits and may endure for up to two and a half years. That the founder of cognitive therapy, after 15 years of experience, can come to such concordance with the psychodynamic therapy this treatment aimed to replace makes one rather wonder.

**Toward a New Personology: An Evolutionary Model,** *by Theodore Millon, Ph.D. New York, John Wiley & Sons, 1990, 177 pp., $29.95.*

Theodore Millon's latest book rides the shifting tides of psychology and psychiatry toward renewed interest in the study of personality and its disorders. After a period in the 1960s and 1970s when personality concepts such as disposition, stability, and generality came under attack by what Millon terms the "anticoherency and anticonsistency movements," the time is once again ripe to develop theories of personality to guide inquiry into the foundations of personality attributes and to unify the classification, assessment, and treatment of personality disturbances. Revival of interest in "personology" has been stimulated by the increased emphasis by mental health practitioners on outpatient care, the enhanced status given to personality disorders in the *DSM-III* multiaxial system, and the births of an international society, a congress, and a journal devoted to the study of personality disorders.

Millon's approach is to borrow principles and substance from more established, advanced sciences in order to escape the "horizontal refinements" in personality theory that he believes have characterized developments over the past 40 to 50 years. The sciences from which his inspirations and content spring are physics and evolutionary biology.

Of this short book (it can be read, although undoubtedly not fully appreciated, in just a few hours), Millon devotes roughly half to the explication of his theory. He begins by describing analogies between evolution and ecology on the one hand and personality on the other. The so-called complex adaptations and strategies of organisms seeking to survive and to reproduce (two essential components of fitness according to Darwin) are likened to personality styles and structures. Millon describes the four domains or spheres in which evolutionary and ecological principles are demonstrated: existence, adaptation, replication, and abstraction. From the first three, he describes "polarities" of process creation versus destruction, accommodation versus modification, and propagation versus nurturance, respectively. From these he derives three corresponding "personality polarities"—pleasure versus pain, passive versus active, and self orientation versus other orientation—which become the fundamental distinctions in personality structure and function. The material might be somewhat heavy going for the readers who, like me, have most of their basic science knowledge (who can state the difference between the r-strategy and the K-strategy of reproductive behavior?) packed in the basement trunk with lab coats and dissecting kit. To Millon's credit, however, the explication is clear and understandable.

The reader is presented next with the personality theories of Freud, Eysenck, Gray, Buss, Russell, Tellegen, Cloninger, and others, whose tripartite models theoretically align strikingly with Millon's evolution-derived polarities. The concepts of pleasure versus pain, passive versus active, and self versus others are demonstrated to be often-occurring themes in the diverse psychological domains of learned behaviors, unconscious processes, emotion, motivation, and their biological substrates.

Following the theoretical argument is a discussion of the *DSM-III-R* personality disorders from the perspective of personality polarities. Personality disorders, according to Millon, result from deficiencies or imbalances in or conflicts between aspects of one or more of the polarities. In Millon's construct of personality disorders, there are 10 basic types and three severe, dysfunctional types (schizotypal, borderline, and paranoid). As an example, narcissistic personality disorder is characterized by primary reliance on self and passive adaptation.

After nosology, Millon describes his own three self-assessment measures. The Millon Personality Type Questionnaire assesses the balance and pattern of a person's three evolutionary polarities. The Millon Personality Disorder Checklist (described in greatest detail) examines eight domains of personality structure (e.g., self-image, mood/temperament) and function (e.g., interpersonal conduct, regulatory mechanisms) that enter into the clinical assessment of personality. Finally, the Millon Clinical Multiaxial Inventory yields a profile of personality disorders per se.

In the final section of the book, Millon discusses the need for integrative therapy for personality disorders. "Integrative" is distinguished from "eclectic" in that the latter involves wise selection from among separate techniques, whereas the former consists of designed composites and progressions among diverse techniques, based on the specific psychological structures and functions causing the patient's problems. This last section is the least well-developed of the book, presumably awaiting a more comprehensive treatment in the future.

On page 14 of *Toward a New Personology,* Millon states that theories "provide the basis for generating hypotheses and stimulating new knowledge." In the book's epilogue, Paul Meehl is quoted as saying, "To 'justify' concocting a theory, all one needs is a problem, plus a notion . . . of how one might test one's theory." It seems fair to ask how this new theory of personology does in generating testable hypotheses. A number of the problems confronting those attempting to make sense of the classification of personality disorders today echo through the pages of the book.

First, personality is proposed as coherent and consistent. The types of personality disorders described by Millon are theoretically distinctive on the three polarities, but can this be shown empirically? Co-occurrence of personality disorders is common in clinical settings, and Millon describes overlap between severe types and basic types, but what of the observed "comorbidity" between narcissistic and antisocial or avoidant and dependent disorders, pairs differing on the passive-active polarity, in which poles are presumed to be mutually exclusive? Axis I and axis II disorders are said to be related to polarities. What distinguishes the two axes or, for example, social phobia from avoidant personality disorder?

Second, certain aspects of personality, it is argued, are stable over time and pervasive in many situations and contexts. Can polarities or derived clinical domains be demonstrated to have greater stability and pervasiveness than traits otherwise defined?

Third, there is an assumption that normal and abnormal personalities are a matter of degree. Are polarities or domains or their combinations found continuously distributed in the general population? Are any types restricted to patients or to individuals with recognized disability?

Finally, can polarities or domains be shown to have value in understanding pathogenesis or in guiding treatment and predicting outcome?

Millon speculates that some readers will find his conjectures "persuasive, a few more will consider them 'interesting' . . . still others will find little merit in them." I guess I place myself in the "interested" group—stimulated, but waiting to be persuaded.

ANDREW E. SKODOL, M.D.
*New York, N.Y.*

**Family Environment and Borderline Personality Disorder,** *edited by Paul S. Links, M.D., M.Sc., F.R.C.P.(C.). Washington, D.C., American Psychiatric Press, 1990, 159 pp., $22.50.*

In the final chapter of this slim but provocative book John Gunderson summarizes the conclusions of the eight chapters by underscoring the centrality of heterogeneity in the pathogenesis of borderline personality disorder. Although this might not seem a landmark finding for those of us who have muddled through the conceptual scaffolding of the borderline concept, Links's focus on the research aspects of the impact of the family environment on borderline pathology does provide a fresh look at the data.

In the first chapter, Links and Heather Munroe Blum state that "all formulations of the etiology of borderline personality disorder have stressed the importance of the family environment." This conclusion is presented against the backdrop of *DSM-III-R,* which they say provides no information on the predisposing factors and familial pattern of borderline personality disorder. Links and his colleagues attempt to fill in the blanks from the perspective of family influences.

Even a casual reading of the literature on borderline personality disorder underscores the influences of both parents and of the family on the pathogenesis of this disorder, although it is not always clear whether some of their influences (which include failure of both parents, sexual abuse, and impulsivity) determine the onset or the course of the disorder. However, some of the conclusions in this book are not always in keeping with our clinical attitudes toward borderline personality disorder. For example, some of the dynamic hypotheses relating traumatic separations and losses to the cause and onset of borderline personality disorder are not borne out by the research. Clearly, there are specific familial influences, but causal relationships and hypotheses concerning borderline personality disorder are not always demonstrated when large numbers of borderline patients are studied.

Evidence is also provided that borderline personality disorder is a valid psychiatric disorder. In one study it was revealed that family members of patients diagnosed as having borderline personality disorder had a greater prevalence of borderline personality disorder in their first-degree relatives. Moreover, alcohol and affective disorders among first-degree relatives also pointed to familial linkages. Another finding provides a different understanding of the gender differences in borderline personality disorder: more women than men are diagnosed as borderline, and one of every nine women with borderline personality disorder has been sexually abused. It is now argued that these gender differences, rather than pointing to a specific etiologic pathway for borderline personality disorder, may suggest a different diagnosis, namely, posttraumatic stress disorder. Alternatively, the trauma of sexual abuse may serve as a marker rather than as a causative agent for borderline personality disorder.

In his summary chapter, Gunderson concludes that a linkage between borderline personality disorder and impulsivity may point to the possibility that dopaminergic or serotonergic systems are involved, suggesting potential areas for further research into the biogenic hypothesis of borderline personality disorder. However, in downplaying the effect of trauma on borderline personality disorder and supporting the view that it is the absence of stable structures, "soothing presences," and "active nurture or able substitutes" which may determine the development of borderline personality disorder, he is essentially taking a therapeutic position (a self psychology one) and arguing against a purely biogenic position. In keeping with the mission of this fine volume, Gunderson points to future research directions for those of us still bold enough to be fascinated by this clinical phenomenon.

## FORENSIC PSYCHIATRY

**Principles and Practice of Forensic Psychiatry,** *edited by Robert Bluglass, M.D., F.R.C.Psych., D.P.M., and Paul Bowden, M.Phil., M.R.C.P., F.R.C.Psych. New York, Churchill Livingstone, 1990, 1,405 pp., $306.00.*

Forensic psychiatry is that challenging subspecialty arising from the intense overlap of two divergent systems—psychiatry and the law. For many psychiatrists and other mental health clinicians, responding to the legal system is fraught with anxiety and misgivings. Indeed, the practice of forensic psychiatry requires special knowledge. Information regarding legal issues, critical assessment of psychiatric data, and the ability to communicate clearly are necessary. This comprehensive book helps provide much of the requisite knowledge to work in this robust area.

*Principles and Practice of Forensic Psychiatry* is a thoughtful, practical, and scholarly compendium of subjects related to forensic psychiatry considered from multiple perspectives. Nearly 150 contributors authoritatively discuss the British legal system, its historical basis, civil law, legislation, juvenile law, competency, criminal responsibility, clinical care, and community psychiatry. The book is outstanding in its practical guidelines. Its documentation of the relationship between specific mental disorders and criminal behavior is noteworthy. There is an excellent blending of current scientific information with practical clinical applications.

Most of the book centers on the United Kingdom, but some discussions are relevant to the practice of forensic psychiatry in other countries. The psychiatrist in the United States will find a detailed state-of-the-art review of forensic and clinical issues such as violence, personality disorders, deviant sexual behavior, and substance abuse. Unfortunately, relatively few landmark cases from the United States receive attention. For instance, only 14 of the approximately 50 legal cases on the reading list of the American Board of Forensic Psychiatry are covered. However, the information on the early tests of insanity, on historical figures, and on legal concepts is useful.

In areas where I consider myself to be reasonably informed, the topics are adequately covered and the discussion valuable. In areas where my knowledge is more limited, I found the book informative and enlightening. In short, *Principles and Practice of Forensic Psychiatry* is an excellent, practical, up-to-date resource for professionals willing to brave the hazards of the legal arena.

A. KENNETH FULLER, M.D.
*Thomasville, Ga.*

**A Conflict of Rights: The Supreme Court and Affirmative Action,** *by Melvin I. Urofsky. New York, Charles Scribner's Sons, 1991, 261 pp., $22.95.*

Affirmative Action and the social and economic conditions that gave rise to it as a public policy are very complex areas. In *A Conflict of Rights,* Melvin Urofsky, a professor of both history and Constitutional law, presents a clearly written story of the complex case of *Johnson v. Transportation Agency,* a case that reached the Supreme Court and involved difficult questions of both law and social policy. In 1974, Diane Joyce and Paul Johnson both applied for the position of road dispatcher, a job in the skilled craft category, in the Santa Clara County Transportation Agency. Diane Joyce had worked for the county since 1970, serving as an account clerk until 1975. In 1974, she applied for the road dispatcher position but was ineligible because she had not served as a road maintenance worker, a prerequisite for the job. In 1975, she transferred from a senior account clerk position to a road maintenance position, becoming the first woman to fill that job. During her 4 years in that position, she occasionally worked at the job she coveted, that of road dispatcher.

Paul Johnson began work for the county in 1967 as a road yard clerk. He, too, applied for the road dispatcher position in 1974 and was turned down. In 1977, he began work as a road maintenance worker and during the next 2 years occasionally worked as a road dispatcher.

In 1979, Joyce and Johnson competed for the job of road dispatcher. Paul was certain that he had the job, having been told by people who should know that he would get it. Joyce feared that she would be kept out of the job by an active "old boy" network. She appealed to the County Affirmative Action officer and ultimately, with that officer's intercession, was awarded the job as part of the county's Affirmative Action program. Paul Johnson thought he deserved the position (and he had been told he would get it) and that reverse discrimination had occurred. Therefore, he began a struggle over the right to be hired that went from the Santa Clara County Court to a Court of Appeals to the Supreme Court of the United State.

In an opinion issued on March 25, 1987, Justice Brennan, writing for the majority, affirmed Diane Joyce's right to a job granted to her by virtue of Affirmative Action. Brennan wrote, "We therefore hold that the agency appropriately took into account . . . the sex of Diane Joyce in determining that she should be promoted to the road dispatcher position. The decision to do so was made pursuant to an Affirmative Action Plan that represents a moderate, flexible, case-by-case approach to effecting a gradual improvement in the representation of minorities and women in an agency's work force. Such a plan is fully consistent with Title VII for it embodies the contribution that *voluntary* employer action can make in eliminating the vestiges of discrimination in the work place. Accordingly, the Judgment of Appeals is affirmed."

*A Conflict of Rights,* the absorbing story of this case, tells the story of two hard-working county employees who both believed that they were right in their pursuit of a job. It tells the story of the lawyers and the courts that supported them in their struggle for justice. A reader gains insight into the workings and machinations of the legal system and the personalities of the individuals involved, including but not limited to the members of the 1987 Supreme Court that issued the decision. Finally, a very detailed description of the history of litigation surrounding Affirmative Action is chronicled through a review, inspection, and interpretation of the case adjudicated by the Supreme Court. *A Conflict of Rights* probably will not share a place with other great books written about Supreme Court justices and the inner workings of the Supreme Court (as in *The Brethren* [1]) or about landmark cases such as *Brown v. Board of Education, Gideon v. Wanewright* (*Gideon's Trumpet* [2]), or *Rowe v. Wade.* On the other hand, it presents an interesting story, a human story, and an illustration of the ongoing struggle of the Supreme Court to define the boundaries of Affirmative Action, a remedy for past racial, religious, or sexual discrimination.

## SUBSTANCE ABUSE

**Alcohol and the Family: Research and Clinical Perspectives,** *edited by R. Lorraine Collins, Kenneth E. Leonard, and John S. Searles. New York, Guilford Press, 1990, 386 pp., $40.00.*

There are a lot of books available on alcohol abuse, but few of them are very good. This book is one of the best I have seen for a while. It is an interesting combination of research and clinical material. The complex relationship between alcohol abuse and the family is an area worthy of more investigation, and the authors make important contributions to the understanding of this issue. The book is divided into three sections: Genetic Research, Family Processes, and Family Treatment. All of the chapters are clear and contain new information as well as clinical material.

The chapter critiquing genetic studies differs from other summaries by giving more detail on research methods. It also compares different ways of studying the family. The material it provides on twin studies is detailed and well explained. The problems of genetic studies range from statistical appropriateness to basic concepts. This chapter is well referenced, and the bibliography could serve as a guide for people looking for further reading.

The next chapter focuses on the implications of current research for our understanding of alcoholism as a familial disease. There is a good overview of adoption studies. The interaction between genes and environment is discussed, as are concepts of the disease model. The comorbidity of alcohol abuse and personality disorders is well presented and scientifically evaluated. This chapter is particularly well documented and has copious references.

The discussion of genetics and alcoholism continues in chapter three with the search for biological markers for the vulnerability to alcoholism and a discussion of the differences between state and trait markers for alcoholism. It also reviews the metabolism of alcohol and describes several markers under investigation. The next chapter deals with the general concepts of behavioral genetics and discusses models that best fit alcohol abuse. As with the preceding chapters, genetic transmission and distribution are well explained.

The second part of the book, Family Processes, begins with a discussion of the impact of the family on the patterns of adolescent drinking. This is put in the context of general problem behaviors, but the implications for the social effects on adolescent alcoholism are clear. This first chapter is good but seems too brief, given all the material it needs to cover.

Johnson and Rolf contribute an excellent review of the research concerning the children of alcoholics, covering topics ranging from fetal alcohol syndrome to the behavioral assessment of high-risk children. Citations are given to a large collection of fine articles regarding the family, culture, and transmission of alcoholism.

An excellent chapter by Leonard reviews the marital interactions of different kinds of alcoholics, providing a very interesting comparison of episodic and steady drinkers. Unfortunately, the list of references is a bit short, a drawback to the researcher interested in further reading.

I was surprised to find an entire chapter devoted to the sexual functioning of male alcoholics. This important area seems to be uniformly overlooked in most texts on alcoholism. The physiological and psychosocial factors are discussed, the course and treatment of dysfunction are briefly summarized, and longitudinal studies are examined. This chapter could have been improved by adding more information about the sexual functioning of female alcoholics.

In the third section, there is a good chapter on the stresses of families dealing with alcoholic members. It describes the areas of family adaptation, communication, and problem solving. Much of this information is from original research and is quite interesting. The last part of this chapter deals with the effect of alcohol abuse on marital relationships. It includes information about gender differences, stress, and coping skills. Implications for treatment are objectively discussed for each area of pathological behavior.

This book has taken on a complex task: the examination of alcohol abuse and the family. It does a fairly good job of handling this material. The contributions by clinicians and researchers are interesting and make this book well worth reading.

JAMES A. WILCOX, D.O., M.S.
*El Paso, Tex.*

**The Nature of Drug Dependence,** *edited by J. Griffith Edwards and Malcolm H. Lader. New York, Oxford University Press, 1990, 233 pp., $59.95.*

*The Nature of Drug Dependence* is a nine-chapter volume from the Society for the Study of Addiction's semiannual meeting of the same title. This society publishes the well-respected monthly *British Journal of Addiction.* The focus of this special-invitation meeting was to bring together world experts in many disciples who work on the issue of drug dependence. Chapters were compiled from papers prepared for the meeting. Each participant received the papers before the meeting. Discussion was held after each paper and is included in an edited format.

Topics covered in this volume include historical concepts of dependence, genetic aspects of alcohol and substance abuse, and the cellular biology of tolerance and dependence. Two chapters focus on drug-seeking behavior. All chapters are well-written by internationally recognized experts.

The final chapter serves as a synthesis in the study of dependence. Written by Jim Orford, this chapter reviews the complexity of studying and understanding drug dependence. He states, "We have to face up to the fact that dependence—itself a multidimensional concept—has many and varied determinants in the biological, psychological, and sociocultural domains, and that these variables interact in complex ways." He goes on to suggest that there are no simple prevention or research solutions. Prevention might best be served by a multifaceted approach targeting early behaviors as well as later behaviors. Research advances are likely to rely on multidisciplinary teams.

The final chapter's discussion highlights the problems of multidisciplinary research. There is a paucity of knowledge and research regarding the nature of multidisciplinary collaboration. University departments often discourage collaboration by dissertation and tenure requirements. Despite these and other problems, the participants cite examples of successful multidisciplinary teams.

This volume's attraction is the combination of excellent and well-referenced chapters with discussions by world leaders in the fields of alcohol and drug dependence. Because of the wide scope of the topics selected, readers are likely to find some chapters less informative than others. As a whole, however, this collection is important for researchers in the area of drug dependence. Some clinicians specializing in alcohol and drug dependence might also find it worthwhile.

**Alcohol and Seizures: Basic Mechanisms and Clinical Concepts,** *edited by Roger J. Porter, Richard H. Mattson, Joyce A. Cramer, and Ivan Diamond. Philadelphia, F.A. Davis, 1990, 342 pp., $65.00.*

This volume addresses the interaction between alcohol abuse and seizure disorders. The editors focus on the neurological and basic science bases of these two important clinical entities as well as their clinical and therapeutic interactions.

The interaction between alcohol and seizures is clearly an emerging field at both the basic science and clinical levels. From a clinician's standpoint, this book would have been more readable if the section entitled Classification and Diagnoses of Syndromes had preceded Basic Mechanisms of Alcohol-Related Seizures. As it is, the reader is asked to dive into the cell biology and physiology of alcohol as well as its mechanisms and its effects on the nervous system after only a brief introduction. I found that rereading this section after I had been grounded in the latest thinking relative to the classification and diagnoses of the interaction put this basic science material into a more cogent context.

This work, however, is important reading for psychiatric clinicians. It is especially important for those who work in the substance abuse area. For example, it includes the latest research and thinking relative to the alcohol withdrawal syndrome. This syndrome is examined in terms of its neural excitability, molecular pathways, drinking patterns, and clinical descriptors. Treatment modalities are also described in terms of this period of heightened excitability. The alcohol withdrawal syndrome is compared with other seizure patterns, especially in individuals who have seizure manifestations from other underlying causes.

The editors have endeavored to provide a diverse and rich mix of sophisticated views in this dual-diagnosis area. Although we know a number of facts about the alcohol withdrawal syndrome and its seizure component, there is much that is still unknown and unanswered. This book ends with a description of these unanswered issues in counterpoint with the known issues and treatment approaches.

This work is a sophisticated volume in an emerging field. It is written primarily by neurologists and basic scientists, but it has a great deal of relevance to clinical psychiatrists, especially those involved in addictionology.

ARON S. WOLF, M.D.
*Anchorage, Alaska*

**Treatment Choices for Alcoholism and Substance Abuse,** *edited by Harvey B. Milkman, Ph.D., and Lloyd I. Sederer, M.D. Lexington, Mass., Lexington Books (D.C. Heath and Co.), 1990, 379 pp., $49.00.*

Alcoholism and drug addiction are matters of major concern both in Western and Eastern countries. This book answers the need to circulate updated information on these topics among the entire scientific community—not just medical personnel—to promote an interdisciplinary approach and avoid an "unidimensional reductionism and simplistic explanation in a field beset by complexity."

The first section of this book, Biological Factors, reviews the genetic influences (Allan Collins and Christopher de Fiebre), the biochemistry of mood and behavior (Stanley Sunderwirth), the biological approach to addiction treatment (John Renner), and nutrition and recovery (Lee Ann Mjelde Mossey). These papers make available updated information on different types of addiction and underlying biological mechanisms. In particular, Sunderwirth mentions the evidence indicating that it is possible to modify the chemistry of the brain by diet and exercise. He also postulates the occurrence of a natural high by such acts as hang gliding: "As the pilot approaches the edge of the cliff and then soars into space, there is a rush of excitatory neurotransmitters into the synapse, which brings about an immediate increase in the rate of neuronal firing . . . and in turn results in a elation of mood, and increased alertness, and a complete elimination of either drowsiness or depression." This seems to be an expensive and risky way to treat depression underlying addictive behavior.

In the second section of the book, Prevention and Recovery From Alcoholism, Peter Nathan shows that it is easier to prevent some consequences of alcohol misuse than it is to prevent chronic abuse itself. Other chapters include "The Assessment and Treatment of Alcohol- and Drug-Related Traffic Offenders" by David Timken, "Prevention and Intervention in Schools" by Mary VanderWall, and "Employee Assistance Programs as an Early Intervention Strategy for Substance Abuse" by Carol Hacker.

Timken points out that alcohol abusers are likely to become traffic offenders; he found that recidivism was consistently higher among offenders who failed to complete the educational program in the Colorado judicial system. Hacker's paper stresses that substance abuse is a major concern for companies. The National Institute on Drug Abuse reports that 23% of all workers use drugs on the job and that 5% have substantial addiction problems.

Part three of this book, Multiproblem Patients, contains contributions by Lloyd Sederer ("Mental Disorders and Substance Abuse"), Sheila Blume ("Alcohol and Drug Problems in Women: Old Attitudes, New Knowledge"), and George Vaillant ("Elements of Recovery: A Longitudinal Analysis").

Part four, Treatment and the Law, contains, among others, papers by Alexander Hunter and Robert Pudim ("Treatment Strategies for Juvenile Delinquents to Decrease Substance Abuse and Prevent Adult Drug and Alcohol Dependence") and Phillip Sidoff et al. ("Rehabilitation of Multiple DUI Offenders: An Innovative Model"). All of these contributions point out that in the management of alcoholism and drug addiction knowledge of forensic psychiatry is at least as important as knowledge of clinical psychopathology and psychopharmacology.

Finally, in part five, Treatment Alternatives, William Miller discusses "Alcohol Treatment Alternatives: What Works?" He points out that there is no overall advantage for residential, intensive, or longer treatment over less expensive alternatives. In "Cognitive-Behavioral Treatment of Problem Drinking" Chad Emrick and Gregory Aarons deal with established behavioral procedures. Other chapters in this section include "Affective Modes in Multimodality Addiction Treatment" by Robert Vaughn Frye, "Family Therapy Approaches to Substance Abuse With a Special Focus on Alcohol Issues" by Victor Harris, "Therapy With Families of Adolescent Substance Abusers" by M. Duncan Stanton and Judith Landau-Stanton, and "Interventions With the Substance-Abusing Nurse" by Vernice Griffin Hills.

This book generally emphasizes social and educational factors that can promote or reduce the use of intoxicants rather than biological determinants and psychopharmacological management. It also mentions the intriguing concept of natural highs. The "natural" altering of our consciousness, providing increased pleasure, seems hardly applicable (and in some way misleading) in such situations as unhappiness, anxiety, or depression, which often underline alcoholism and drug addiction. Such conditions, which are at least partly biologically determined, cannot be affected simply by exercise or diet. They need proper diagnostic recognition and psychopharmacological and/or psychotherapeutic management. Moreover, this books does not include contributions on such recent biological findings as changes in cerebral blood flow and neuroimaging in drug addiction, molecular biology of alcoholism, and new treatment strategies of withdrawal syndromes.

In conclusion, this book could be of some interest to psychiatrists and to nonmedical staff for its prominent educational and social content; its main quality is in supporting (at least in principle) a multimodal therapeutic approach.

CARLO A. ALTAMURA, M.D.
*Milan, Italy*

**Cocaine in the Brain,** *edited by Nora D. Volkow, M.D., and Alan C. Swann, M.D. New Brunswick, N.J., Rutgers University Press, 1990, 188 pp., $40.00.*

This is a compact and friendly introduction to the neurobiological and phenomenological dimensions of cocaine abuse. The scope of the book, which is largely exclusive of treatment issues, neatly covers relevant topics. All chapters have been authored by well-known experts in cocaine research.

The text comprises eight chapters. The first, by Burt Angrist, is a tight comparison summary of cocaine and amphetamine that includes interesting speculation on the phenomenology of these drug-induced psychoses. The next chapter, about populations at risk for cocaine use, provides a useful summary of the epidemiologic data collected for the 1985 National Survey on Drug Abuse by the National Institute on Drug Abuse but may leave the reader with curiosity about more recent trends and for predictions of future at-risk groups. Roy Wise, writing on the neural mechanisms of the reinforcing action of cocaine, punctuates his summary of a highly complex literature with an excellent set of references. In a brief but stimulating section he speculates about the role of memory in cocaine craving.

Several chapters are devoted to the putative mechanisms of cocaine effects. The chapter by Alan Swann attempts to digest an extremely large body of preclinical data on acute and chronic effects of cocaine, covering behavioral effects, in vitro models, sensitization, kindling, and transmitter interactions. Despite the complexity of the topic, this chapter is highly readable. The author's necessarily cursory exploration of models and evidence is certainly sufficient to provide the reader with an appreciation of the intricacy of brain processes during and after cocaine use.

Nora Volkow follows with a chapter on the applications of imaging modalities. The sections on single photon emission computed tomography (SPECT), magnetic resonance imaging, computerized EEG, and CT seem to focus on descriptions of these technologies and are a bit short on practical application to studies of cocaine use in humans. Indeed, the use of iodinated dopamine receptor radioligands in SPECT has greatly expanded since the publication of this book, thus dating parts of it. The section on positron emission tomography is more developed and clinically meaningful; this is consistent with the more advanced state of research and the author's research interest.

The next chapter, by Charles Ashley and Robert Hitzemann, is a fine synopsis of the clinical pharmacology of cocaine, with clear figures and concise prose. This is followed by descriptions by Charles Dackis and Mark Gold of clinical aspects of cocaine use, including an inventory of medical sequelae of use, neuroendocrine alterations in cocaine withdrawal states, and the pharmacological management of cocaine abstinence. This chapter is a bit syncopated and moves suddenly from one topic to the next. In the final chapter, Frank Gawin and Everett Ellinwood present an overview of the clinical phenomenology of cocaine abuse. They refer to amphetamine effects and are generally careful to acknowledge differences between the two stimulants. One wishes more recent descriptive data were incorporated; there are no clinical references past 1986.

In all, the chapters clearly present the conventional wisdom that has been presented recently in more dense form as journal articles. (The epidemiologic and descriptive chapters might have benefited from survey of more current literature, however.) The chapter bibliographies are quite extensive and provide a very good reference base for those who wish to explore subjects in greater depth. These qualities, as well as the conciseness of the book, lead us to recommend it as a solid introductory text for medically or biologically trained students and professionals.

## Blood Groups in Panic Disorder

Sir: Substantial evidence suggests that panic disorder runs in families, but the genetic locus, if any, has been elusive (1). One approach is to study chromosomal markers such as ABO blood type or human leukocyte antigen (HLA) in individuals with the illness. In early studies (2–4) investigators found a higher frequency of blood group O among patients with manic-depressive illness than among control subjects and a higher frequency of blood group A among unipolar patients. The finding of a relationship of panic disorder with certain blood groups would be a significant step toward understanding the disorder.

We incidentally observed that six of eight consecutively admitted patients with panic disorder had type B blood. This finding prompted further inquiry, and data were collected from 45 patients diagnosed as having panic disorder. Of these 45 patients, 14 patients had blood type A, seven had type B, one had type AB, and 23 had type O. This distribution of blood types was normal compared to that of the general population.

The search for a genetic marker for panic disorder has been disappointing, and our investigation suggests that blood type in panic disorder offers no new leads. However, the discovery of new probes continually raises hopes that a definite genetic marker for panic disorder and other important psychiatric disorders may be found soon.

## An Unusual Presentation of Multiple Sclerosis

Sir: Behavioral changes, including alterations in cognitive functions and psychiatric abnormalities, have been recognized with increasing frequency in patients with multiple sclerosis (1, 2). Except for a single case report (3), the literature indicates that multiple sclerosis is usually diagnosed long before the appearance of any cognitive dysfunction (2, 4). We report an unusual case in which a frontal syndrome was the first manifestation of multiple sclerosis.

Ms. A, a 37-year-old woman, was referred to a psychiatric outpatient clinic by Social Services because of marital difficulties. A college graduate and mother of three young children, she was showing behavioral changes that had started insidiously 6–8 months prior to referral. When questioned, her family reported that she had no history of neurological or psychiatric disturbance. She was neglecting her household chores, engaging less in activities outside the home, and showing indifference toward her husband's complaints. Because of her apathy about her condition, she had not sought medical assistance but was brought to Social Services for counseling at her husband's insistence. The psychiatric liaison to Social Services examined her and found her fully oriented in time and place. Her affect was blunted, remote, and somewhat apathetic, and her thought processes were mildly slowed, with an impaired capacity for abstract thinking. Her vocabulary was surprisingly poor for a college graduate. She was unable to copy simple geometric forms or draw a clock. She demonstrated little insight with regard to her condition.

The abnormal cognitive functioning prompted a full neurological examination and workup, which disclosed bilateral frontal release signs, mild left-side pyramidal signs, and bilateral vibration loss in her legs. Laboratory studies revealed oligoclonal bands in her CSF. Visual evoked potentials were abnormal. Brain magnetic resonance imaging (MRI) showed generalized atrophy, with foci of long relaxation time in the white matter of the brainstem and cerebellum. Results of blood cortisol and thyroid tests and levels of vitamin $B_1$, vitamin $B_{12}$, arylsulfatase, hexosaminidase, and very-long-chain fatty acids were all normal. HTLV-I, HIV, and VDRL test results were negative.

Neuropsychological testing demonstrated a severe frontal lobe dysfunction, with difficulties in abstraction, concept formation, judgment, and praxis. In addition, there was marked mental slowing and mild attention deficit.

Ms. A fulfilled Poser's diagnostic criteria for "laboratory supported definite MS," having frontal, pyramidal, and posterior column signs, pathological visual evoked potentials, oligoclonal bands in the CSF, and a brain MRI compatible with focal demyelination. Her presentation was that of frontal syndrome, with organic personality disorder supported by neuropsychological testing.

The range of cognitive deficits in MS is broad (5). It appears that certain functions, such as conceptual processes and attention, tend to be preferentially impaired (4), as was true in this case. Organic personality disorder usually develops years after the diagnosis of multiple sclerosis (2, 4). Our case seems to be unique, because an overt organic personality disorder appeared to be the first manifestation of multiple sclerosis. We are reporting this case in order to stress the importance of careful neurological examination and extensive laboratory workup for young patients presenting with behavioral changes.

## Cyproterone Acetate in the Treatment of Aggression

SIR: Medroxyprogesterone acetate has been reported to reduce aggression in patients with temporal lobe epilepsy (1) and in male schizophrenic patients (2). Its efficacy is thought to be due to its lowering of testosterone levels and competitive inhibition of androgen action in the brain. However, medroxyprogesterone acetate has major side effects, such as weight gain, feminization, and even adrenal insufficiency. We report here the efficacy of a new competitive inhibitor of androgen binding, cyproterone acetate, in three neuroleptic-refractory aggressive male patients. Cyproterone acetate is considered to be devoid of the side effects we have mentioned. All three patients consented to the trial.

> Mr. A, a 29-year-old man with mild mental retardation and intermittent explosive disorder, had a long history of unpredictable assaults. He was admitted to the hospital because he attempted to set a fire. During this hospitalization aggressive episodes, including verbal and physical assaults on staff members, occurred almost every day despite increasing doses of neuroleptic medication. His mean level of aggression was 19 on the Overt Aggression Scale (3). Cyproterone acetate was gradually added to the existing medications (sultopride, 2400 mg/day; levomepromazine, 400 mg/day; clorazepate, 150 mg/day), and Mr. A's aggressive behavior disappeared within 3–4 weeks. The maintenance dose of cyproterone acetate was 200 mg/day. This improvement has been maintained for 22 months and has permitted the patient to be discharged from the hospital. At this writing, the concurrent neuroleptic medication has been gradually reduced by more than 50% of the initial dose.
>
> Mr. B, a 30-year-old man with a diagnosis of infantile psychosis, had shown aggressive and impulsive behavior since the age of 10. During the months that he was on our ward, his level of verbal and physical aggression had gradually increased and reached 18 on the Overt Aggression Scale in spite of large doses of medications, including levomepromazine, 300 mg/day; carbamazepine, 600 mg/day; and diazepam, 200 mg/day. Following the administration of cyproterone acetate, increased to a dose of 200 mg/day, the patient showed clear improvement within 1 month. His aggressive behavior disappeared. The other medications were gradually reduced until Mr. B was taking only levomepromazine, 150 mg/day. After 4 months, when cyproterone acetate was discontinued for a month, the patient relapsed within 2 weeks, but his condition improved upon resumption of cyproterone acetate, 200 mg/day.
>
> Mr. C, a 40-year-old man with a diagnosis of disorganized schizophrenia, had a long history of psychosis with unpredictable assaults. He had been hospitalized on our ward for 13 years. During the previous 3 months, his aggressive behavior had gradually increased, resulting in daily physical aggression against either himself or staff members that led to occasional injuries (his mean level on the Overt Aggression Scale was 23). Mr. C was placed on a regimen of cyproterone acetate, increased to a dose of 300 mg/day. His other medications (haloperidol, 20 mg/day; sultopride, 2 g/day; lorazepam, 10 mg/day) were continued. His aggressive behavior was brought completely under control within 8 weeks, but his hallucinations and delusions worsened. The dose of haloperidol was increased to 30 mg/day in order to control the psychotic symptoms. The improvement has been maintained for 10 months, and Mr. C did not relapse when cyproterone acetate was gradually discontinued 3 months ago.

All three patients responded to treatment with cyproterone acetate within 3–4 weeks, whereas other treatments had previously been unsuccessful. No major side effect except moderate weight loss in two cases was encountered in these patients. Plasma testosterone levels remained in the normal range.

Cyproterone acetate may be a promising treatment for some male patients whose aggressiveness is unmanageable by conventional methods, and it would have an advantage over medroxyprogesterone acetate, which can induce important side effects. Additional studies of violent patients are required to confirm these preliminary results.

## Possible Interaction Between an MAOI and "Ecstasy"

SIR: Harvey Sternbach, M.D. (1) recently reviewed the serotonin syndrome and recommended a heightened awareness of agents that may induce such a state. I would like to report a case in which a patient on a regimen of a monoamine oxidase inhibitor (MAOI) plus lithium seemingly developed the serotonin syndrome when exposed to 3,4-methylenedioxymethamphetamine (MDMA), a drug of abuse referred to as "Ecstasy." A review of the literature yielded one other reported case of a similar interaction (2).

> Ms. A was an 18-year-old woman with bipolar disorder who was treated with lithium carbonate, 1200 mg/day (average serum level=0.7–0.9 meq/liter), and phenelzine, 60 mg/day. While at a party, she consumed a glass of juice that was purported to contain four doses of Ecstasy. She shared this with three other friends, who reported only the expected and no untoward effects. Ms. A developed markedly

increased muscle tension within 15 minutes and was transported to an emergency room. She was described as comatose and tremulous, with decorticate-like posturing and limited response to deep pain. Her pulse was 150 bpm and shallow, her temperature was 100.5 °F, and her blood pressure was 150/100 mm Hg, with a WBC count of 11,000/mm$^3$. Blood gas analysis suggested respiratory and metabolic acidosis. Her lithium level was 1.2 meq/liter (about 8 hours after her lithium dose) and her creatine phosphokinase level was 394 U/liter. Other laboratory examinations produced unremarkable findings.

One hour after the ingestion, Ms. A was described as delirious and agitated. Five hours after the ingestion, she became fully alert and her muscle tone returned to normal, as did all other clinical and laboratory measurements. There were no obvious causes of lithium toxicity. She was discharged after a 2-day hospitalization and there were no apparent sequelae. The patient's phenelzine was initially discontinued but subsequently resumed after a relapse. She has been essentially asymptomatic since that time.

The clinical effects of MDMA typically begin within half an hour and last 4–6 hours. While chemically related to amphetamines, MDMA seems to affect serotonin neurons preferentially (3). It is believed that MDMA stimulates the release of serotonin from presynaptic nerve terminals, particularly those arising in the dorsal raphe. It is interesting to speculate that MDMA's effect on serotonin was responsible for the clinical syndrome observed. It is worth noting that lithium potentiates the effects of serotonin; however, the previously reported case of a presumed MAOI-MDMA reaction occurred in a patient who had not been exposed to lithium.

In sum, this is the second case report suggesting a toxic interaction of MDMA with an MAOI. At this point, it is prudent to be alert to the dangers of such an interaction.

### Bleeding, a Side Effect of Fluoxetine

SIR: The common side effects reported for fluoxetine are agitation, headache, and insomnia. During fluoxetine treatment of a patient, we encountered the hematological side effect of spontaneous bleeding, which caused bruises and menorrhagia. These symptoms improved upon discontinuation of the drug and recurred upon rechallenge, indicating that fluoxetine was related to the side effect. In this case report, we present the clinical picture of this patient.

Ms. A, a 40-year-old woman, manifested insomnia, anxiety, suicidal ideation, and loss of appetite that had lasted for a few months. The findings of pretreatment laboratory tests and a physical examination were normal. The patient enjoyed normal physical health, with no history of family or personal bleeding disorder. She was prescribed fluoxetine, 20 mg/day, which was increased gradually to 40 and then 60 mg/day. Her response to the treatment was very good, and she resumed her daily activities. By the end of the month after she began taking fluoxetine, she noticed a heavy menstrual flow, which continued for a few days, but she did not consider it to be abnormal. Two months later, she began developing spontaneous ecchymoses; the largest, on her right thigh, was 12–15 cm in length and 3–4 cm in width. A few days later her spleen was palpable, and laboratory tests revealed that her platelet count was 195,000/mm$^3$, WBC count was 4200/mm$^3$, hemoglobin was 13.3 g/dl, prothrombin time was 12.5 seconds, and partial thromboplastin time was 31.3 seconds. Hence fluoxetine was discontinued. Four days later the ecchymosis was fading and the spleen was no longer palpable. The WBC count was 5,000/mm$^3$, hemoglobin was 12.9 g/dl, platelet count was 131,000/mm$^3$, and bleeding time was 6.5 minutes. About a month later Ms. A became so depressed that she took one 20-mg capsule of fluoxetine for 3 consecutive days. She again developed extensive ecchymosis from knee to hip, encircling from front to back. She became frightened and discontinued the fluoxetine. All her symptoms resolved again.

Yaryura-Tobias et al. (1) reported eight cases of bleeding after fluoxetine therapy. In our patient recurrence of bruises upon rechallenge with the drug provides substantial proof of a drug-related adverse reaction. One should be aware of the possibility of the occurrence of bleeding with fluoxetine.

### Imipramine and Suicidal Thoughts

SIR: A number of case reports have been published associating fluoxetine (1–3) and desipramine (4) with the development of unexpected, possibly ego-dystonic suicidal ideation. In one (4), subsequent use of amoxapine, trazodone, and nortriptyline was associated with the return of suicidal ideation. While the issue is far from decided, especially given Fava and Rosenbaum's retrospective survey (5) that found emergent suicidal ideation not only with fluoxetine (3.5%) but with tricyclic antidepressants in general (specific drugs unspecified) (3%), I present a case of suicidal ideation which developed while a patient was taking imipramine.

Mr. A, a 59-year-old man, had been treated as an outpatient, from early 1986 to the end of 1988, with imipramine in doses of 150–200 mg/day for chronic back pain and depression. He had presented with passive suicidal thoughts ("Why go on?") and had made a self-aborted suicide attempt 16 years previously. His concurrent medications included sulindac, metoprolol, nitroglycerin, and hydrochlorothiazide. He had been treated with 150 mg/day of imipramine, with remission of his depression and better pain control, until the end of 1986, when the dose was in-

> creased to 200 mg/day in an attempt to relieve what were felt to be remaining depressive symptoms (e.g., disrupted sleep). His sleep improved and his mood continued to be improved, although 5 months later he reported that he had been forgetting things and having nightmares. A repeat blood level determination at this dose was the same as at the lower dose, 221 μg/liter. He was worried that he would "have to stop the imipramine and get worse."
>
> In December 1988, although he still reported good relief of both his depression and his back pain, Mr. A unexpectedly decided to stop his medication. A review revealed that while taking imipramine, and despite feeling less depressed and calmer, he would have "crazy impulses to walk downstairs and do things." These thoughts were dystonic, and he was fearful enough that he gave his gun collection, stored in his cellar, to a relative to hold for him. These thoughts had begun to occur sometime after the dose of imipramine had been raised to 200 mg/day. Although the thoughts came only occasionally, he decided that he would rather deal with his pain than continue to take the medicine. There were no obvious life stressors at the time, and he was ashamed to tell anyone that he was feeling these things. The dysphoric feelings and dystonic suicidal impulses passed after he stopped taking his medicine. There was no associated akathisia or anxiety and no personality disorder (although there were avoidant and dependent traits).
>
> Other negative consequences of imipramine use, which also remitted when Mr. A stopped the drug, were excessive body movements during sleep (to a point where he once jumped from his bed into a wall and hurt himself), an increase in nightmares, thinking less clearly, and curtailing his driving because he felt slowed up in his responses. He reported some intermittent memory concerns which vacillated with the amount of pain he experienced.

Although case reports have described the association of suicidal impulses with desipramine and fluoxetine, to my knowledge this is the first report of an association with imipramine. While caution has been recommended in associating suicidal ideation with antidepressants, physicians must be alert to the possibility of suicidal impulses emerging as a drug effect not only late in a course of treatment but in the context of a positive response to an antidepressant. We must be reminded that whatever the origin of these impulses, attention to the doctor-patient relationship is essential in encouraging a patient to feel comfortable about reporting them, especially in the context of depression, where the patient is often self-effacing.

## Fluoxetine and Fluvoxamine in PTSD

SIR: The serotonin uptake inhibitors have now become the latest in a long line of medications touted as possibly effective in the treatment of posttraumatic stress disorder (PTSD) (1). Continuing this trend, I wish to report a patient whose PTSD symptoms responded to the serotonin uptake inhibitors fluoxetine and fluvoxamine but not to a wide variety of standard pharmacologic interventions.

> Mr. A, a 41-year-old Vietnam veteran with severe PTSD, was seen regularly for supportive group psychotherapy. Despite inpatient treatment on a specialized PTSD unit and multiple trials of neuroleptics, tricyclic antidepressants, and phenelzine, Mr. A's PTSD symptoms gradually worsened after Vietnam. At the time treatment with fluoxetine was initiated, Mr. A's only medication was diazepam, 80 mg/day in divided doses. Fluoxetine was started to help Mr. A with secondary depressive symptoms, which improved somewhat at a dose of 40 mg/day. At a dose of 60 mg/day of fluoxetine, Mr. A noted moderate improvement in his PTSD symptoms, including a decrease in intrusive memories and nightmares (despite no improvement in his sleep pattern), a reduction in overall anxiety, and a lessened need to avoid cues capable of eliciting the symptoms. Unfortunately, Mr. A also developed severe anorexia. After a 30-lb weight loss over 3 months, fluoxetine was discontinued, with the return, over a matter of weeks, of PTSD and, less noticeably, depressive symptoms. A trial of fluvoxamine, 250 mg/day, was then initiated under a compassionate-use protocol for depression. This intervention resulted in a reduction in both PTSD and depressive symptoms similar to that seen with fluoxetine.

The response of this patient to treatment with two structurally different serotonin uptake inhibitors is certainly noteworthy. It is prudent to note, however, that the history of PTSD is replete with anecdotal reports of pharmacologic treatment successes, largely unconfirmed by general clinical experience or controlled trials. My patient also had depressive symptoms, took other medications, was not followed with structured rating scales or rated by blind observers, and received behavior therapy during treatment, thereby limiting the generalizability of the findings.

In any case, the intent of this communication is not to suggest that the serotonin uptake inhibitors will prove to be a panacea for patients with PTSD, particularly since the case for a noradrenergic diathesis in PTSD has been persuasively drawn. On the other hand, the seemingly robust response of PTSD patients to this class of drugs and the phenomenological similarity between PTSD and obsessive-compulsive disorder does suggest that a serotonergic connection might be profitably explored. One prediction from a serotonergic model of PTSD is that drugs useful in the treatment of obsessive-compulsive disorder may also be useful in treating PTSD. Given the marginal performance of antipanic treatments for PTSD (2), properly controlled clinical trials of serotonin reuptake blockers would seem to be in order.

## Mania During Hemodialysis: Causal or Casual Association?

SIR: Hemodialysis is listed by Kaplan and Sadock (1) among the causes of secondary mania. However, this is based on scant evidence. I have found nine single case reports of mania during hemodialysis (list available on request), of which only three satisfy the criteria for mania secondary to hemodialysis: 1) a manic syndrome appearing during hemodialysis, 2) no delirium or dementia (to rule out dialysis disequilibrium, uremic encephalopathy, and dialysis dementia), 3) no other organic causes of mania, 4) no past history of affective illness, and 5) no family history of bipolar disorder.

A retrospective study was carried out in the hemodialysis unit of a public hospital in Italy to ascertain the incidence of mania during hemodialysis since the opening of the unit. Case notes were reliable because a case of mania (*DSM-III-R*) would have led to psychiatric consultation, which would appear in the notes. I found 30 cases of acute renal failure (21 male patients and nine female) and 103 cases of chronic renal failure (62 male patients and 41 female). In the chronic group 51 patients had died and 52 were still alive. They had started hemodialysis at a mean age of 55 years. The mean age at death was 61 years. The mean age of the patients still alive was 60 years. Patients with acute renal failure were treated for a total of 446 days. Patients with chronic renal failure were treated for a total of 492.6 person-years.

I found only one case of mania, which did not meet the criteria for mania secondary to hemodialysis. In this patient with chronic renal failure, whom I have previously described (2), mania had started weeks before the beginning of the first hemodialysis session, soon after abrupt nicotine withdrawal. During hemodialysis the clinical picture worsened, with the appearance of psychotic symptoms. The incidence (new cases per year) of mania is 1.2/100 for men and 1.8/100 for women (3). I expected to see, for 492.6 person-years of hemodialysis, between five and eight cases of mania; I found only this one.

One possible explanation is that the mean age at the start of hemodialysis was 55 years. The mean age at onset of mania is 30 years (3). However, onset of mania in old age is not unusual (26% of cases) (4). If hemodialysis induced mania, one would expect many more than nine case reports, since over 90,000 patients have undergone hemodialysis in Europe alone. My results suggest that there is no causal relationship between mania and hemodialysis.

## Folie à Deux Involving a Dog

SIR: Folie à deux, or induced psychosis, is a paranoid delusional system that appears to have developed in an individual as a result of a close relationship with a person who has an established delusional system. Induced psychosis is rare (1). I report a case in which an elderly psychotic woman involved her dog in her deluded behavior, so that the dog itself developed bizarre behavior.

> Ms. A, an 83-year-old widow who had lived alone for 15 years, complained that the occupant of an upstairs flat was excessively noisy and that he moved furniture around late at night to disturb her. Over a period of 6 months, she developed delusional persecutory ideas about this man. He wanted to frighten her from her home and had started to transmit "violet rays" through the ceiling to harm her and her 10-year-old female mongrel dog. Ms. A attributed a sprained back and chest pains to the effect of the rays and had become concerned that her dog had started scratching at night when the ray activity was at its greatest. For protection, she had placed her mattress under the kitchen table and slept there at night. She constructed what she called an "air raid shelter" for her dog from a small table and a pile of suitcases and insisted that the dog sleep in it. When I visited Ms. A at her home, it was apparent that the dog's behavior had become so conditioned by that of its owner that upon hearing any sound from the flat upstairs, such as a door closing, it would immediately go to the kitchen and enter the shelter. When restrained in the living room, the dog reacted to noises from upstairs with agitated barking directed at the ceiling. Ms. A had no previous psychiatric history, and apart from bilateral sensorineural deafness, there was no physical abnormality. A diagnosis of late paraphrenia (*ICD-9,* 297.2) was made. She had no insight and refused admission to a psychiatric facility.

The behavior of Ms. A's dog cannot be considered as delusional but rather as behavioral responses conditioned by the owner's delusional beliefs and behavior. True induced psychoses are rare, but abnormal behavior in the nonhuman companions of the mentally ill is probably common but unrecognized.

## Antisemitism and Jung's Concept of the Collective Unconscious

SIR: Most (orthodox) psychiatrists and psychologists have never wholeheartedly accepted Jung's ideas of the collective unconscious psychic life. They have, however, not been able to explain the mechanism of intergenerational transmission, through which tendencies such as antisemitism remain virulent. The reasons for the persistence of such irrational and destructive social phenomena as antisemitism urgently need to be dealt with, and Jung's approach could prove useful. As is generally known, Freud's concept of the unconscious is a purely individual one, at least in its definite, concrete appearance. Jung, in contrast, described a kind of unconscious that is common to all humans. The entities that he designated as archetypes are primarily of a religious nature. The manner in which they are transmitted from generation to generation eludes rigorous experimental analysis. Jung once wrote of a "precipitation from the primeval ancestors," and this kind of rather metaphysical explanation can be frequently encountered in his works.

Of course, mechanisms of genetic transmission (i.e., the inheritance of factors that cause disease or certain types of behavior) can be much more precisely defined, but it would be a mistake to try to confine psychology and psychiatry within the straitjacket of the strict scientific paradigm.

In any case, a thorough discussion of the intergenerational aspect of phenomena such as antisemitism would be desirable. Here Jungian ideas could prove helpful; for example, one could use Jungian analysis to find "negative archetypes" such as antisemitism or xenophobia. Of course, every other approach (Friedrich Hacker, Sigmund Freud) could also be applied.

### Monitored Conditional Release of Persons Found Not Guilty by Reason of Insanity

SIR: The April 1991 issue of the *Journal* contained an article about persons found not guilty by reason of insanity (1). Our findings (2) are similar to the conclusions of that review.

Before 1978, crime relapses of offender patients discharged from security hospitals were very uncommon in Finland. The previous Mental Health Act of Finland (1952) included conditional release. In 1977 the Act was changed. All possibilities of setting terms for offender patients during the outpatient period after hospitalization were abolished, and outpatient care became completely voluntary. We have found out about numerous relapses since then. Up to the end of 1989 we had obtained data on seven homicides and eight other serious violent crimes. The relapses into crime occurred 1.7 years after discharge, on the average. The total number of offender patients discharged from Niuvanniemi Hospital (Department of Forensic Psychiatry) between the years 1978 and 1989 was 258. Thus, the relative frequency of relapses was remarkably high. For discharged offender patients, during the first year outside the hospital, the risk of homicide was about 800 times higher than it was among the general population. We are now finishing our follow-up study because the Act was changed again in 1991.

Contrary to the findings about predicting dangerousness in the review we have cited, we found some predictors. In Finland we have remarkable opportunities for follow-up studies because according to Finnish law, forensic psychiatrists not only give expert testimony in court cases but are also responsible for psychiatric care of offender patients. With a few exceptions, the crime relapses have occurred among patients who were without insight, had neglected to contact a mental health center, and had rejected their psychiatric medication. Relapse into crime was associated with abuse of alcohol in 13 cases, which may have some link to the role of serotonin in aggressive behavior (3).

The risk of crime relapse among offender patients who have previously committed violent crimes is very high. Our opinion is that some terms or requirements are needed during the outpatient period in order to prevent dropping out of treatment.

### Bone Loss in Patients With Anorexia Nervosa

SIR: Juanita J. Salisbury, Ph.D., and James E. Mitchell, M.D., in their review of bone mineral density in women with anorexia nervosa (1), discussed the relative importance of factors that correlate with bone loss. They commented that duration of amenorrhea, reflecting caloric deprivation and concurrent depression of estrogen levels, was important in the development of bone loss, but this only contributed an average of 25% of the variance to bone loss in the studies reviewed. They concluded that "future experiments need to address more precisely the roles of calcium intake, exercise, estrogen, and other hormones" in women with anorexia nervosa.

We evaluated retrospectively the longitudinal risk factors for bone loss in a controlled study of 69 female adult outpatients with past or current anorexia nervosa (2, and P.J. Hay et al., manuscript submitted for publication). Weight and menstrual histories were assessed by semistructured interviews, and current and lifetime exercise and dietary calcium levels were quantified by detailed questionnaires and interviews. Serum hormones were measured and total calcium assays done. Our results support those of others who have found significantly lower bone density in women with anorexia nervosa than in control subjects. A multivariate analysis of risk factors for bone loss found that the best predictor of bone loss on stepwise multiple regression analyses was duration of anorexia nervosa (19% of the variance, $p<0.001$). A second regression analysis was done with duration of anorexia nervosa removed from the analysis. In the second analysis, duration of amenorrhea explained 18% of the variance ($p<0.001$), and duration of an inadequate calcium intake in adolescence explained 7% of the variance ($p=0.02$). There was no evidence that regular exercise and adequate dietary calcium prevented bone loss related to prolonged periods of low weight and amenorrhea in these subjects.

This is the first study to have found an association between dietary calcium in adolescence and adult bone loss in women with anorexia nervosa, and it supports the finding of Sandler et al. (3) that in postmenopausal women, adequate adolescent dietary calcium is important to adult bone density. However, while adequate dietary calcium is important in postpubertal bone accretion, it will not prevent later bone loss due to a relative estrogen deficiency. Our detailed assessment of exercise and dietary calcium levels suggests that modification of lifestyle factors such as exercise and dietary calcium intake are unlikely to improve bone density when there is continued low weight and amenorrhea. We support the conclusion of Drs. Salisbury and Mitchell that the most important aspect of treatment is to reverse weight loss and obtain resumption of normal menstruation, while the role of other treatments, such as oral estrogen, remains unproven.

## Mania in AIDS and Syphilis (Paresis)

SIR: Recently, Karl Kieburtz, M.D., and associates reported on eight AIDS patients with mania (1). The report included detailed data from a variety of neuropsychological tests and CSF and magnetic resonance imaging (MRI) studies but nothing about the patients except age, race, sex, and homosexual orientation. Five of the eight had depression following the initial HIV diagnoses. The mania improved with lithium and neuroleptics, but the course of illness was not typical for bipolar disorder because of persisting cognitive impairment. Unfortunately, there was no follow-up of the eight patients. The authors suggested, as have others, that the mania was a secondary disorder associated with rapidly emerging cognitive decline due to increased cerebral viral activity.

Certainly, the mania is "associated" with AIDS, but it is primarily a psychobiological reaction, and a fairly adaptive one at that, in the face of absolute hopelessness and certain death, rather than directly related to and "caused by" the underlying neuropathology as revealed in MRI studies and autopsy reports. The fact that five of the eight patients had a prior depression, (not an unusual finding) lends support to the possibility that the mania was a more adaptive response—a denial of impending disintegration. Better to be "Jesus" or "God" than face the dreadful reality of abandonment and death.

A few months ago, in a clinical teaching conference, I interviewed a 38-year-old homosexual man with AIDS who had been admitted to the hospital in a manic state. He was grandiose (with delusions that he, like Jesus, had started a new religion), euphoric, hyperactive, and irritable but had no cognitive impairment on clinical and psychological testing. When faced with the seriousness of his disease, his eyes filled with tears and he said, "I cry myself to sleep every night," then quickly became manic, exclaiming that he was looking forward to "joining God, my father, in paradise." He was treated with lithium and neuroleptics and after 4 weeks was discharged as improved. After a week he relapsed and was admitted to another hospital, given ECT, and once again discharged as improved. Currently, he is doing well.

After the interview I was struck by the similarity of this patient to grandiose paretic patients I had seen 50 years ago. Amazingly, I remembered some articles published in 1941 (first from the Menninger Clinic) on the treatment of paresis with metrazol and ECT. I reviewed these articles published between May 1941 and November 1945 (2, 3). Most were favorable, a few not. The first report of the treatment of paresis by penicillin appeared in December 1945, following which treatment by ECT stopped.

In both CNS syphilis and AIDS, the basic disorder is the dementia. Depression is the most frequent of the psychiatric syndromes, while mania, although most striking, is relatively infrequent (4, 5).

The paretic patients treated with ECT also received fever and chemotherapy, similar to the treatment of AIDS with zidovudine (AZT), ECT, and neuroleptics. But today we are more aware of the shame, guilt, humiliation, and anger of AIDS patients. Probably, these feelings existed in paretic patients too, but were ignored. When the "penicillin" for AIDS appears, the manias along with the treatment by ECT and "modern chemotherapy" will disappear. History repeats itself.

## Stress and HIV Infection

SIR: Ronald C. Kessler, Ph.D., and his colleagues (1) found no relation between certain stressful life events and either decrease in percent of CD4 cells or symptom onset in HIV infection. While we agree with the general spirit and conclusions of this careful study (2), we wonder whether the authors might wish to reconsider their statement that "intervention programs designed to help people with HIV infection cope with stress are unlikely to be useful in prolonging health."

First, stressful life events must be distinguished from "stress" (3), which was not reported. Second, some studies suggest a relation between emotional distress and behaviors that transmit HIV (4). Interventions that reduce distress might therefore prolong health within the community as a whole. Third, reduction of emotional distress in HIV-positive individuals (5) might help increase compliance with effective maintenance medications and, more generally, might increase hope and seeking early medical intervention for treatable opportunistic infections and tumors. Studies of patients with other medical illnesses (6) suggest that further investigation is warranted before concluding that psychotherapeutic interventions for those with HIV infection will not prolong their health.

## Dr. Kessler and Colleagues Reply

SIR: We thank Dr. Perry and associates for their thoughtful comments. Our conclusions might indeed be altered by a consideration of a broader series of stresses. In particular, several studies (1–3) suggest that chronic stress is more strongly related than life events to a variety of mental health outcomes. There is considerable controversy, though, about the validity of currently available scales to measure chronic stress (4), so we chose to measure only major life events in our study. We also agree that intervention programs designed to help people manage stress might successfully reduce behaviors that transmit HIV, but evidence on this possibility is scant.

Dr. Perry and colleagues note an association between emotional distress and risky sexual behaviors. However, there is little known about the mechanisms involved in this association and virtually nothing known about the role of stress. We carried out some new analyses on this issue in the Chicago Multicenter AIDS Cohort Study/Coping and Change Study data after seeing the letter from Dr. Perry and associates and discovered no relation between stressful life events and risky sexual behaviors. This result is not inconsistent with the possibility that intervention programs might influence behaviors that transmit HIV or, as suggested in the third point of the letter, that such programs might encourage active help seeking and compliance with medication regimens. Our failure to find an effect of stressful life events on behavior change does suggest, though, that the recent occurrence of a major life event is not a good indicator of risk status. Individual differences in emotional reactivity are more likely intervention targets. Naturalistic research on these possibilities, ideally including a broader assessment of stress than was used in our work, is needed to help identify the populations most in need of interventions.

## Nicotine Gum in Tourette's Disorder

SIR: With reference to "Nicotine Potentiation of Haloperidol in Reducing Tic Frequency in Tourette's Disorder" by Brian J. McConville, M.D., and associates (1), while I appreciate the theoretical reasons for using nicotine to ameliorate tics, methodological flaws in the study detract from the validity of the authors' conclusions.

They stated that "a placebo gum that tasted similar to the active gum was not available." Consequently, in the control situation the subjects did not chew gum. However, if gum had been used as a placebo, it would have "blinded" the independent raters and controlled for the effect of chewing per se on tics, adding to validity.

Chewing may have had an independent effect on facial and/or vocal tics, either directly or indirectly, through general relaxation. No indication of the differential effect on facial and/or body tics was given.

The method of interviewing patients over 2 hours could have been better standardized. No controls were used to see how tics varied naturally over the time period (perhaps the subjects relaxed over the first half-hour). Patients could have been filmed performing set tasks such as reading, computing, or sitting silently, which has been shown to have excellent reliability and validity in measuring change (2). Although interviewers "avoided topics of known stress" at interview, there must have been considerable interpatient and intrapatient variation that was avoidable.

While the findings of Dr. McConville and associates are of interest and may suggest further research, the points I have mentioned, added to the small number of patients (N=10), make statistical analysis irrelevant and misleading.

E. HUGH G. RICKARDS, M.B., CH.B.
*Birmingham, England*

SIR: We were very interested in the report by Dr. McConville and associates concerning the effect of chewing nicotine gum on tics in patients with Tourette's disorder treated with haloperidol. Anything that could reduce the dosage of neuroleptics and their side effects is an important area of study. We have a few questions about the report and would appreciate the authors' comments.

First, since the authors did not do a placebo gum chewing trial, could they address the possibility that gum chewing itself may have been responsible for the reduction in tics? Brill (1) reported the case of a 12-year-old boy with Tourette's disorder whose tics were reduced by gum chewing. Apparently, this also occurs with facial dystonias (1). It has been our experience with many patients that repetitive, low-level, apparently voluntary movements are utilized by Tourette patients to discharge energy and ease the need for tics. Children who chew gum report that this decreases facial tics. Those who tap their hands feel that it lessens arm and shoulder tics. Patients who shake their legs feel that they do it to prevent large, embarrassing leg jerks. We realize that it is difficult in Tourette's disorder to distinguish a tic from a compulsion, as well as voluntary from involuntary, or even unvoluntary, movements.

Second, in table 1, for most patients tics were less frequent after gum chewing than at baseline. However, in all but two cases, there was an increase toward the baseline number after gum chewing stopped. Would the authors postulate that the nicotine potentiation of haloperidol decreases so quickly, or could this point to a possible gum chewing effect? The authors stated that the effects were seen dramatically within 3 minutes. Does the time action of nicotine gum chewing and haloperidol potentiation fit this pharmacologically?

Our final concern is a clinical one. With the known toxicity and addictive potential of nicotine and its questionable safety in children, adolescents, and pregnant women, we feel that the authors should have more clearly listed potential harmful effects (*Physicians' Desk Reference,* 1991). A pilot study such as this could encourage people to try this treatment despite the authors' general cautions. Potentially harmful effects should be listed specifically.

We are encouraged that the authors are continuing to study this fascinating topic. We look forward to their comments.

### Dr. McConville and Dr. Norman Reply

SIR: We have reviewed with great interest the letters from Dr. Rickards and Dr. Arevalo and associates with regard to our article. These letters certainly indicate the wide interest in any potential new treatments for Tourette's disorder.

A placebo gum with a taste similar to that of the nicotine gum was not available to us during these studies. However, such a gum was subsequently made available, and we have recently conducted a study that compared nicotine gum to placebo gum. This overcomes the problems with blinding and also controls for the independent effects on facial and vocal tics through general relaxation while chewing. These data are now being considered for publication. We were aware of the interesting paper by Brill, and we have had similar clinical experiences. However, although gum chewing might be independently relaxing, the subjects chewed gum for only 30 minutes during the 2-hour period. The effects on tics (both facial and body) were apparent during the two subsequent 30-minute periods when no gum was being chewed. In our analysis of results, different tics were observed from videotapes of each patient, with independent assessments made of each type of tic. No differential effect was noted in the responses of facial versus other body tics.

Interpatient variation occurred, but in the study design each patient served as his or her own control. Intrapatient variation during the measurement period was minimized by quiet conversation, avoiding stress, with an interviewer who was familiar to the patient. Our earlier attempts at having children read silently or perform routine tasks over a 2-hour period had variable success, in part because of comorbid attention deficit hyperactivity disorder symptoms in subjects with Tourette's disorder, which we described earlier (1). The statistical analyses (one-within repeated measures analysis of variance) were appropriate for this study, and since the effect noted was large, significant differences were obtained with 10 subjects.

We observed some diminution in tic frequency and severity 3 minutes after subjects began chewing gum, and the effect was robustly present at 10 minutes. Benowitz et al. (2) have indicated that there was a sharp increase in average blood nicotine concentration while subjects chewed 2-mg nicotine gum for 20 minutes. These data imply that blood concentrations of nicotine achieve a physiologically relevant level within a time frame consistent with our observations. Furthermore, these authors reported a subsequent fall of approximately 50% over the next 40 minutes. This finding also correlates with our observed increases in tic frequency and severity over the 60 minutes following gum chewing.

We agree with the concern of Dr. Arevalo and associates about the toxicity and addictive potential of nicotine. We had listed such potential harmful side effects more fully in an earlier version of the paper and stated in the final condensed version that we do not recommend the uncritical and excessive use of nicotine.

We are pleased that both letters note that our data are interesting and suggest further research. A number of the suggestions have already been incorporated into our latest studies. We thank the writers for their comments and suggestions and look forward to further studies in this interesting area.

### Seven-Day Mood Cycles

SIR: In their study of mood variance in depression, Donald P. Hall, Jr., M.D., and colleagues (1) demonstrated an ultradian mood rhythm in both depressed and nondepressed subjects, with the former subjects showing ultradian cycles of greater amplitude than did the latter. The authors concluded that "repeated assessments of mood at different times of the day may be necessary to obtain an accurate impression of a patient's mood state." Over the past several years, my research (assisted by L. Crosby, J. Trynan, and M. Palmerino) has shown analogous findings in the weekly mood cycles of certain predisposed individuals. Such "circaseptal" rhythms have been suspected in several physiologic parameters, but have come to light only recently (unpublished manuscript by F. Halberg, October 1984).

In a survey completed by 111 individuals, we assessed the presence and severity of Sunday-Monday dysphoria, often termed the "Monday blues." Thirty-one of the respondents had previously answered a query seeking individuals suffering from the Monday blues. Eighty other individuals were selected at random from the Boston-area telephone directory. On the basis of the frequency of Monday blues indicated by the respondents (varying from every week to once every couple of months), we defined a high-frequency blues group. In a one-way analysis of variance design, we found that this group was much more likely to experience their weekly dysphoria as qualitatively different from symptoms experienced on other days of the week than were the low-frequency sufferers ($F=10.05$, $df=3, 91$, $p<0.0001$). The high-frequency group was also more likely to say that their weekly dysphoria affected their jobs or personal lives ($F=2.65$, $df=3, 91$, $p<0.05$). Other research (Pies, unpublished data) suggests that a high frequency of circaseptal dysphoria is correlated with a past history of depression or other emotional problems. The work of Dr. Hall and associates and the findings I have reported suggest that both ultradian and circaseptal rhythms should be considered when evaluating a patient's mood state.

### Dr. Hall Replies

SIR: Dr. Pies offers an interesting observation regarding 7-day mood cycles. However, it is not clear from his letter whether he is suggesting that these 7-day cycles represent an endogenously controlled rhythm or a response to cycles of environmental stimuli. It is possible that these "circaseptal" cycles represent responses which are predominantly affected by environmental variables. Ultradian mood cycles, however, do not appear to be correlated with repeating environmental stimuli and probably reflect underlying physiological cycles. The greater amplitude of ultradian rhythms that we observed in depressed persons may represent a dysregulation of neurotransmitter output, leading to a more variable, high-amplitude fluctuation of intradaily mood. It has been suggested that similar phenomena are related to bipolar disorder (1) specifically and affective disorders (2) in general.

With the data presented by Dr. Pies, we can not be certain what factors contribute to the 7-day cycles. However, a history of Monday blues may indicate a susceptibility to depression, and we concur that this may be a useful symptom to consider in the evaluation of depression.

### Magnetic Resonance Imaging in the Diagnosis of Dementia

SIR: The report by Peter V. Rabins, M.D., and associates (1) was cited by the authors as the first of its kind concerning cortical magnetic resonance imaging (MRI) changes in elderly depressed patients. This line of investigation is laudable and integral to the elucidation and characterization of the neuroanatomic correlates of clinical phenomena seen daily by practicing clinicians.

However, in the Results section, the authors stated, "There were no differences between the depressed patients and the patients with Alzheimer's disease on any measure" (of the MRI). Furthermore, no stratification of patients was done according to Mini-Mental State examination scores to separate depressed persons with accompanying cognitive decrement and those without (i.e., the "pseudodemented"). Therefore, except for the conclusion that individuals with illness (in this case, the depressed elderly and those with Alzheimer's disease) differ similarly in their MRI scans from control subjects, I am curious about how, on the basis of the authors' findings, MRI would assist in the differential diagnosis of the clinically demented (i.e., individuals with Alzheimer's disease versus the pseudodemented depressed elderly).

The authors' topic is most exciting, and I share their tacit assumption that these questions may be more readily answered with newer and more advanced cortical imaging techniques.

### Dr. Rabins and Associates Reply

SIR: Dr. Dentino raises a question about the diagnostic implications of the imaging abnormalities we reported in elderly depressed subjects. To our knowledge, no imaging technique has yet demonstrated adequate sensitivity and specificity for use in making a diagnosis of any psychiatric disorder. Therefore, the clinical assessment remains the gold standard, with imaging findings as one of the factors to be considered. Dr. Dentino also raises questions about imaging distinctions between individuals with the dementia syndrome of depression and cognitively normal depressed persons. We have addressed this in studies using CT head scans (1, 2) and found that patients with primary major depression and Mini-Mental State examination scores below 24 have lower CT attenuation numbers than patients with major depression who have Mini-Mental State scores above 24.

## Proposed Model for Self-Injurious Behavior

SIR: The excellent review of self-injurious behavior by Ronald M. Winchel, M.D., and Michael Stanley, Ph.D. (1) makes clear that we have no unifying theory or model for self-injurious behavior. Rather, it is approached from a variety of perspectives, including the affected population, putative psychodynamic issues, and possible neurotransmitter abnormalities. I wish to propose a heuristic model in which two broad types of self-injurious behavior are distinguished.

In type I, onset is usually during early adulthood, and the self-injurious behavior entails one or more isolated but serious acts. The lesion is frequently "ablative" (e.g., autocastration) and associated with either a circumscribed somatic delusion or a severe identity disturbance. Such self-injurious behavior is generally seen in schizophrenic or other psychotic patients. I hypothesize that a primary excess of dopaminergic function is the principal neurotransmitter abnormality in type I and that both $D_2$ and $D_1$ receptors are implicated (possibly with $D_2$ dysfunction predominant). Dopamine agonists would tend to worsen this type of self-injurious behavior, which may respond to conventional antipsychotics.

In contrast, type II has its usual onset in childhood or adolescence, in association with a variety of neurodevelopmental and character disorders, for example, Tourette's disorder, autism, attention deficit hyperactivity disorder, and Lesch-Nyhan syndrome. Some individuals with borderline personality disorder and "obsessive spectrum" disorders also fit the type II pattern. Self-injury is usually chronic, repetitive, and "irritative" rather than ablative. The lesion is usually not "symbolic" (as in autocastration) but is associated with a more general relief of tension, anxiety, or anger. Clear secondary gain is sometimes involved, as when a patient with borderline personality disorder engages in low-lethality wrist cutting to delay discharge from the hospital. Although endogenous opiate dysregulation may be involved, I postulate two principal neurotransmitter abnormalities in type II self-injurious behavior: a primary dopamine deficiency which, over time, may lead to secondary dopamine receptor hypersensitivity and/or a dysregulation of serotonergic systems (1–4). $D_1$ receptors—possibly in nigrostriatal more than in mesolimbic tracts—are involved preferentially. Treatment with either dopamine agonists or antagonists may be helpful, depending on the point of "transition" between primary dopamine deficiency and dopamine receptor hypersensitivity. Serotonergic agents (e.g., fluoxetine, clomipramine) are also helpful in this type, particularly in patients with "obsessive spectrum" symptoms such as trichotillomania (5).

I propose this dichotomy as a spur to the development of a unified theory of self-injurious behavior and not as the definitive statement on this complex condition.

*Boston, Mass.*

## Dr. Winchel and Dr. Stanley Reply

SIR: The possibility of dopaminergic and serotonergic dysfunction among individuals who self-mutilate—as we discussed in our review and is emphasized again by Dr. Pies—is a reasonable basis from which to pursue investigations of self-injurious behavior. We agree on the value of an approach that cuts across diagnostic categories and is based on characterization of specific common behaviors, i.e., a dimensional rather than a categorical view. The utility of this approach is exemplified by the finding that suicidal behavior is associated with altered serotonergic function. The evidence that disrupted serotonergic function is independent of primary diagnosis and is associated with suicidal behavior per se demonstrates that neurophysiologic markers may be associated with individual behaviors rather than with traditional syndromal categories.

A similar finding (that self-injurious behavior across diagnoses is associated with a consistent biological marker) would indeed set the stage for a "unified field" theory of such behavior. While Dr. Pies's ambition in suggesting the framework for constructing such a theory is admirable, we would argue that it is still too early to do so. Until self-injurious behavior is further characterized, patient groups are still distinguished more by the differences in their patterns of self-mutilation than they are by what is common. For example, Dr. Pies suggests that the type II behavior may be characterized as "repetitive," yet a patient with a character disorder might repeat self-injurious behavior several times in a year, whereas among the developmentally disabled, it may occur several times in an hour. Until we have a firmer basis for behavioral classification of self-mutilation, it will remain difficult to make meaningful comparisons of biochemical findings.

Attempts to impose order on the chaos of disparate findings in self-injurious behavior may have the benefit of guiding a developing research agenda regarding this behavior. However, the available data, in our view, do not yet support any general unifying theory.

## Serotonin and Effect Sizes of Antiobsessive Agents

SIR: Michael A. Jenike, M.D., and associates recently reported results on the use of pharmacologic agents that inhibit serotonin uptake in treating obsessive-compulsive disorder (1). They conducted meta-analyses to determine effect sizes by subtracting the endpoint mean from the baseline mean and dividing this by the standard deviation at baseline. They found that clomipramine was most effective in producing antiobsessive activity: effect size=1.53 (N=13). It was followed by fluoxetine, 1.34 (N=61); fluvoxamine, 1.09 (N=18); and sertraline, 0.80 (N=10). This outcome was consistent with their earlier finding that a controlled trial of clomipramine produced a greater effect size than an open trial of fluoxetine (2). These results led them to conclude that less selectivity in inhibiting serotonin uptake may be associated with a greater effect size.

We decided to do a similar analysis of our recently reported data on subjects who had received buspirone or clomipramine (3). We conducted a meta-analysis of these two groups of patients with obsessive-compulsive disorder (each N=9), using the same formula to compute effect size. Obsessive-compulsive symptoms were assessed with the Yale-Brown Obsessive-Compulsive Scale in all of the studies, and the effect sizes were based on this instrument, as in the work of Dr. Jenike and colleagues. The effect size for clomipramine was 1.50, similar to that reported by those authors. Also of interest, however, was our finding that the effect size for buspirone was 1.42, higher than that reported by Dr. Jenike and associates for fluoxetine, fluvoxamine, and sertraline. This is particularly interesting in light of a report by Dr. Jenike and Dr. Baer (4) that buspirone was ineffective in an open trial in patients with obsessive-compulsive disorder.

Possible interpretations of this result must be tempered by the fact that the numbers were small in both buspirone studies (N=9 in ours and N=10 in Jenike and Baer's) and by the fact that effect size may be influenced by the baseline level of symptoms as well as the standard deviations within the sample. It is also hard to equate the relative potency of the serotonin activity of buspirone with that of the agents that Dr. Jenike and associates reported on (clomipramine, fluoxetine, fluvoxamine, and sertraline), because unlike these agents, buspirone is a partial serotonin$_{1A}$ agonist and not a serotonin uptake inhibitor.

Recently, Hewlett et al. (5) reported that clonazepam had shown some efficacy in treating obsessive-compulsive disorder. Clonazepam, while it also affects serotonergic transmission, does not do so by uptake inhibition (5). Thus, this preliminary finding would seem to support the notion that other aspects of the serotonin system besides uptake inhibition might be involved in antiobsessional efficacy (1) and warrants further exploration.

## A Serotonergic Component in Splitting?

SIR: The conclusion of John G. Gunderson, M.D., and Katharine A. Phillips, M.D. (1) that the borderline syndrome is linked with serotonergically mediated impulsiveness may be a testable conceptual bridge between the psychoanalytic and biological models of severe pathology. One of the consequences of the defense of splitting which is found in borderline and other patients is an impulsiveness that derives from this defensive failure to invest people with human (i.e., whole object) qualities that can be empathized with. Instead, they are only experienced as inanimate (i.e., part objects) to be controlled and collected. This trance-like reduction of others and one's self and body into a "thing" status that is without memory limits one's relatedness to them to impulsive and addictive monotony and reduces self-empathy into compulsive food binging and/or self-mutilation. Such self-abusive enactments derive from this impersonal, split sense of self that only recognizes one's body as a foreign entity, similar to its being one's own imaginary companion.

The action and somatic impulsiveness that the defense of splitting leads to is the very same symptom that one regularly reads is responsive to fluoxetine in bulimia, kleptomania, trichotillomania, etc. It is the underlying frenzy of the impulsiveness, independent of its content, that is reduced by the new antidepressants. This may be due to their ability to correct the underlying serotonergic deficiency that contributes to the defense of splitting and its manifestation in various forms of addictive impulsiveness.

## Response of Schizophrenic Patients to Benzodiazepines

SIR: The extensive review article by Owen M. Wolkowitz, M.D., and David Pickar, M.D. (1) on the use of benzodiazepines in the treatment of schizophrenia raised a number of possibilities to explain the variability and prediction of response. One additional factor that might be considered is the possibility of alcohol abuse and its subsequent withdrawal symptoms. Recent studies (2) indicate that schizophrenic patients have a lifetime prevalence of alcohol dependence/abuse of 47%. Patients with comorbid alcohol use and schizophrenia would experience more dysfunction and more frequent hospitalization than schizophrenic patients without alcohol (or other substance) abuse. This would then bias any acute treatment setting toward a higher percentage of alcohol-abusing/dependent patients with schizophrenia, whose symptoms would be improved when the subsequent withdrawal or cravings were treated with benzodiazepines. This would result in lessening of agitation, restlessness, tension, hostility, irritability, and perhaps also the delusions and hallucinations associated with an overstimulated state. In addition, those whose withdrawal symptoms were thus cleared might then show a lessening of effects over the following weeks as the withdrawal symptoms diminished.

It would be most interesting to see whether treatment based on the separation of alcohol-using schizophrenic patients from abstinent ones resulted in clarification of the noted variability in response and would provide a good predictor of response as well.

GEORGE K. DREHER, M.D.
*Portland, Me.*

## Dr. Wolkowitz and Dr. Pickar Reply

SIR: We thank Dr. Dreher for his thoughtful comments on our review article. He has highlighted one of the most perplexing issues in the evaluation of the double-blind study literature on benzodiazepine efficacy in schizophrenia, namely, the variability and prediction of response. We agree that patients who have recently engaged in alcohol or other sedative/hypnotic abuse or who present during drug withdrawal may benefit from benzodiazepine treatment. Such benefit, as Dr. Dreher points out, would be nonspecific and would be due primarily to amelioration of withdrawal symptoms.

While such circumstances occur with some frequency in clinical settings, the double-blind research studies we reviewed generally carefully screened out patients with significant recent alcohol abuse as well as patients in the midst of alcohol or sedative/hypnotic withdrawal. Thus, we believe that such an explanation is unlikely to account for the variability in response seen in these studies. Indeed, we have been struck, in our own studies, by the lack of reliable clinical predictors of response.

Since our review article was written, we have studied an additional 23 patients with schizophrenia (screened to rule out substance abuse for at least 1 year) for whom either placebo or alprazolam was added to stable neuroleptic regimens. We have continued to observe both significant antipsychotic effects of alprazolam and considerable interindividual variability, with 42% of individual patients showing decreases in psychotic symptoms greater than the mean decrease (+2 SD) seen in the placebo group.

We have previously suggested that schizophrenia is a heterogeneous disorder and have suggested several strategies for interpreting ambiguous or inconsistent data obtained in pharmacologic trials in this population (1). We hope that by delineating individual characteristics which underlie treatment responsivity, we may be able to identify homogeneous (and possibly pathophysiologically distinct) subgroups of patients.

## Olfactory Hallucination After Intravenous Caffeine

SIR: The article "Caffeine Augmentation of ECT" by C. Edward Coffey, M.D., and associates (1) prompts us to report a case in which the intravenous administration of caffeine seemed to precipitate an aura-like olfactory hallucination.

Ms. A was a 53-year-old woman with a history of psychotic depression, a seizure disorder, and also the possibility of an undiagnosed degenerative brain disorder. She had had several generalized seizures within the last several years but no complex partial seizures. Neurologic evaluation included a normal EEG, a CT scan showing a lacunar infarct in the left external capsule, and a normal lumbar puncture. She had been treated with carbamazepine for her neurologic and psychiatric illness. When this medication was withdrawn, she had a series of generalized convulsions within hours. She had never described any aura prior to her seizures.

Since Ms. A's psychiatric illness was refractory to medications, ECT was initiated. Because of concern about precipitating status epilepticus if her carbamazepine were withdrawn completely, she was treated while on a regimen of a lower dose of carbamazepine. Her seizure length was short during ECT (<15 seconds) despite the use of the highest setting on the ECT machine. Accordingly, by the 11th treatment she was given 250 mg of intravenous caffeine sodium benzoate 5 minutes before ECT. This had little effect and the dose was subsequently increased to 500 mg before treatment 13. This had the desired effect of prolonging her seizures to 40 seconds. It is interesting that at the 500-mg dose, 30 seconds after the intravenous injection of the medication, she stated, "I smell something bad." When asked to describe this further, she was unable to do so. The sensation seemed to persist for only several seconds. At the next three treatments, she received 500 mg of caffeine and had exactly the same reaction. After several seconds, she said, "Oh, I smell something funny. Ooh! It's bad." She was clearly distressed by this sensation. When her seizure length again decreased, the dose of caffeine was increased to 750 mg and subsequently to 1000 mg; however, at the highest dose, she did not have the olfactory hallucination.

We believe that this clinical phenomenon represents some effect of caffeine on the medial temporal lobe. Although this patient did not have a seizure aura during her spontaneous seizures, we believe that her smelling an unpleasant odor is analogous to what epileptic patients experience during an "uncinate fit," which is thought to reflect stimulation of the primary olfactory cortex in the medial temporal lobe. This would be in keeping with work by Nakajima et al. (2) and others showing that caffeine induces seizures in rats and may preferentially activate various brain regions, including the medial temporal lobe and olfactory tubercle. Since intravenous caffeine is given to a large number of patients to increase seizure length in ECT (1), it would be interesting to discover whether others experience activation of temporal lobe structures. It is possible that our patient's preexisting epilepsy made her vulnerable to such stimulation and that most patients would not respond this way. Indeed, we have not seen this phenomenon in any of the other patients to whom we have administered caffeine.

## Conditions Not Attributable to a Mental Disorder

SIR: John M. de Figueiredo, M.D., Sc.D., and associates, in their study on conditions not attributable to a mental disorder (1), found that persons with family problems but without mental disorders constituted about 20% of all individuals (N=382) admitted to an outpatient psychiatric clinic during a 2-year period. The authors suggested that more research was needed on the patterns of use of psychiatric services by individuals with *DSM-III* V code conditions.

I have recently concluded a review of the persons attending our public psychiatric service with all *DSM-III-R* V code conditions and without mental disorders. Using *DSM-III-R* criteria, I reviewed records of all new patients who had attended our service from January to December 1990. I found 490 new patients; only 45 (9.18%) had unequivocal *DSM-III-R* V code conditions without mental disorders, of which 25 (5.10% of total cases) were family problems. Twenty-seven (60%) of these 45 patients had been seen repeatedly by psychiatrists (the mean number of visits was 8.68 during 1 year); 20 patients had been treated with psychotropic drugs (according to my view, inappropriately) and supporting psychotherapy; and two had been referred to a psychologist for cognitive psychotherapy. Reviewing case notes of the last 5 years, I found that attendance for family or social problems had increased gradually (from about 6% in 1986 to 9.18% in 1990). The proportion of patients with *DSM-III-R* V code conditions was similar to that observed in other Italian services (presentation by R. Chiecchio et al. at a conference in Naples, Italy, 1989).

Unlike Dr. de Figueiredo and associates, who found that patients without mental disorders who had family problems were mostly referred by their families, I found that only 26% were referred by their own families, 15% were self-referred, and over 37% were referred by their family doctors or by other physicians. To me this suggests that nonpsychiatric physicians in our region do not have a clear idea of the function of a mental health service. Patients with *DSM-III-R* V code conditions without mental disorders are clearly a heavy burden for psychiatric services, consuming time that could be used more appropriately for more severe disorders; in my study they represent almost 10% of patients seen at least once in 1 year.

## Environmental Factors in Psychiatric Disorders

SIR: The article "Genetics and Psychiatry: An Unheralded Window on the Environment" by David Reiss, M.D., and associates (1) provided an important balance of perspective to our understanding of mental disorders. However, it also reflected a somewhat pessimistic view of the contributions of genetics to psychiatry. This has been eloquently commented on by Miron Baron in an editorial in *Biological Psychiatry* (2).

We would like to point out an important potential problem raised by the review by Dr. Reiss and colleagues. Although juxtaposing "genetic" and "environmental" perspectives may be useful for heuristic and research purposes, polarizing the two can appear to create "debates" that are confusing to policy makers and ultimately undercut support for research on mental illness. As Baron noted, "Coexistence and cross-fertilization might be the optimal modus operandi for these two views of psychiatry" (2).

There may be another basis for misunderstanding here. "Genetic" is not a synonym for "biological," nor is the environment equivalent to psychosocial factors. As we made clear in our own article (3), a wide array of psychosocial considerations must be taken into account when considering the potential effects of genetics on psychiatric disorders. While Dr. Reiss and associates acknowledged that biological factors play a part in the environment, these were not given substantial attention. Ultimately, we may find that the neurodevelopmental "environmental" processes at work in utero and in early childhood are of the utmost relevance to psychiatric disorders. This possibility underscores the need for broader-based, integrative research at all levels to understand better the etiology and treatment of these profound and devastating conditions.

## Involuntary Treatment

SIR: I wish to take issue with the conclusions drawn by Julie Magno Zito, Ph.D., and associates in their study of drug treatment refusal (1). As a frequent independent evaluator of and witness for patients who have been referred for adjudication to obtain orders for involuntary treatment, my experience has led me to quite different conclusions.

The high rate of withdrawn applications ("nearly one-third") for court review of proposed involuntary treatment reported by the authors is certainly confirmed by my own experience. Their conclusion that "the court-driven system . . . is used . . . almost exclusively for cases in which the legal outcome is clear" is contradicted by this evidence. I have found that the most common cause of withdrawal of applications for involuntary treatment has been one also noted by the authors, a lack of belief by the applicant that a "satisfactory decision" (an order for involuntary medication) will result. The application can be used as a coercive manipulation to prod patients into accepting treatment but is withdrawn if challenged, to avoid the negative court decision. Thus, in fully one-third of cases, the outcome may not be a foregone conclusion, and in an additional 8%–9% of cases, the authors noted that applications were denied by the court. When nearly one-half of applications do not result in orders for involuntary treatment, the legal outcome is not at all clear.

Dr. Zito and associates pointed out that the delays in scheduling court hearings (30 days or more) may represent a violation of patients' right to due process, but they then drew the peculiar conclusion that as a result of this, patients should be deprived even further of due process by denying them the right to a court hearing at all! Similarly, their arguments that the inefficiency and costliness of court hearings should result in their discontinuation is discriminatory. The need for sometimes time-consuming court proceedings is not restricted to the psychiatric population, yet no one suggests that other citizens be denied the opportunity for judicial resolution of disagreements which are generally less significant than deprivation of personal liberty. The issue of unnecessary delays in the court system must be addressed in this as well as in other spheres, but it cannot be solved by substituting a system that provides for abandonment of such proceedings and safeguards.

The central issue is that the deprivation of personal liberty either by involuntary hospitalization or by involuntary treatment is a major occurrence. All persons who are faced with the temporary or permanent loss of these most basic rights of citizenship should be entitled to a hearing before an impartial judge, not a committee of colleagues of those seeking to deprive them of these liberties. We know that circumstances do exist when such drastic action is necessary and we can provide our expert testimony to the court, but it is not our role as physicians to make judgments affecting basic civil rights.

*Cranston, R.I.*

## Dr. Zito and Associates Reply

SIR: We appreciate Dr. Greer's interest in patients' right to refuse treatment. It appears that his experience in Rhode Island is different from that in New York. Anecdotal reports of withdrawn applications, in our experience, have been related to the agreement by patients to take medication and not to anticipation by the treatment team of a judgment against involuntary treatment. Our view is consistent with that of Dr. Lisa Callahan, which we cited in an earlier article (1). In her evaluation of treatment refusal by Ohio forensic patients, she reported that among the 36% of applications that were withdrawn, many involved patients who had decided to take medication because they were pessimistic about the outcome of court review. Overall, our experience does not support the inference of Dr. Greer's statement that "nearly one-half of applications do not result in orders for involuntary treatment," because the one-third of applications that are withdrawn mainly represent agreement by patients to be medicated.

The second point raised in the letter indicates a misreading of our basic position. We fully advocate access to court review of drug refusal for individuals (whether treatment team or patients) who fail to be satisfied by clinical review.

## Involuntary Interventions: Does the Benefit Exceed the Cost?

SIR: I was pleased to see two provocative articles in the April 1991 issue that began to evaluate critically the costs and benefits of involuntary interventions with patients.

Fred S. Berlin, M.D., Ph.D., and colleagues (1) called into question the mandatory reporting of suspected sexual abuse of children. In their sexual disorders clinic, this policy has ended the flow of such information from adult patients to their clinicians and has diminished the number of adult patients seeking voluntary treatment. The net result may be that children are actually less protected by a well-intentioned policy which invades and strains the doctor-patient relationship. The study was severely limited because it only looked at a sexual disorders clinic, but it was provocative nonetheless.

Francine Cournos, M.D., and colleagues (2) examined the long-term outcome of involuntary antipsychotic medication among state hospital patients. Their data demonstrate that the outcome for patients who are involuntarily medicated by court order is essentially the same as for those voluntarily taking medication. The authors concluded that these results argue against the substantial effectiveness of involuntary medication. One could equally well argue that outcomes similar to those of voluntarily medicated patients support the utility of this intervention. However, this comparison is not the vital one. What we as clinicians would really like to know is whether the involuntarily medicated do better than medication refusers who are not coerced. Other than medication given involuntarily to protect patients and others from acute danger, which is clearly clinically mandatory, are we accomplishing anything by medicating patients against their will? Is this violation of individual rights and perturbation of the doctor-patient relationship—so costly in professional time and energy as well—worth it? Unfortunately, Dr. Cournos and associates' study, unlike that of Dr. Berlin and colleagues, is a tease. I look forward to publication of a set of data that give me some useful insight into this critical issue.

CHARLES E. SCHWARTZ, M.D.
*Bronx, N.Y.*

## Dr. Berlin and Associates Reply

SIR: We agree with Dr. Schwartz that our data support the conclusion that mandatory reporting of suspected child sexual abuse may sometimes result in children being less well, rather than better, protected. We also agree that our data documented a decreased flow of important clinical information from patients to physicians—information that possibly could have led to early preventive intervention.

Others apparently share our concerns. Some clinical researchers operate under a federal Certificate of Confidentiality. This certificate supersedes state mandatory reporting statutes. It is used because of the recognition that accurate and relevant data cannot be obtained unless patients feel free to communicate openly and honestly.

In a recent survey of 1,196 mandated reporters in 15 states, almost 40% of those polled admitted that they sometimes failed to report suspected child abuse or neglect (1, 2). Those surveyed included general and family practitioners, pediatricians, psychiatrists, clinical psychologists, social workers, school principals, and heads of child care centers. Finkelhor and Zellman (3) documented that much of the noncompliance with reporting requirements was the result of "reasoned decisions by well trained and committed child abuse professionals." According to these researchers, otherwise compliant reporters knowingly and purposely violated the law in cases where they believed that a report would compromise a given child's best interests. We appreciate the possible motives but disagree with this practice. It would be better to try to have the relevant laws changed.

We believe that important legislative decisions which affect the physician-patient relationship should be based on objective evidence regarding what is best for patients and/or society rather than on what is politically popular or "politically correct." Our article attempted to present objective data in the hope that this would be helpful.

We believe that the psychiatric profession itself, as well as legislators, should strive for professional objectivity. The diagnostic category of "paraphilic coercive disorder" was omitted from *DSM-III-R* in large part because of political pressure from feminist groups who believed that the existence of a psychiatric disorder which might predispose some men to rape was troublesome and unacceptable. The decision to exclude that diagnosis was made by the Board of Trustees of APA in spite of a consensus by members of the subcommittee on the paraphilias that there were sufficient scientific data to support its inclusion. Paraphilic coercive disorder is a psychiatric condition in which afflicted individuals recurrently experience intense eroticized fantasies and urges about coercing others into sexual activity.

Dr. Schwartz's letter addresses the issue of involuntarily medicating psychiatric patients. We again agree that relevant evidence needs to come from objective studies—in this case, from studies showing that involuntarily medicated patients do better than medication refusers. We are not convinced, however, that involuntary administration of medication involves the same sort of potential conflict of interest between patient and physician as does mandatory reporting. Understandably, mandatory reporting statutes are not based on a concern about what is best for the reported patient. On the other hand, the purpose of involuntary medication is often to restore mental functions, such as impaired reasoning, in the belief that a given patient, once restored to a rational state, will be better off and perhaps even appreciative. Safeguards against abuse of involuntarily administered medications are, of course, crucial.

## Dr. Cournos and Associates Reply

SIR: We appreciate Dr. Schwartz's interest in our study on the outcome of involuntary medication and his sensitivity as a clinician. His letter expresses important concerns about how involuntary medication affects the doctor-patient relationship.

Psychiatrists are undoubtedly reluctant to strain the doctor-patient relationship by using coercion to get patients to take medication. This probably explains why involuntary medication appeared to be a last resort in the settings we studied and was formally petitioned for only 0.37% of patients in New York City's adult state hospitals during the study period. As part of the involuntary treatment decision-making process, the psychiatrist is required to explain available treatments, including their risks and benefits, and assess the patient's capacity to reach a treatment decision (1). In this process, it is likely that the patient and the psychiatrist will achieve a better understanding of each other and that patients who are less ill can either be persuaded to accept medication or be discharged without it (2). The most desirable long-term outcome is, of course, that the patient will continue appropriate treatment without coercion (3).

Dr. Schwartz would like to know whether, among nondangerous patients who refuse medication, those who are involuntarily medicated do better than medication refusers who are not coerced. This question is very difficult to study. Only six of the 51 involuntarily medicated patients in our sample did not present a significant danger to themselves or others. In practice, dangerousness is probably the principal criterion used by clinicians for deciding to pursue formal involuntary medication. For obvious ethical reasons, it is not possible to use random assignment to decide which cases to pursue.

Nevertheless, we feel that our study answered some of Dr. Schwartz's questions about the substantial effectiveness of involuntary medication. Involuntary medication appeared to be an essential short-term management strategy for most of our subjects. Treating psychiatrists reported improvement of symptoms in a majority of involuntarily medicated patients. Almost all patients in our study were being treated under duress, since, whether they took medication voluntarily or by coercion, 90% were in the hospital on an involuntary status. Both groups demonstrated long-term limitations in efficacy of and compliance with medication. We feel that our article presented a useful insight into these long-term limitations, and we hope it will contribute to the development of more informed and effective approaches to treatment refusal.

## Outcome of Schizophrenia

SIR: Although it was primarily concerned with the course of schizophrenia, the recent excellent study by Joanne Marengo, Ph.D., and associates (1) presented some unemphasized features of interest. The authors' data contradict Kraepelin's view that schizophrenia inevitably has a chronic, deteriorating course and, in fact, actually support an upbeat view of the course and outcome of the schizophrenias.

The authors' "glass-half-empty" view of the outcome of schizophrenia was expressed by the statement that "approximately one-fifth of the group showed recovered or mild outcomes, one-fifth showed very severe impairment, and the remaining three-fifths showed intermediate outcomes" (p. 609).

A "glass-half-full" view of the data can be generated when the recovered and mild outcome groups in the authors' study and those of Ciompi and of Bleuler are combined: 51.4%, 48.7%, and 51.9%, respectively (Dr. Marengo and associates' table 3). An equally upbeat interpretation has been made by Bleuler (2), Ciompi (3), and Harding et al. (4), who rightly emphasize the "wellness" potential inherent in schizophrenic disorders and urge therapists to eschew despair in treating these individuals. As Harding et al. put it, "Systems of treatment are not as yet able to cure, but they should be able to remove the obstacles that stand in the way of natural self-healing processes" (5, p. 483).

The widespread "glass-half-empty" view of schizophrenic disorders probably originates in the fact that the contact of mental health workers with schizophrenia has almost exclusively involved the 40%–50% of patients with schizophrenia who do poorly (i.e., the moderately severe and very severe outcome groups in the studies by Dr. Marengo and associates, Ciompi, and Bleuler). The fact that certain schizophrenic subgroups, presently not recognizable a priori, have the potential for a good outcome has profound implications for research and treatment strategies. Objective definitions of these subtypes would facilitate their early recognition. Identification of "wellness" factors, not inherent in the nuclear schizophrenic process but profoundly influencing its course and outcome, is also obviously desirable.

*Sepulveda, Calif.*

## Dr. Marengo and Associates Reply

SIR: We thank Dr. Kopelowicz and Dr. Bidder for addressing some important issues relevant to this area of research. Actually, the intended phrase should have correctly read, "Approximately one-fifth of this group showed recovered outcomes, one-fifth showed very severe impairment, and the remaining three-fifths showed intermediate outcomes." This does not alter the issues that Dr. Kopelowicz and Dr. Bidder raise, issues with which we struggle as well.

Whether one wishes to combine recovered and mild outcomes in a conceptualization that promotes an upbeat view or one wishes to conceptualize mild outcome as lying within an intermediate range may be decided differently depending on the context of discussion or the meaning of such groupings for the interpreter. Our presentation of the criteria used for all outcome categories allows readers to grapple with such issues themselves.

Patients with a mild end state experience psychopathology and differ from patients experiencing recovery. To reiterate, a mild end state, as defined in Manfred Bleuler's 1978 study (1) (and therefore also in our and Ciompi's [2, 3] comparative investigations), is entered by patients who can maintain a sensible conversation, at least about topics that do not concern their delusional or hallucinatory experiences. Overt behavior is generally normal, and the illness is not immediately obvious if one becomes involved in conversations. These patients perform useful work. Bleuler noted that definite schizophrenic symptoms do exist in these patients, that they can live either outside the institution or on quiet wards, and that the group includes patients whose delusional or hallucinatory ideas lie near the surface, although deterioration of personality is not in evidence. Since we did not have any older adult patients in our patient group (a group that was, on average, 31 years old at the 10-year assessment point of our study), we did not use Bleuler's final inclusion criterion; that is, the mild outcome group may include "some aged eccentrics who have rejected life, who scarcely manifest any normal interests, are incapable of performing even simple mechanical tasks, or who pursue any sort of whimsical idea" (1, p. 191).

Regarding what Dr. Kopelowicz and Dr. Bidder feel is an underemphasis of the outcome results, we had hoped that our "course" approach would bring an additional perspective to the data that exist on outcome alone. Illness onset, the course of symptoms (i.e., episodic or chronic), and outcome were given equal weight in defining and discussing syndrome courses.

Finally, with regard to the significant issue of identifying subgroups of individuals with schizophrenia who may be targeted for specific research or treatment strategies, we too supported this goal in the Discussion section of our article. Along with other longitudinal investigators, we propose that information on onset and course as well as outcome may serve to improve the definition of such subgroups. As additional or longer-term studies accumulate, we hope to be in an even better position to consider the full range of possibilities for treatment and prognoses in schizophrenia.

### Borderline Patients' Perceptions of Their Parents

SIR: Hallie Zweig-Frank, Ph.D., and Joel Paris, M.D. (1) reported that patients with borderline personality disorder perceive their parents as having been less caring and more overprotective than do nonborderline patients. Although the authors appropriately included a number of cautions regarding extrapolation from their findings, they suggested that the results support the etiologic theory of Masterson and Rinsley (2).

The differences between borderline and nonborderline patients were statistically significant, but were they meaningful? The average difference in ratings between the two groups of patients was less than one-half of a standard deviation. Thus, the great majority of the borderline patients' ratings of parental care and protectiveness fell well within the comparison group's range and, apparently, the reported "normal" range as well. This small effect size cannot provide any substantial support for a developmental theory which suggests that parental interactions with the child, particularly between the ages of 18 and 36 months, are vital to the development of borderline personality disorder.

As Dr. Zweig-Frank and Dr. Paris noted, borderline personality disorder is likely to be of heterogeneous origin. For some individuals, parental behaviors, particularly extreme behaviors such as physical and sexual abuse, may be major contributing factors. For other individuals, the causation may be reversed. A child who is intrinsically difficult to comfort may correctly (or incorrectly) perceive less comfort. A child with attention problems or impulsive behavior may evoke more protective parental behavior. Finally, for some individuals, there will be no evidence of abuse, neglect, and overprotectiveness. Theories of borderline personality disorder must encompass this apparent etiologic heterogeneity.

We applaud the quantitative design used by Dr. Zweig-Frank and Dr. Paris but would emphasize that the available retrospective data about the family environment and early experiences of individuals with borderline personality disorder are not particularly consistent across studies and do not shed much light on the validity of various conflicting developmental theories of the etiology of the disorder. We might add even more emphatic cautions about the limitations of existing data regarding possible biological underpinnings for borderline personality disorder. It seems most likely that the disorder arises from complex interactions between biological predisposition and experience.

REX WILLIAM COWDRY, M.D.
KATHLEEN M. O'LEARY, M.S.W.
*Washington, D.C.*

### Dr. Paris and Dr. Zweig-Frank Reply

SIR: We appreciate the thoughtful letter from Dr. Cowdry and Ms. O'Leary, which also gives us the opportunity to clarify some points raised in our article. We agree that the etiology of borderline personality disorder is complex and that there is most likely a biological predisposition involved. We also agree that no single factor can account for the etiology of the disorder; we are, in fact, in the midst of a large-scale study of a number of risk factors for borderline personality disorder. We therefore look forward to contributing to a multidimensional framework, as proposed by Dr. Cowdry and Ms. O'Leary.

We did not claim that our findings were specific to borderline personality disorder, but only that they were more common in this group of patients than in comparison groups. As the letter correctly points out, there was important overlap in the scores of borderline and nonborderline patients. We wish to make clear that in quoting Masterson and Rinsley, we did not intend to support all of their ideas. Our point was that this was the first time that there was any empirical evidence, however partial or indirect, to support their position. In fact, our findings of combined neglect and overprotection are not consistent with Masterson and Rinsley's hypothesis of simple maternal overinvolvement. Moreover, our research does not suggest that such overinvolvement is limited to any particular developmental stage. Our instrument, the Parental Bonding Index, is designed to measure recollections of abnormal parenting over the first 36 years of life. Our borderline group reported that their parents interfered with their autonomy all through their childhoods.

We do not agree with Dr. Cowdry and Ms. O'Leary that findings across studies have been inconsistent. We feel that our hypothesis of biparental failure accounts for most of the evidence. However, we do not believe that childhood experiences alone can account for the psychopathology of borderline personality disorder.

### Change in Ideational Content as a Prodromal Symptom in Affective Disorders

SIR: "Prodromal Symptoms in Affective Disorders" by Giovanni A. Fava, M.D., and Robert Kellner, M.D., Ph.D. (1) is an important contribution. The concept itself is significant. The illustrative material clearly demonstrates that prodromal symptoms do occur with notable frequency.

For two decades—a generation—American psychiatry has been going through the laborious process of defining the area of our work. That enormous effort, which produced the *Di-*

*agnostic and Statistical Manuals,* has been remarkably successful, not only in this country but around the world. It is now time to go further, to explore more deeply into the nature of these now operationally well-defined entities we call disorders. Dr. Fava and Dr. Kellner did that. They opened a door to a developmental, longitudinal understanding of the disorders, which so far have been defined by cross-section.

There is one omission from the list of prodromal symptoms described. I could not find any reference to ideational content, i.e., to preoccupations, thoughts, and ideas. In my paper "Transitional and Pre-psychotic Symptoms in Depression" (2) I described cases in which depressions were preceded by spontaneous memories of traumatic situations of childhood, either as overt memories or as dreams, occurring several weeks before the onset of the depression. These experiences had a strikingly vivid sensory quality and felt "forced" on the patient. For example, one woman kept seeing the hallway of her father's house, in which his casket had stood, as she had seen it years before. She could not get it out of her consciousness. Another woman who had not had a depression for several years came into therapy because she had had a dream "of when we were children and lived behind the store. All the things I could not change."

Some of these experiences resemble "flashbacks" of the kind seen in marijuana smokers. They also resemble the induced hallucinatory experiences described by Penfield (3), elicited by electrical stimulation of the temporal lobe. This kind of "return of the repressed" is much more sudden than the gradual recovery of memories during psychoanalysis. These observations were made with long-term patients, for whom the onset, the course, the recovery, and the aftermath could be followed. I doubt that they would have been elicited by any statistically oriented paper test. My conclusion was that depression is a longitudinal process that goes through stages. Sensory illusions, repetitive dreams of death, and memories of childhood trauma occur at a time when a more advanced stage of depression threatens to develop.

As for mania, Loeb and Loeb (4) described cases in which an oncoming manic episode was heralded by a marked increase in conscious and unconscious sexual thoughts, feelings, and behavior before any observed deterioration in ego or superego functioning.

Thus, there is evidence that changes in ideational content should be included in the list of prodromal symptoms of affective disorders.

DANIEL W. BADAL, M.D.
*Cleveland, Ohio*

## Dr. Fava and Dr. Kellner Reply

Sɪʀ: We are grateful to Dr. Badal for his comments. In our review we did not deal with ideational content, preoccupations, thought, and ideas as prodromal symptoms. We limited ourselves to published empirical studies of prodromal symptoms, and in our search we had found no reference to such studies of these phenomena. We have observed in our clinical work with some patients that intrusive ideas and images, which Dr. Badal describes, preceded an episode of melancholia or an endogenous depression. We have also observed thoughts as well as behaviors that were uncharacteristic for the patient which preceded the onset of mania, as described by Loeb and Loeb. We agree with Dr. Badal that these phenomena are important, they should be included in a list of prodromal symptoms, and they should be a topic for further systematic research.

## Information Theory Perspective on the Mind-Body Problem

Sɪʀ: In his article on the mind-body problem, Aviel Goodman, M.D. (1) presented an interesting merger of biopsychosocial systems theory and mental-physical identity theory. Identity theory asserts that mental and physical events are identical but are experienced as different forms of knowledge, because the physical is intersubjectively confirmable, whereas the mental is only subjectively confirmable. I believe that this argument of identity theory is erroneous. There are substantial reasons for believing that something exists which is differentiable from the physical.

The physical (matter and energy) has measurable properties such as mass, volume, and frequency. Measurement has an objective nature, since it is a quantitative process and quantities are the same, within limits, to any observer in the same frame of reference. Transforming the physical changes it into something else.

In order to analyze the mental in a similar fashion, I agree with MacKay (2) that considering the problem from an information-processing point of view is most useful. The following arguments can then be made.

1. Information must also exist. Information can reproducibly generate activity, such as a computer magnetic tape directing a machine or the will directing the body. It is the information contained in an encoded message that controls activity, rather than a direct mechanical process.

2. Information exists in a form of the physical, but it is differentiable from the physical. a) Information is communicable, not measurable. The essence of information is the meaning contained in a physical representation. We can measure the letter "I" or the sound "I" but we cannot measure what it means. Representations become understood through a process of information exchange, i.e., communication. b) Information is transformable. It is essentially the same no matter what physical form it is in so long as the meaning is retained. "I" means myself whether it is spoken or written. c) Information is subjective and qualitative, not objective and quantitative. It is meaningless without an observer who understands it. Understanding is a subjective quality that depends upon and varies with the individual observer.

3. Since one aspect of mind is that it is the information in an information processor—the brain—the meaningful mind is differentiable from the physical brain. The mental is dominant over the physical in the sense that information can direct

activity. Causality is not violated, since information exists in a physical form.

In the information-processing view, then, mental events correspond directly with physical events in the brain, but they are not identical. The physical events are objectively measurable. The information related to those events exists in its own right but is only known subjectively unless it is communicated to others. A neurophysiologist can make an infinite variety of measurements but will not be able to associate those measurements with the thoughts that occurred when the measurements were made unless he or she asks what they were. This supports the psychotherapeutic method of asking patients what things mean to them, for that is the only way we will find out.

ANDREW J. HERITCH, M.D.
*Milwaukee, Wis.*

## Dr. Goodman Replies

SIR: In his letter Dr. Heritch presents an information theory perspective on the mind-body problem, which he contends is incompatible with mental-physical identity. I appreciate the value of the information theory and the insights it entails, and I see it as entirely compatible with mental-physical identity. Information theory represents a mode of knowing events and processes in the realm of mental concepts, much as theories that pertain to objective measurement represent a mode of knowing events and processes in the realm of physical concepts. It is precisely because these modes of knowing are different that mental-physical identity theory is so important, as a framework for understanding the relation between informational and objective knowledge.

Dr. Heritch's main point against mental-physical identity is that "something exists which is differentiable from the physical." Identity theory concurs that mental is differentiable from physical: they are different classes of concepts that are associated with different ways of experiencing and knowing. The identity specified by the theory is identity of reference or extension: the referent of every mental concept is identical with the referent of some physical concept. Identity theory does not state that mental and physical concepts are identical, and intensional identity is specifically excluded, as I discussed in my article (p. 556).

Perhaps Dr. Heritch's argument is asserting not merely that mental and physical concepts are differentiable but that there exist mental entities and events that are differentiable from physical entities and events. In that case, he would be arguing against mental-physical identity by advocating dualism. The philosophical and scientific arguments against dualism are many, and to reiterate them would exceed the scope of this communication. The following brief sample is reproduced from my article (p. 555).

> Perhaps the most decisive argument is that dualism fails to account adequately for the causal relationship between mind and brain, as first argued by Kant; how could a mind with no spatial existence or extension influence a physical brain extended in space? More recently, Fodor . . . wondered how a nonphysical mind can give rise to physical changes without violating the laws of conservation of mass, energy, and momentum. Furthermore, if a mental force that could influence physical entities and processes were postulated, it would then by definition also be a physical force, which would not be consistent with dualism.

Other than this question of differentiability, on which I may or may not agree with Dr. Heritch (depending on whether he is advocating dualism), the only other points with which I might take issue are those in the paragraph preceded by the numeral 3. I am willing to consider the hypothesis that the physical term which shares the referent of the mental term "human mind" is "human brain," although I believe that arguments could be made in favor of hypotheses of correspondence that relate other physical terms with "human mind"—for example, "human organism" or even transpersonal terms like "human society" (I touched upon this issue on p. 559 of my article). I would, however, dispute the locution that describes information as being "in" the brain, on grounds related both to mental-physical identity theory and to information theory. From the standpoint of identity theory, mental terms like "information processing" can be said to correspond with (have the same referent as) physical terms describing neurophysiological processes that occur in the brain; but to say that information itself is in the brain reflects a confusion of logical categories. And, according to (at least some versions of) information theory, information is not a thing but an aspect of the relationship between a potentially meaningful sign and an active interpreter (i.e., interpreting system). It is thus not located "in" either the sign or the interpreter but is a property of the system that they together comprise. I would also dispute the notion that "the mental is dominant over the physical," since 1) it presupposes dualism and 2) it would be questionable even if dualism were valid (for example, it does not seem to be consistent with the fact that psychoactive drugs, even those administered against one's will, have predictable mental effects). Finally, I am not sure how the statement "information exists in a physical form" could be meaningfully interpreted except in the context of mental-physical identity theory.

I thank Dr. Heritch for his interest and for stimulating my own interest in integrating mental-physical identity theory with information theory.

*St. Paul, Minn.*

## Comments on the Proposal to Eliminate the Organic Mental Disorders Category in *DSM-IV*

SIR: A recent letter to the Editor commented on a crucial development in diagnostic psychiatry. Robert L. Spitzer, M.D., and associates (1) supported the proposal to eliminate the category of organic metal disorders from *DSM-IV*, replacing the term "organic" with other terms such as "cognitive impairment disorders" and "secondary" syndromes. Organic mood disorders, for instance, would become secondary mood disorders. Z.J. Lipowski, M.D. (2) provided valid general arguments for retaining the rubric of organic mental disorders in *DSM-IV*. I would like to add some specific comments on depression and challenge the idea that the term "secondary" is more precise and appropriate, as Dr. Spitzer and associates suggested.

There is a considerable body of knowledge, reviewed in detail elsewhere (3, 4), suggesting the occurrence of "organic mood syndromes" or "symptomatic depressions" in which a specific organic factor, on the basis of brain pathology or neurotransmitter balance, is judged to be etiologically related to the mood disturbance, and the organic factor is part of an illness or is a drug (not just any illness or drug) for which there is evidence in the literature that there is resolution of the mood disorder upon specific treatment of the medical disease or discontinuation of the drug. Such diagnosis entails important clinical implications (e.g., often, poor response to antidepressants) that warrant separation from other mood disorders. The primary-secondary differentiation is mainly based on Robins and Guze's distinction (5) between primary depression (affective illness that is not part of another psychiatric or physical disorder) and secondary depression (a mood disorder chronologically superimposed on a nonaffective disturbance). Its reliance on chronology may be appropriate when depression is secondary to another psychiatric disorder, but it may be misleading in the medically ill, when depression may be one of the earliest manifestations of medical illness (3, 4).

For instance, 40% of patients with Cushing's syndrome reported a major depressive disorder either immediately before or at the onset of illness (6). Should those cases be classified as "primary depressions"? The likelihood of recovery after successful correction of hypercortisolism (3, 4) makes this categorization questionable, if not misleading. In Cushing's disease, depression and hypercortisolism may be two distinct yet ostensibly related manifestations of suprapituitary disease (6). Setting a primary-secondary hierarchy would be arbitrary and not in keeping with current understanding of the complex interaction of neurophysiological, biochemical, and behavioral factors in medical disease. The definition of organic mood disorder in *DSM-IV* can be improved—for instance, by setting the intensity threshold of a major depressive disorder and adding a tentative list of medical diseases and drugs known to cause it (4)—and should not be replaced by a term ("secondary") that is likely to generate confusion.

*Bologna, Italy*

## Dr. Spitzer and Dr. First Reply

SIR: We appreciate Dr. Fava's comments on our suggestion to remove the term "organic mental disorders" from *DSM-IV*. We are in complete agreement with Dr. Fava about the importance of distinguishing cases of mood disturbance that are judged to be etiologically related to a known physical illness or drug from cases without such a relationship. We recognize the potential confusion with our suggested term, "secondary mood disorder" to mood disturbances that are judged to be due to a physical illness. As Dr. Fava points out, this term was used by Robins and Guze to refer to mood disturbances that temporally followed a nonaffective illness. Our use of the proposed term does not depend on the temporal relationship but is entirely an etiological judgment, as it now is in *DSM-III-R* for "organic mood disorder." Although in most cases the mood disturbance of a secondary mood disorder would follow the appearance of the symptoms of the physical illness, Dr. Fava correctly notes that this is not always so.

As we have noted elsewhere (1), Robins and Guze's use of the term "secondary" was only a research strategy for maximizing homogeneity of research subjects in studies of affective disorders. We therefore expect that for researchers and in general clinical settings, there will be little confusion with our recommended use of the term.

## Update of Review of Guides for Patients

SIR: We appreciate the review by Brian L. Cook, D.O., of several of our guides for patients (1). Since we pride ourselves on the timeliness of our publications, we want readers to know that the guides are regularly revised. To update Dr. Cook's review, *Carbamazepine and Manic-Depression: A Guide* was revised in 1990, and *Obsessive Compulsive Disorder: A Guide* was revised in 1991 (in part to incorporate the availability of clomipramine).

We should also like to correct the prices that were listed in the review. The cost per booklet is $3.95 (which includes postage and handling), with reduced rates for orders of 10 or more.

## Prescription Writing

SIR: In his response to the presidential address (1), Lawrence Hartmann, M.D., the President-Elect of APA, offered his position on psychologists with the slogan "No medication without medical education." However, the horse left the barn a long time ago. Psychologists, social workers, pastoral counselors, drug therapists, etc. are already prescribing medication.

For over 10 years, I worked at community mental health centers and other government clinics. Social workers, psychologists, and nurses do the diagnosis and treatment. When they decide that a patient needs medication, they schedule the patient for the "medication clinic." At intervals—perhaps twice a week, once a week, or once a month—a psychiatrist is brought in to sign prescriptions for an unlimited number of patients. Instead of seeing patients individually in the traditional doctor-patient relationship, the psychiatrist frequently sits on a committee as a member of the "treatment team." The only resemblance to standard protocol as taught in medical schools is that the psychiatrist holds the pen.

I believe that psychologists and social workers should sign their own prescriptions, so the public will then be aware of whose cognitive efforts are responsible for a particular prescription. When this century opened, asylums were filled with cases of general paresis of the insane. A little effort should close the century the same way, with nonphysicians feeding antidepressants and antipsychotics to syphilitic patients.

REFERENCE

1. Hartmann L: Response to the presidential address: humane values and biopsychosocial integration. Am J Psychiatry 1991; 148:1130–1134

L.A. NELSON, M.D.
*Huntsville, Tex.*

### Dr. Hartmann Replies

SIR: Horses have been leaving barns in various ways for centuries, but many of them have returned. Even I, mostly a city dweller, have ridden a good many horses back into barns. Is Dr. Nelson suggesting that any horse that leaves a barn should be given up for lost? Is that a Texan custom? Is that a local interpretation of (if you will forgive a play on words) a hippocratic oath?

I do not fully understand Dr. Nelson's letter, but my "No medication without medical education" seems to me a minimal sensible slogan to protect patients. I hope and assume he is being ironic when he suggests that in the 1990s social workers should medicate patients with syphilis.

Certainly, there are pressures on many of us in hospitals, health maintenance organizations, community mental health centers, and elsewhere to write prescriptions for patients we do not adequately know or have not even seen. But psychiatrists, all of us, have an ethical obligation to resist such pressures. Ethics and good patient care command us not to write prescriptions for patients we have not seen and/or do not adequately know. Courage may be needed—and tenacity, patience, and support from colleagues—and it is often difficult; but I do not think it takes a particularly unusual grasp of humane values and biopsychosocial integration to be aware of medical and psychiatric ethics and, as individuals and as a profession, to resist pressures against our ethics.

Some horses should sometimes be ridden back into barns.

# Depression and Parkinson's Disease: A Review

Jeffrey L. Cummings, M.D.

*Objective: The purpose of this review is to provide an update of the research regarding depression in Parkinson's disease and to synthesize the information into a neurobiological model relating the structural and biochemical changes in this disorder to the behavioral manifestations. Method: The author used a computer-based search of the literature, augmented by extensive bibliography-guided article reviews, to find information on depression and Parkinson's disease. Findings: Depression occurs in approximately 40% of patients with Parkinson's disease; depression in Parkinson's disease is distinguished from other depressive disorders by greater anxiety and less self-punitive ideation. Lower CSF levels of 5-hydroxyindoleacetic acid, a past history of depression, and greater functional disability are associated with a greater risk of depression in Parkinson's disease. Female gender, early age at onset of Parkinson's disease, and greater left brain involvement may also be risk factors. Approximately half of depressed patients with Parkinson's disease meet criteria for major depressive episodes; half have dysthymia. Depression is more common in Parkinson's disease with prominent bradykinesia and gait instability than in tremor-dominant syndromes. Depressed patients with Parkinson's disease have greater frontal lobe dysfunction and greater involvement of dopaminergic and noradrenergic systems than nondepressed patients with the disease. Mood changes in Parkinson's disease respond to treatment with conventional tricyclic antidepressants or ECT. Conclusions: Neurobiological investigations suggest that depression in Parkinson's disease may be mediated by dysfunction in mesocortical/prefrontal reward, motivational, and stress-response systems. Neuropsychological, metabolic, clinical, pharmacological, and anatomical studies support the involvement of frontal dopaminergic projections in patients with Parkinson's disease and depression.*

(Am J Psychiatry 1992; 149:443–454)

Dramatic strides have been made recently in understanding the pathophysiology and treatment of Parkinson's disease. In addition to the well-established success of dopaminergic therapy, administration of selegiline, a monoamine oxidase B (MAO-B) inhibitor, may intervene in the degenerative process (1), and transplantation of fetal tissue into the basal ganglia may permanently ameliorate the motor disability (2). Despite these advances, many aspects of Parkinson's disease remain poorly understood, particularly its behavioral manifestations. Depression is the most common neuropsychiatric disturbance of Parkinson's disease, but its frequency, characteristics, course, treatment responsiveness, and neurobiological substrates are at best only partially established. In this review, the literature regarding mood changes in Parkinson's disease is examined, the relationship of depression to the neuropathology and neurochemistry of Parkinson's disease is dis-

cussed, and a potential integrative psychobiological model is proposed.

## REVIEW METHOD

A computerized search of MEDLINE, the online computer database of the National Library of Medicine, was conducted to identify articles pertaining to depression in Parkinson's disease. A key-word search was made for depression and synonyms of depression, behavior and Parkinson's disease, and psychiatry and Parkinson's disease, as well as tricyclics and ECT in Parkinson's disease. Review articles and individual research articles were consulted and bibliography-guided searches were pursued to augment the computer-based canvas of the literature. Books summarizing symposia on Parkinson's disease were consulted to obtain additional information and to expand the bibliographic pool. The search was limited to articles published in English. Nearly all of the primary research articles specifically addressing depression in Parkinson's disease are referenced in this review.

## DEMOGRAPHIC FEATURES OF DEPRESSION IN PARKINSON'S DISEASE

### *Frequency*

Table 1 summarizes the rates of depression in Parkinson's disease reported in the principal studies addressing this issue (3–27). The mean frequency reported in the 26 studies was 40%; the range was 4%–70%. The lowest reported frequencies were found in studies that were done before standardized rating scales, scripted interviews, or operationalized diagnostic criteria were in general use. Moreover, the dominant theoretical construct in these studies was that depression was a reactive phenomenon; this assumption militated against counting mood changes among the manifestations of Parkinson's disease. The low rates of depression found in some of the early studies can be attributed to these methodological and conceptual contingencies. In the nine studies reported in 1987–1990, the rate of depression ranged from 25% to 70% (mean=43%). Discrepancies in the reported frequencies reflect the use of different definitions of depression, thresholds for identification of a mood disorder, and assessment strategies. None of these studies applied demographic methods with random or comprehensive sampling, and all were subject to patient selection biases. The consistency of the detection of depression across studies supports a relationship between depression and Parkinson's disease, but determination of the true prevalence awaits further study.

Another approach to investigating depression in Parkinson's disease is to administer standardized rating scales and compare the results with known standards for the scale or with simultaneously studied comparison subjects. The Beck Depression Inventory (28) is the instrument most widely used in the quantification of mood changes in Parkinson's disease. Table 2 lists the principal studies of Parkinson's disease in which Beck Depression Inventory scores were reported (14–16, 29–39). With the

**TABLE 2. Reported Beck Depression Inventory Scores of Patients With Parkinson's Disease and Comparison Subjects**

| Study | Year | Mean Score: Patients With Parkinson's Disease | Mean Score: Comparison Subjects | Description of Comparison Subjects |
|---|---|---|---|---|
| Mayeux et al. (14) | 1981 | 11.1 | 6.2 | Spouses |
| Gotham et al. (15) | 1986 | 14.1 | 14.3 | Arthritis patients |
| | | 14.1 | 6.4 | Normal elderly |
| Santamaria et al. (16) | 1986 | 11.9 | 7.0 | Spouses |
| Direnfeld et al. (29) | 1984 | 9.7 | 7.1 | Nonneurological patients |
| Stern et al. (30) | 1984 | 7.9 | 3.8 | Volunteers |
| Freedman and Oscar-Berman (31) | 1986 | 8.5 | 3.8 | Volunteers |
| Levin et al. (32) | 1988 | 11.6 | 6.1 | Spouses and elderly volunteers |
| Huber et al. (33) | 1989 | 8.1 | 4.7 | Spouses |
| Gibb and Lees (34) | 1988 | 13.1 | | |
| Spicer et al. (35) | 1988 | 12.3 | | |
| Huber et al. (36) | 1989 | 9.3 | 5.1 | Spouses |
| Beatty et al. (37) | 1989 | 9.8 | 4.0 | Community members |
| Ehmann et al. (38) | 1990 | 11.0 | 6.7 | Disabled |
| Huber et al. (39) | 1990 | 9.7 | 4.0 | Volunteers and spouses |

exception of a study that used arthritis patients as the comparison subjects (15), the Beck Depression Inventory scores of patients with Parkinson's disease were higher than the scores of comparison subjects. The range of scores for the patients with Parkinson's disease was 7.9–14.1; the range for the comparison subjects (excluding the study that used arthritis patients) was 3.8–7.1. All of these studies were based on clinical populations and were subject to referral and research participation biases.

The Beck Depression Inventory contains items that might be endorsed by patients with Parkinson's disease without depression, confounding motor and mood changes. Levin et al. (32), however, demonstrated with cluster analysis that the potential crossover somatic items clustered with depression rather than with motor elements, suggesting that the Beck Depression Inventory scores are representative of mood changes. Similarly, Starkstein et al. (40) found that potential crossover items accurately reflected the presence of a mood disorder in Parkinson's disease.

### *Current Age, Age at Onset, and Duration of Parkinson's Disease*

A majority of studies have found no relationship between depression and the patient's current age (7, 8, 24, 26, 27, 41) or the patient's age at onset of the Parkinson's disease (7, 15, 33, 34, 42, 43). Santamaria et al. (16) and Starkstein et al. (44), however, found that depressed patients with Parkinson's disease tended to be younger at the time of onset of parkinsonian symptoms. The number of depressed patients in the study by Santamaria et al. (16) was relatively small (N=11), limiting confidence in extrapolating from this study to the general population. The boundary age for early-onset versus late-onset Parkinson's disease has varied among studies, perhaps contributing to the lack of agreement regarding the importance of this variable as a risk factor for depression. Conclusions based on the available data regarding the potential role of age at onset as a contributing factor to the vulnerability to depression would be premature.

The duration of Parkinson's disease might be expected to influence the rate of depression, but most investigators have found no relationship between length of illness and mood changes (7, 8, 15, 24, 27, 38, 41).

### *Gender*

Several studies (7, 8, 15, 27) have found a higher rate of depression among women with Parkinson's disease, but others (9, 38, 39, 41, 45–47) have failed to identify any relationship between gender and mood. Being female may be a risk factor for depression in Parkinson's disease, but a consensus is lacking.

### *Personal and Family History of Depression*

Two studies (14, 26) have identified a past history of depression as a risk factor for a major mood disorder after the onset of parkinsonian symptoms. If confirmed, this observation could be interpreted as demonstrating that individuals vulnerable to depression are more likely to become depressed after onset of parkinsonism or that depression and Parkinson's disease have a linked neurobiology and either may express temporal precedence.

Studies assessing the influence of a family history of psychiatric illness (14, 26) have not found a higher rate of psychiatric illness in the family members of patients with Parkinson's disease or, more specifically, a higher rate of mood disorders in the family members of depressed patients with Parkinson's disease. These reports suggest that, in most patients, depression in Parkinson's disease is unlikely to be a product of an independently inherited familial disorder.

## CHARACTERISTICS OF DEPRESSION IN PARKINSON'S DISEASE

### *Profile of Depressive Features*

Most investigators concur that the profile of depressive symptoms observed in Parkinson's disease is not

**TABLE 3. Reported Rates of Mild and Moderate-to-Severe Depressive Syndromes in Patients With Parkinson's Disease**

| Study | Year | Mild Symptoms (%) | Moderate–Severe Symptoms (%) |
|---|---|---|---|
| Warburton (7) | 1967 | 11 | 81 |
| Celesia and Wanamaker (8) | 1972 | 33 | 67 |
| Mayeux et al. (14) | 1981 | 65 | 35 |
| Gotham et al. (15) | 1986 | 43 | 57 |
| Santamaria et al. (16) | 1986 | 91 | 9 |
| Mayeux et al. (17) | 1986 | 33 | 67 |
| Starkstein et al. (26) | 1990 | 49 | 51 |
| Ehmann et al. (38) | 1989 | 31 | 68 |

identical to that reported in patients with idiopathic depression. Brown et al. (22) analyzed the Beck Depression Inventory scores of 132 patients with Parkinson's disease and found elevated levels of dysphoria and pessimism about the future, irritability, sadness, and suicidal ideation but little guilt, self-blame, or feelings of failure or punishment. This pattern of sadness without guilt or self-reproach has been confirmed by several investigators (19, 32, 39). Other distinctive features of depression in Parkinson's disease include a high rate of anxiety symptoms (15, 48), a relative lack of delusions and hallucinations (27), and a low suicide rate despite a high frequency of suicidal ideation. These observations indicate that depression in Parkinson's disease is subtly different from idiopathic mood disorders and raise the intriguing possibility that there may be disease-specific depression syndromes with distinctive mood profiles in different conditions.

### *Severity and Type of Depression*

Several studies have assessed the intensity of depressive symptoms in Parkinson's disease by using clinical criteria to distinguish between major depressive episodes and dysthymia or by applying rating scales to differentiate mild from moderate-to-severe syndromes. Table 3 summarizes the results of these investigations (7, 8, 14–17, 26, 38). On average, slightly more than half (54%) of depressed patients with Parkinson's disease met criteria for a major depressive episode (moderate-to-severe symptoms) and slightly less than half (45%) had dysthymia or minor depressions (mild symptoms). The proportions varied considerably among studies, again suggesting the influence of considerable selection biases in different study populations. Major and minor syndromes differ in several respects in addition to severity: minor depressions are more likely to remit (49) and are more closely related to disability (26).

### *Course of Depression*

The course of depression in Parkinson's disease has received little study. Brown et al. (22) found that 14 months after preliminary assessment, 11% of depressed patients with Parkinson's disease no longer evidenced mood changes but that an equal percent of patients who had been free of mood changes had developed depressive episodes. Sixteen percent of the entire group of patients were depressed at both assessment periods, and 61% were depressed at neither. Mayeux et al. (49) followed 49 patients with Parkinson's disease for a mean period of 2.5 years; during that time the mood disorders of one of 14 patients with major depression and three of seven patients with dysthymia remitted. No new cases of depression occurred among the 28 nondepressed patients during the follow-up period. These studies suggest that patients with Parkinson's disease may be divided into two groups—one with and one without mood changes—and that the two groups are relatively stable over time.

### *Biological Markers of Depression*

Table 4 summarizes the principal studies of the dexamethasone suppression test (DST) in Parkinson's disease (17, 50–54). The studies indicate that DST results are often abnormal in Parkinson's disease but that the DST lacks adequate sensitivity or specificity to serve as a marker for depression. Thyrotropin-releasing hormone and L-dopa stimulation tests also failed to differentiate between Parkinson's disease patients with and without mood disorders (17).

Studies of CSF 5-hydroxyindoleacetic acid (5-HIAA), the principal metabolite of serotonin, have found concentrations to be lower in nondepressed patients with Parkinson's disease than in comparison subjects, and several studies have found lower levels in patients with Parkinson's disease plus major depression than in those without mood changes (17, 20, 45, 49). The severity of depression, however, did not correlate with the 5-HIAA levels, and not all patients with low levels of 5-HIAA were depressed. Substantial differences between CSF 5-HIAA levels of depressed patients with Parkinson's disease were reported by different laboratories (20, 45). These investigations suggest an important role for serotonin in mood alterations but also indicate that the level of CSF 5-HIAA is not by itself an adequate marker for depression in Parkinson's disease.

Neuroimaging studies provide another means of investigating the neurobiology of depression in Parkinson's disease. A recent study using fluorodeoxyglucose positron emission tomography (PET) (55) found that metabolism in the caudate nuclei and orbitofrontal cortex of depressed patients with Parkinson's disease was lower than that of nondepressed patients with Parkinson's disease. The location of the metabolic changes differed from that observed in idiopathic depression, where dorsolateral frontal cortical hypometabolism has been reported (56). The metabolic differences suggest that the pathophysiology of the mood changes may differ in the two disorders. Only a few patients have been studied with PET, and the reproducibility of these results requires demonstration.

Sleep studies have also been used to study the neurobiology of depression in Parkinson's disease. Mean

**TABLE 4. Reported Results of Dexamethasone Suppression Tests in Parkinson's Disease Patients With and Without Depression**

| | | | | Positive DST Results (%) | |
|---|---|---|---|---|---|
| Study | Year | Antiparkinsonian Treatment | Number of Subjects | Parkinson's Disease With Depression | Parkinson's Disease Without Depression |
| Mayeux et al. (17) | 1986 | No | 49 | 75 | 28 |
| Pfeiffer et al. (50) | 1987 | No | 14 | 45 | 17 |

| Kostic et al. (53) | 1990 | No | 34 | 75 | 28 |
| Rabey et al. (54) | 1990 | Yes | 32 | —[c] | 47 |

[a] 10 of 56 were untreated.
[b] Depression was defined as Hamilton Rating Scale for Depression score greater than 10.
[c] Depressed patients were excluded from this study.

REM latency has been found to be shorter in depressed than in nondepressed patients with Parkinson's disease, and more depressed than nondepressed patients exhibited shortened REM latency (57). Shortened REM latency is also characteristic of idiopathic depression.

### *Neuropathology*

Neuropathological investigations seeking morphologic correlates of depression in Parkinson's disease are rare and currently inconclusive but point toward changes in noradrenergic and dopaminergic transmitter systems as major contributing factors. Chan-Palay and Asan (58) investigated alterations in the locus ceruleus (the major source of brain norepinephrine) of Parkinson's disease patients with and without depression. The depressed patients had extensive cell loss both rostrally and caudally in the nucleus, whereas patients without depression had relative sparing of caudal neurons. Although the differences between the two groups are provocative, their interpretation is obscure because the caudal cells project to spinal cord and would not be expected to influence mood.

Torack and Morris (59) reported a study of six patients with Parkinson's disease, four of whom were depressed. The common neuropathological correlate of depression was involvement of the ventral tegmental area, hippocampus, and entorhinal cortex. The ventral tegmental area is the source of mesocortical, medial temporal, and orbitofrontal dopaminergic projections, and these cases suggest a role for dopamine loss in depression in Parkinson's disease.

Levels of serotonin in the frontal and temporal poles have been found to be equally low in Parkinson's disease patients with and without depression (decreased by 37% and 47%, respectively) (60).

## RELATIONSHIP OF DEPRESSION TO MOTOR AND COGNITIVE DYSFUNCTION

### *Motor Features*

Several authors have investigated the relationship of mood changes to the classical signs of Parkinson's disease—rigidity, bradykinesia, and tremor—and most investigators (16, 20, 26, 27, 38, 45) have found no association between the mood and motor manifestations of Parkinson's disease. Brown and Wilson (9) observed a modest relationship of depression to rigidity but did not rigorously quantify the association and found no other correlations with the mood disturbance. Huber et al. (21) found that depressed patients with Parkinson's disease exhibited significantly more bradykinesia and tended to have greater rigidity than nondepressed patients, who had more tremor. This observation was supported by the recent multicenter study of selegiline, which found that Parkinson's disease patients with postural instability and gait disturbance evidenced more depression than Parkinson's disease patients with tremor (61). This was a methodologically and analytically sophisticated study, but depressed patients were excluded at entry and the mood changes observed during the course of the research may not be representative of the overall relationship between mood and motor alterations in Parkinson's disease. In general, motor abnormalities do not appear to be major correlates of mood abnormalities, but depression may be more common in syndromes with pronounced gait and postural changes. Among the symptoms of Parkinson's disease, tremor is less responsive to dopamine than are gait changes, akinesia, and rigidity. Thus, depression is most common in syndromes with more prominent dopamine-responsive signs.

### *Disability*

The relationship of depression to disability in Parkinson's disease has been studied with three major approaches: 1) contrasting depression in Parkinson's disease to mood changes in patients with other types of disabilities, 2) correlating depression with severity of impairment of activities of daily living, and 3) studying the relationship of depression to the Hoehn and Yahr staging scale (6).

Several authors compared the frequency of depression in Parkinson's disease with that in other disabled groups. Patients with Parkinson's disease were found to be more depressed than medically ill (7, 47) and paraplegic (41) subjects. Gotham et al. (15), however, compared Parkinson's disease patients with arthritis victims and found that the two groups had similarly elevated Beck Depression Inventory scores. Ehmann et al. (38) overcame many of the methodological flaws of earlier studies and found that patients with Parkinson's disease were significantly more depressed than other disabled patients matched for extent of functional impairment.

In studies of the relationship between depression and severity of functional impairment, a few investigators found no association (7, 16, 46), but most have identified a modest correlation between mood abnormalities and functional deterioration (10, 22, 26, 38).

Finally, the relationship between mood and disability has been investigated by exploring the correlation of depression with the Hoehn and Yahr staging scale (6) (1=unilateral involvement, 2=bilateral involvement without balance difficulties, 3=able to live independently but posture and righting reflexes moderately involved, 4=severe disease but able to walk and stand, 5=confinement to bed or wheelchair). Some investigators found no relationship between Hoehn and Yahr stage and depression (8, 24, 38). Huber et al. (21) reported that depressed patients with Parkinson's disease had a slightly but significantly more advanced stage of disability than nondepressed patients with Parkinson's disease (2.5 versus 1.8). Starkstein et al. (26) noted that patients in stages 1 and 4 had higher depression ratings than patients in the other stages. Thus, there is little agreement about the relationship of mood changes to Hoehn and Yahr staging in Parkinson's disease; no consistent or compelling association between depression and staging is evident.

Analyses of motor symptoms and disability in relation to depression in Parkinson's disease suggest that there is a limited relationship between the severity of disability and the presence of mood changes. The correlation is not sufficiently robust to support disability as a primary determinant of depression in Parkinson's disease. Moreover, these studies do not indicate if the relationship between depression and disability is a product of greater depression in patients with more disability or if depression is another factor increasing the disability of the patient with Parkinson's disease.

### *Lateralized Motor Disturbances*

Parkinsonism may begin unilaterally or may be asymmetrical throughout most of its course. A relationship between depression and lateralized motor changes would imply a role for contralateral structures in the pathophysiology of mood changes. Direnfeld et al. (29) reported that patients with right hemiparkinsonism (greater left brain dysfunction) had somewhat higher Beck Depression Inventory scores than those with a predominance of left-sided signs or those with bilateral involvement (right-sided=13.6, left-sided=7.6, bilateral=9.1), and Starkstein et al. (26) also found that those with more right-sided abnormalities had higher depression rating scale scores. Barber et al. (62), however, found no difference in depression self-ratings between patients with right and left hemiparkinsonism, and Spicer et al. (35) reported a nonsignificant trend toward higher Beck Depression Inventory scores in patients with left hemiparkinsonism (14.1 versus 10.3). Huber et al. (36) found low and approximately equal Beck Depression Inventory scores in patients with right and left hemiparkinsonism (5.2 and 5.8, respectively) and in those with bilateral but asymmetric syndromes (right more severe, 10.5; left more severe, 10.1). At present the evidence concerning a relationship between depression and lateralized basal ganglia dysfunction is inconclusive. Where differences have been shown, they usually suggest greater depression in patients with right hemiparkinsonism and more marked left-brain disease.

### *Depression and Intellectual Impairment*

Overt dementia with prominent intellectual impairment occurs in approximately 30% of patients with Parkinson's disease. Depression is equally frequent in Parkinson's disease with and without overt dementia (12, 24, 31, 63).

Subtle neuropsychological deficits are common in Parkinson's disease, affecting up to 40% of patients without overt dementia (64). Several investigators have found that patients with Parkinson's disease and depression exhibit more neuropsychological impairment than nondepressed patients with Parkinson's disease. Mayeux et al. (14) and Starkstein et al. (26) found a significant association between depression and deficits on screening mental status examinations. Taylor et al. (19) and Starkstein et al. (65) found that depressed patients with Parkinson's disease performed significantly worse on a number of tasks mediated by frontal lobes or frontal-subcortical systems, and Rogers et al. (66), using reaction time experiments, demonstrated excessive slowing of central processing in patients with Parkinson's disease and depression compared with those without mood changes.

Complete agreement has not been achieved in this area of investigation, but the available studies indicate that patients with Parkinson's disease and depression have more marked frontal lobe dysfunction than those without mood alterations. There may be a common underlying disturbance in frontal-subcortical systems responsible for the depression and the characteristic neuropsychological deficits. Although depression per se could be hypothesized to account for the neuropsychological disturbances observed in depressed patients with Parkinson's disease, comparative studies demonstrate that depression contributes to the memory impairment but not the frontal system abnormalities (65).

### *Depression and the "On-Off" Phenomenon*

The "on-off" phenomenon refers to marked motor fluctuations that occur after chronic L-dopa therapy and includes end-of-dose deterioration occurring as the effect of each administered dose declines as well as unpredictable shifts between mobile or dyskinetic "on" states and akinetic "off" states unrelated to medication

**TABLE 5. Findings of Double-Blind Studies of Antidepressant Treatment for Patients With Parkinson's Disease and Depression**

| Study | Year | Agent | Dose (mg/day) | Number of Subjects | Patients Whose Depression Responded (%) | Effect on Parkinson's Disease | Study Design |
|---|---|---|---|---|---|---|---|
| Strang (5) | 1965 | Imipramine | 150–200 | 20 | 60 | Rigidity improved in 42%, tremor improved in 28%, akinesia improved in 54% | Double-blind |
| Andersen et al. (78) | 1980 | Nortriptyline | 150 | 22 | —[a] | No effect | Double-blind crossover |
| Laitinen (79) | 1969 | Desipramine | 100 | 39 | 50 | Rigidity improved in 25%, tremor improved in 15% | Double-blind |
| Goetz et al. (80) | 1984 | Bupropion | 450 | 20 | 42 | 30% of patients improved | Double-blind followed by open-label phase |

[a] Depression rating scale scores were significantly improved in the active treatment group.

schedules. Numerous investigators (67–73) have documented mood changes—greater depression during akinetic periods—in "on-off" patients. Nissenbaum et al. (72) assessed the frequency and type of mood changes occurring in "on-off" periods. They found that 23% of 136 patients reported having "on-off episodes" and that 68.7% of these described greater depression when "off."

These investigations demonstrate that mood changes are common in patients who experience the "on-off" phenomenon and that depression is commonly exaggerated while patients are in the "off" state. The occurrence of abrupt mood changes in concert with dopamine-mediated motor fluctuations in the "on-off" phenomenon suggests a role for dopamine in mood regulation.

## MOOD EFFECTS OF ANTIPARKINSONIAN TREATMENT

### *Pharmacological Agents*

Pharmacotherapy of the motor deficits of Parkinson's disease exerts little effect on mood. Anticholinergic agents, particularly trihexyphenidyl, have mild euphorigenic effects but are relatively ineffective as antidepressants. Similarly, amantadine has little antidepressant activity.

L-Dopa has limited or no antidepressant efficacy and has occasionally been suspected of producing depression. The frequency of depression reported among patients treated with L-dopa, however, is within the range of that observed in Parkinson's disease before the introduction of L-dopa therapy (8). These observations do not support a marked tendency for L-dopa to increase the frequency of depression, although a role for L-dopa in precipitating or exacerbating mood changes has not been excluded.

Dopamine receptor agonists may have mood-altering effects. Jouvent et al. (74) reported that after 8 days of therapy with bromocriptine, depression ratings of 10 depressed patients with Parkinson's disease had improved 65%. The mood response was more variable than the motor response, and the two did not correlate.

Selegiline, an MAO-B inhibitor thought to slow progression of Parkinson's disease by limiting generation of hydroxyl radicals destructive to neuronal membranes, may have mild antidepressant properties. Ruggieri et al. (75) reported the prevalence of depression in a group of patients to be 35% before the addition of selegiline to their therapeutic regimen and 21% after treatment with the agent. Birkmayer (76) reported that 15% of 1,414 patients with Parkinson's disease treated with L-dopa were depressed; none of 381 patients treated with L-dopa plus selegiline, however, exhibited depressive disorders.

### *Surgical Therapies*

Thalamotomy and pallidectomy are now rarely performed for relief of parkinsonism, but transplantation of adrenal medullary tissue or fetal substantia nigra tissue to the head of the caudate nucleus recently has been introduced as an experimental therapy for Parkinson's disease. The effect of this surgical approach on mood has not been extensively studied. One study (77) found no change from baseline in Beck Depression Inventory scores 6 and 12 months after transplantation in seven patients.

## TREATMENT OF DEPRESSION IN PARKINSON'S DISEASE

### *Pharmacotherapy*

Imipramine, nortriptyline, desipramine, and bupropion have all been shown to be efficacious in the treatment of depression in Parkinson's disease. Table 5 summarizes the doses, treatment responses, effects on Parkinson's disease, and study design of the four available double-blind studies of antidepressants in patients with Parkinson's disease and depression (5, 78–80). Only the study by Andersen et al. (78) used standardized assessments of both depression and Parkinson's disease. These authors observed an effect of nortriptyline on the mood disorder, including improvement in depressed mood, hopelessness, helplessness, and anxiety, but no change in the Parkinson's disease. Imipramine and desipramine were reported to have beneficial effects on both mood and motor abnormalities, and these agents may be more efficacious in relieving Parkinsonian symptoms, but the assessment methodology was less rigorous in these studies. Bupropion, an antidepressant with indirect dopaminergic properties, improved depression in less than half and symptoms of Parkinson's disease in about a third of the depressed patients with Parkinson's disease (80). Mayeux et al. (49) treated seven depressed patients with Parkinson's disease with 5-hydroxytryptophan in an open-label study and observed clinically significant improvement in six. No well-controlled studies using contemporary design technologies have expanded on the earlier studies or addressed the efficacy of other new antidepressants in the treatment of depression in Parkinson's disease.

One study explored the usefulness of psychostimulants in mood changes associated with Parkinson's disease. Cantello et al. (81) found that depressed patients with Parkinson's disease had no euphoric response to intravenous methylphenidate, whereas nondepressed patients with Parkinson's disease, depressed patients without Parkinson's disease, and normal comparison subjects all experienced feelings of euphoria and well-being, talkativeness, psychic activation, and greater locomotor activity. The authors posited the existence of changes in dopaminergic synapses of the limbic system of depressed patients with Parkinson's disease, rendering them incapable of responding to the agent.

Although depression is common in Parkinson's disease and antidepressant agents have demonstrated efficacy in relieving mood disturbances, most studies indicate that depression in Parkinson's disease is undertreated. When reported, the number of patients receiving antidepressant therapy is usually considerably smaller than the number with substantial mood changes (17, 19, 21, 26, 32, 45, 81).

### *ECT*

ECT has also proven to be effective in the amelioration of depression in Parkinson's disease. In most cases, both the mood and the motor syndrome improve, although patients exhibiting ECT-related relief of Parkinson's disease without concomitant mood changes (82) and patients with mood improvement in the absence of a motor response (83) have been reported. All aspects of Parkinson's disease—tremor, rigidity, bradykinesia—improve with ECT, and the motor response usually antedates the mood response in the course of ECT treatments (83–88). The improvement in the motor manifestations of Parkinson's disease is usually short-lived, lasting only a few days or weeks, but is occasionally more sustained (85).

## MECHANISMS OF DEPRESSION IN PARKINSON'S DISEASE

The most daunting challenge in contemporary neuropsychiatry is the translation of neurobiological alterations into models that convincingly relate chemical and structural changes to subjective personal experience. In the case of depression in Parkinson's disease, how do observations regarding pathological and biochemical changes in brainstem nuclei provide insight into the intensely personal experience of sadness, hopelessness, and helplessness? Development of a comprehensive psychiatry embracing both biological and psychosocial domains depends on the ability to construct answers to such questions. Although far from sufficiently comprehensive to define such relationships conclusively, information regarding depression in Parkinson's disease allows construction of a tentative psychobiological model relating neurobiology and behavior.

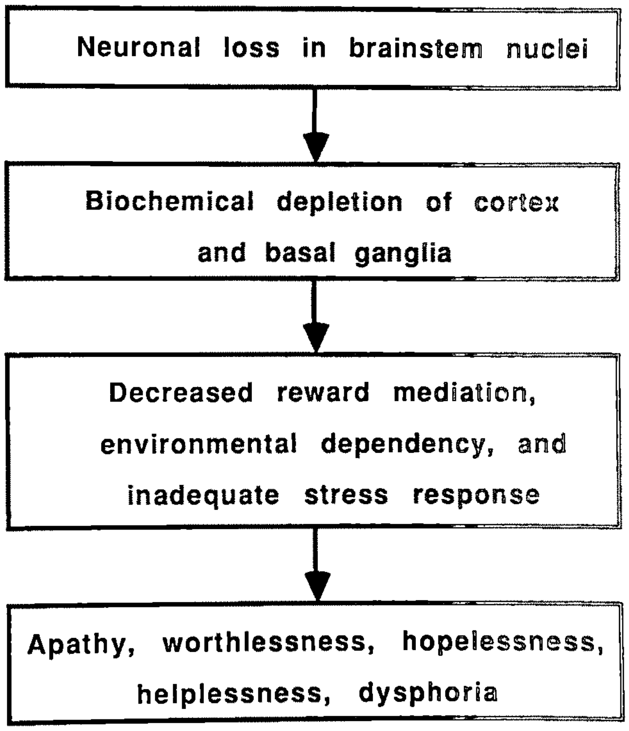
The morphological changes of Parkinson's disease involve a variety of subcortical nuclei, including the substantia nigra, ventral tegmental area, nucleus basalis, hypothalamus (particularly the lateral and posterior nuclei), pedunculopontine nucleus, dorsal raphe nucleus, locus ceruleus, central pontine nucleus, dorsal motor nucleus of the vagus, and autonomic ganglia (89, 90). There is considerable variability in the severity of involvement of these structures at autopsy: cell loss in the substantia nigra and the locus ceruleus varies from 50% to 85%, in the dorsal raphe nucleus from 0% to 43%, and in the nucleus basalis from 32% to 87% (89). On this basis, substantial heterogeneity in the motor and behavioral manifestations of Parkinson's disease would be predicted.

Subcortical nuclei are major sources of neurotransmitters, and pathological involvement leads to neurochemical depletion remote from the nuclei. The substantia nigra and ventral tegmental area project to the striatum and mesocortical/mesolimbic regions; involvement of these structures in Parkinson's disease results in dopamine depletion in the caudate (75% reduction), putamen (90% reduction), lateral hypothalamus (90% reduction), medial temporal structures (45%–68% reduction), nucleus accumbens (58% reduction), and cingulate cortex (52% reduction) (91). Norepinephrine is reduced 43% in the locus ceruleus, 52% in the substantia nigra, 60% in the nucleus accumbens, and 68% in the posterior hypothalamus (92). Serotonin concentrations are reduced approximately 40% in the caudate nucleus and hippocampus (93) and 40% and 50% in the frontal and temporal poles, respectively (60). High-affinity serotonin binding sites are reduced in the basal ganglia (94). Moderate to marked reductions (up to 70% in some brain regions) in specific neuropeptides also occur in Parkinson's disease, including met-enkephalin, leu-enkephalin, substance P, and bombesin (95). Of these chemical constituents, dopamine, norepinephrine, and serotonin have all been implicated in the pathogenesis of depression in Parkinson's disease. Again, regional variations of involvement, differences in the severity of transmitter depletion, and variable combinations of transmitter loss may contribute to individual differences in the occurrence and severity of mood changes observed in Parkinson's disease.

Transmitter and peptide alterations produce neurophysiological changes relevant to the mediation of mood. The transmitter systems involved in Parkinson's disease mediate reward processes, motivational mechanisms, and stress responses. Dopaminergic neurons of the ventral tegmental area/mesocortical system are a preferred site for self-stimulation in animal experiments, suggesting that the dopamine system plays an important role in reward and reinforcement (96). Febiger (97) hypothesized that the abnormalities in these systems in Parkinson's disease would diminish the effectiveness of reward mechanisms and contribute to anhedonia, loss of motivation, and apathy. Taylor and Saint-Cyr (98) emphasized the important role of forebrain dopaminergic systems in the behavioral functions of expectancy and anticipation. These systems play key roles in motivation and the incentive to act; dysfunction would result in exaggerated environmental dependency with diminished desire to perform activities, decreased sense of personal control, and lessened expectations from one's activities. Clinically, a reduced sense of personal control could manifest as a sense of worthlessness and loss of self-esteem. Environmental dependency and inability to generate activities internally could also spawn feelings of helplessness and hopelessness. Diminished self-efficacy would limit the generation of effective coping strategies, adding to the depression, and patients with Parkinson's disease have been observed to use fewer and less effective coping methods than comparably disabled comparison subjects (99). Experimentally induced stress markedly increases dopamine utilization (96), and dopamine deficiencies in Parkinson's disease might be expected to impair adaptive adjustments to stress and contribute to the dysphoria of depression. Thus, dysfunction of reward-oriented systems could account for anhedonia; prefrontal impairment could explain many of the cognitive elements of the depression syndrome (hopelessness, helplessness, worthlessness, loss of self-esteem); and impairment of the stress response may contribute to the dysphoric experience. Together, these elements constitute the clinical syndrome of depression.

Most of the dysfunctional events described here are mediated by prefrontal dopamine systems, and a series of observations support the hypothesis of greater involvement of these systems in depressed than nondepressed patients with Parkinson's disease. Depressed patients with Parkinson's disease exhibit more frontal-lobe-type neuropsychological deficits, more severe hypometabolism in the frontal lobes when studied with PET, more marked dopamine-based gait and posture abnormalities, an impaired response to a dopamine-receptor-mediated methylphenidate challenge, and more marked involvement of the ventral tegmental area/prefrontal dopaminergic projections at autopsy. The dopamine deficiency would be exaggerated during the "off" state, coinciding with the observed increase in depression during this period. The occurrence and content of depression could be further modified by alterations of noradrenergic and serotonergic systems, opiates, and peptides.

**FIGURE 1. Model of Pathogenesis of Depression in Parkinson's Disease**



Neuronal loss in brainstem nuclei
Biochemical depletion of cortex and basal ganglia
Decreased reward mediation, environmental dependency, and inadequate stress response
Apathy, worthlessness, hopelessness, helplessness, dysphoria

Figure 1 summarizes the processes potentially contributing to depression in Parkinson's disease. In this tentative model, neuropathological changes leading to transmitter depletion are hypothesized to produce mesocortical and prefrontal dysfunction, with ensuing disruption of "hedonic," motivational, incentive, and stress-alleviating mechanisms and consequent symptoms of worthlessness, helplessness, hopelessness, and dysphoria, recognized as the syndrome of depression. Heterogeneity of the severity of structural involvement, degree of transmitter loss, functional reserve and plasticity of the nervous system, ability to develop effective coping strategies, availability of social supports, and the patient's premorbid personality may all influence the occurrence of the mood changes.

## RESEARCH AGENDA

Several critical areas for research can be identified on the basis of this review. Large-scale demographic studies are needed to establish the prevalence of mood changes in unselected populations of patients with Parkinson's disease. Such studies would also help settle unresolved issues concerning the relationship of depression to age at onset, laterality of Parkinson's disease, and gender. Longitudinal follow-up studies will be required to establish the course of mood changes in Parkinson's disease and to determine if they are characteristic of a limited subgroup of patients with the disease. Combined PET and neuropsychological studies are needed to confirm the association of lower frontal lobe metabolism, cognitive deficits, and mood changes. Well-designed studies of traditional and emerging antidepressants are needed to further define the treatment-response characteristics of depression in Parkinson's disease. Comparative studies of depression in Parkinson's disease with depression in other disorders (e.g., stroke, multiple sclerosis, Huntington's disease) will address the potential existence of disease-specific depression profiles. Autopsy investigations of patients who have been well-characterized clinically are required to illuminate the relationship of mood changes to cellular, transmitter, modulator, and receptor alterations. Synthesis of these data into a comprehensive model will provide insight into the relationship of neurobiological changes to psychiatric syndromes.

# Is Childhood Sexual Abuse a Risk Factor for Bulimia Nervosa?

Harrison G. Pope, Jr., M.D., and James I. Hudson, M.D.

*Objective: It is of considerable theoretical and clinical importance to assess whether childhood sexual abuse is a risk factor for the development of bulimia nervosa. The authors reviewed the scientific literature bearing on this issue. Method: Since prospective studies on this question have not been done, they assessed 1) controlled retrospective studies comparing the prevalence of childhood sexual abuse among bulimic and control groups, 2) uncontrolled retrospective studies of the prevalence of childhood sexual abuse in samples of 10 or more bulimic subjects, and 3) studies of the prevalence of childhood sexual abuse in the general population, which were chosen to match as closely as possible in methodology the available studies of bulimia nervosa (i.e., in geographic location, age and ethnicity of subjects, interview method, and criteria for defining childhood sexual abuse). Results: Controlled studies generally did not find that bulimic patients show a significantly higher prevalence of childhood sexual abuse than control groups, especially when allowance is made for possible methodologic effects. Furthermore, neither controlled nor uncontrolled studies of bulimia nervosa found higher rates of childhood sexual abuse than were found in studies of the general population that used comparable methods. When it is taken into consideration that several methodologic factors might have exaggerated the rates of childhood sexual abuse among subjects with bulimia nervosa relative to rates in the general population, the absence of actual observed differences becomes particularly striking. Conclusions: Current evidence does not support the hypothesis that childhood sexual abuse is a risk factor for bulimia nervosa.*

(Am J Psychiatry 1992; 149:455–463)

Over the last several years, a growing literature has suggested that experiences of childhood sexual abuse may contribute to the development of bulimia nervosa in adolescence or young adulthood. This hypothesis, if confirmed, would have great clinical and theoretical significance, both for our understanding of the etiology of bulimia nervosa and for the development of appropriate treatment strategies for individuals suffering from bulimic symptoms. Thus, the role of childhood sexual abuse in bulimia nervosa deserves careful assessment. This review evaluates the accumulated studies on this subject and suggests avenues for future research.

## STUDIES OF SEXUAL ABUSE AMONG PATIENTS WITH BULIMIA NERVOSA

### *Prospective Studies*

The most satisfactory test for a postulated risk factor in a given disease is the prospective study. Most readers are undoubtedly familiar with classic studies of this design, such as the Framingham Heart Study (1), in which individuals with potential risk factors (elevated serum cholesterol levels, smoking, or obesity) were followed for many years to assess for heart disease. By analogy, a prospective investigation of bulimia nervosa would recruit a large sample of children, document those who experienced instances of childhood sexual abuse, and follow the entire group into adulthood to determine, after controlling for potential confounding variables, whether the abused children ultimately displayed a higher prevalence of bulimia nervosa than matched nonabused children.

To our knowledge, no such study has been conducted, but it is not unreasonable to expect such an investigation in the future. Although difficult and expensive, a prospective study could test the role of childhood

| | Intermediate | Yes (<19 years) | No | Yes[h] |

[a] Criteria were rated as narrow if the study required that abuse 1) occur at age 18 or under, 2) involve physical contact, and 3) involve a perpetrator at least 3 years older than the victim and/or clear evidence of coercion. Criteria lacking one of these requirements were rated as intermediate; criteria lacking two or more requirements were rated as broad. If some requirements were unclear, an intermediate rating was assigned.

[b] In 85% of the cases, abuse occurred before age 17 years, but subjects in 15% of the cases were aged 17 years or older.

[c] Personal communication from C. Ross, February 1991.

[d] Personal communication from G. Stuart, March 1991.

[e] Ten percent of the subjects were between the ages of 15 and 20 at the time of the abuse.

[f] No specific age criterion was used, but most cases of abuse occurred before age 14 (personal communication from P. Fallon, March 1991).

[g] Coercion was required if the perpetrator was less than 5 years older than the victim.

[h] Although a formal requirement of age difference was not included, only 4% of victims reported perpetrators less than 4 years older than themselves.

sexual abuse not only as a risk factor for bulimia nervosa but also for the entire spectrum of other psychiatric disorders, thus yielding a great deal of information in return for the investment.

### *Controlled Retrospective Studies*

Given the obvious difficulty of performing a prospective study of sexual abuse, it seems only reasonable to admit the evidence of other less methodologically sophisticated study designs. Of these, the best are controlled retrospective studies, in which a group of bulimic patients (or, more often in practice, patients with anorexia and/or bulimia nervosa) is compared with a group of control individuals. The latter must, of course, be matched as closely as possible in age, sex, and other demographic attributes that may be correlated with the prevalence of childhood sexual abuse.

Six such studies are known to us. In the first, Hall et al. (2, 3) compared 56 bulimic and 16 anorexic patients with a control group of 86 other patients admitted to the same unit but apparently assessed by "colleagues treating adolescents for other reasons on an adolescent treatment unit" (3). Sexual abuse was assessed by "clinical interview and subsequent therapeutic interventions" (2); it was apparently defined to include only events involving physical contact between perpetrator and victim (table 1). Twenty-eight (50%) of the 56 bulimic patients (table 2) and eight (50%) of the 16 anorexic patients were rated as having experienced sexual abuse, compared with 24 (28%) of the control subjects. The rate of sexual abuse in the bulimic and anorexic groups combined was reported to be significantly higher than in the control group ($p<0.01$).

However, the authors apparently failed to match their control group for sex. They stated that 98% of the anorexic and bulimic patients were female (3) and also that 98% of all of the abused patients were female (2); but only 85% of the nonabused patients were female (2). Therefore, at least 14 of the control patients were male, in comparison with only one of the patients with eating disorders. When the control group is corrected to be sex-matched with the eating disorder group, the difference between groups in the prevalence of sexual abuse is no longer significant.

Second, the authors noted that in 15% of the cases, sexual abuse occurred at age 17 or above. Since bulimia and anorexia nervosa commonly begin in adolescence (4), it seems likely that in at least some cases, sexual abuse began after the onset of the eating disorder. While their importance should not be denied, these particular instances of abuse cannot be credited toward the

| Lacey (21) | 112 | Bulimia | 8 | 7 | | | | |
| Subjects in the general population | | | | | | | | |
| Russell (32) (ages 18–36 only) | 470 | | 200 | 43 | 276 | 59 | | |
| Wyatt (33) | | | | | | | | |
| Entire sample | 248 | | —[b] | 45 | 154 | 62[c] | | |
| White women only | 122 | | —[b] | 51 | 82 | 67[c] | | |
| Bagley & Ramsay (34) (under age 40 only) | 134[d] | | —[b] | 28 | | | | |
| Finkelhor et al. (35) (ages 18–39 only) | 670 | | —[b] | 27 | —[b] | 31 | | |

[a] Criteria were rated as narrow if the study required that abuse 1) occur at age 18 or under, 2) involve physical contact, and 3) involve a perpetrator at least 3 years older than the victim and/or clear evidence of coercion. Criteria lacking one of these requirements were rated as intermediate; criteria lacking two or more requirements were rated as broad. If some requirements were unclear, an intermediate rating was assigned.

[b] N not provided by authors.

[c] If peer abuse cases are deleted entirely, the rates according to intermediate criteria decline only slightly, to 59% for the entire sample and 65% for the white women only.

[d] This figure is an approximation calculated from the authors' table 1.

hypothesis that sexual abuse is a risk factor for eating disorders.

A third possible methodologic limitation of this study is in its methods of assessing sexual abuse. It is not clear whether control patients were evaluated as extensively for sexual abuse as were the anorexic and bulimic patients and whether the two groups were evaluated by the same person or persons. Although a "structured questionnaire" was mentioned in one of the two reports of the study (3), it was not described.

By contrast, a structured diagnostic interview of established reliability, the Dissociative Disorders Interview Schedule (5) was used by Ross et al. (6) in the second controlled retrospective study that we reviewed. These authors assessed sexual abuse, among many other variables, in 20 patients with anorexia or bulimia nervosa, 20 with panic disorder or agoraphobia, 20 with schizophrenia, and 20 with multiple personality disorder. All groups were recruited from specialized clinics at the same center, and more than 85% of the consecutive subjects in each group agreed to participate in the study. By the criteria of the Dissociative Disorders Interview Schedule, four (20%) of the anorexic and bulimic patients were rated as having experienced childhood sexual abuse (table 2)—a rate not significantly different from the rate of 10% in the groups with anxiety disorders and schizophrenia. Further, since all of the patients with eating disorders were female, whereas 15% of the patients with anxiety disorders and 70% of the schizophrenic patients were male, these small differences may be partially due to sex distribution. By contrast, 16 (80%) of the patients with multiple personality disorder reported sexual abuse, a significantly higher rate than that of the patients with eating disorders ($p<0.0005$).

The two studies we have mentioned so far, it might be argued, may have failed to reveal an association between sexual abuse and bulimia nervosa because the control groups were also composed of psychiatric patients. Of course, to make this argument, one would have to posit that most or all of the various psychiatric disorders of subjects in the control groups were themselves associated with sexual abuse—a broader assumption. In this context, the next two studies are of interest, since they used nonpsychiatric populations.

In the first of these, Stuart et al. (7) compared 30 bulimic women and 15 depressed women, recruited from the clinical research section at their center, with 100 sociodemographically matched control women. The control women were not a random population but "supernormal": they were required to have no psychiatric diagnosis, to have never sought psychiatric treatment, and even to have no first-degree relatives with psychiatric diagnoses. Sexual abuse was assessed by a written victimization inventory modified from the original Crime Victimization Inventory (8). On this scale, no significant difference was found between the bulimic subjects and either of the other two groups on any of the measures of sexual mistreatment, although there was a trend on the item of sexual molestation, reported by 50% of the bulimic subjects (table 2) and 40% of the depressed subjects, compared with 28% of the normal control subjects.

This trend, however, may be an artifact of the use of supernormal control subjects in the study design, as can be illustrated by a medical analogy. Consider a comparison of the prevalence of smoking by patients with rheumatoid arthritis and a control group of age-matched patients screened to show no medical illness of any type. The prevalence of smoking would almost certainly be lower in the supernormal control subjects in such a comparison, leading to the erroneous conclusion that smoking is associated with rheumatoid arthritis. When it is considered that the control subjects in the Stuart et al. study were screened to exclude not only personal psychiatric disorder but even familial psychiatric disorder, a similar effect seems possible.

In the fourth and largest controlled retrospective study, Folsom et al. (9, and personal communication from V. Folsom, February 1991) compared 102 female inpatients with eating disorders (57 with bulimia nervosa, 17 with anorexia nervosa, 19 with both disorders, and nine with eating disorders not otherwise specified, according to *DSM-III-R*), 49 general psychiatric inpatients with a wide range of other *DSM-III-R* axis I diagnoses, and 44 college and graduate student control subjects. The instruments they used were the Finkelhor Sexual Life Events Questionnaire (10), the Eating Disorders Inventory (11), and the SCL-90 (12). Personal interviews were not administered. When the results were analyzed, only the broadest definition of sexual abuse revealed a significant difference between groups (general psychiatric patients, 81%; patients with eating disorders, 69% [table 2]; college and graduate students, 48%). Looking only at sexual abuse that occurred before the age of 18, the authors found no significant differences between the patients with eating disorders and the other two groups on any of the various comparisons they performed. In addition, among the patients with eating disorders, a history of sexual abuse was not significantly associated with higher scores on any of the eight subscales of the Eating Disorders Inventory.

In this study, as in the preceding one, it must also be recognized that the control group represented to some extent supernormal individuals; women admitted to college and graduate school are a selected and successful group who might well have a lower prevalence of sexual abuse than an entirely random population. Therefore, the already nonsignificant differences between the patients and the control subjects might be further reduced if allowance were made for the possibility that data from college and graduate students underestimate the prevalence of childhood sexual abuse in the population at large.

Steiger and Zanko (13) examined populations similar to those of the previous study: 73 women with eating disorders (28 with anorexia nervosa and 45 with bulimia nervosa according to *DSM-III-R* criteria); 21 psychiatric comparison subjects with affective (N=8), anxiety (N=7), adjustment (N=2), personality (N=3), and schizophrenic (N=1) disorders; and 24 normal control subjects obtained from among the hospital staff, patients' friends, and students. Data on sexual abuse was elicited by a brief self-report questionnaire, without personal interview. The criteria for sexual abuse were thus somewhat vague, since subjects were free to use their own interpretation of various terms on the questionnaire, such as "inappropriate touching." Sexual abuse was reported by six (21%) of the anorexic patients, 16 (36%) of the bulimic patients (table 2), and seven (33%) of the psychiatric comparison subjects, but by only two (9%) of the 23 normal control subjects assessed.

Although no difference in the rate of sexual abuse was found in this study between the bulimic patients and the psychiatric patients without eating disorders, the difference between the bulimic patients and the normal control subjects was significant ($p=0.03$ by Fisher's exact test, two-tailed). However, the 9% rate of sexual abuse reported by the normal control subjects in this study seems peculiarly low: in the previous two studies reviewed, normal control subjects displayed rates of 28% and 48%. One possible explanation for this discrepancy may be that normal control subjects in the Steiger and Zanko study included hospital staff and possibly other individuals known socially or occupationally to the authors. Since the questionnaire was apparently not anonymous, these individuals may have been reluctant to reveal instances of sexual abuse in their personal lives.

A sixth controlled study used a "reverse" design: it compared sexually abused and nonabused women for their current and lifetime prevalences of eating disorders. In this study, Finn et al. (14) administered a sexual abuse screening checklist to 87 women recruited from a variety of psychotherapy groups. Patients checking "yes" or "unsure" on any item on this checklist (N=71, or 82%) were subsequently administered a structured interview about sexual abuse by interviewers who had established good interrater reliability with this instrument. Sixty-one women were rated as abused. "Abuse" was defined to require actual sexual contact but included instances of contact with a physician or therapist as well as the more usual categories of abusers. Eating disorders were assessed by an Eating Patterns Questionnaire previously developed and published by the same group (15). Although subjects were not reassessed for eating disorders by personal interview, the questionnaire appeared reliable: two raters independently rated 10 Eating Patterns Questionnaires and generated 100% agreement on all diagnostic ratings.

No significant difference or, apparently, even trend toward a significant difference, was found between the 61 abused and 26 nonabused women in the prevalence of current bulimia nervosa, of lifetime bulimia nervosa, or of current or lifetime episodes of more broadly defined bulimic behaviors (including binge eating, vomiting, and severely restrictive dieting). Two further analyses—the first redefining abuse to include only instances of direct genital contact and the second comparing subjects with incestuous abuse, subjects with nonincestuous abuse, and nonabused control subjects—also failed to show significant differences between any of the groups on any of the diagnostic categories of eating disorder examined. The authors speculated that clinicians might perceive an "illusory correlation" between sexual abuse and eating disorders because each of these phenomena is so common that frequent co-occurrence would be expected by chance alone. They cited a study of bias in clinical judgment (16) which notes that people tend to base their estimate of covariation on observed instances of co-occurrence of the variables in question, while tending to ignore instances in which one variable occurs in the absence of the other.

Thus, of the six controlled retrospective studies that we reviewed, four found no significantly greater prevalence of childhood sexual abuse among bulimic patients (or, in one case, prevalence of bulimic behaviors among sexually abused patients) in any of their comparisons with control subjects. The fifth study found a significantly higher prevalence of sexual abuse in anorexic and/or bulimic patients than in control subjects, but after sex matching, this difference also fails to reach significance. The sixth study found a significant difference between bulimic patients and normal control subjects, but this difference may reflect the atypically low rate of sexual abuse found in the control group.

### *Uncontrolled or Anecdotal Studies*

Several uncontrolled studies of sexual abuse among bulimic patients have also appeared. Those with samples of 10 or more bulimic patients are reviewed here.

Oppenheimer et al. (17) administered a written questionnaire, followed by a verbal interview, to 78 consecutive women with eating disorders presenting at a clinic. Of these women, 33 met the *DSM-III* criteria for bulimia, 36 met the criteria for anorexia nervosa, and nine were "mixed." Adverse sexual events were defined in the manner of the 1979 study of Finkelhor (10), a relatively broad definition that included noncontact experiences such as "an invitation or request to do something sexual." By these criteria, eight (24%) of the bulimic women and 23 (29%) of the entire sample reported sexual abuse. Eleven of the 78 subjects failed to complete the questionnaire; since it is likely that some of these subjects had experienced sexual abuse, the resulting figures may be conservative. When the authors expanded their criteria further to eliminate the age-difference criterion (shown in the second line for the Oppenheimer et al. study in our table 1), the prevalence rose to 22 (67%) of the bulimic patients (table 2) and 50 (64%) of the entire sample.

Sloan and Leichner (18), in a primarily anecdotal report, described five cases of inpatient women with eating disorders who, in the course of treatment, revealed histories of childhood sexual abuse. All of these cases would meet rigorous or narrow criteria for childhood sexual abuse, since they involved contact by a perpetrator older than the subject. At the end of the study, the authors noted that nine (39%) of 23 subsequent new inpatients on the same unit reported past or present sexual abuse or incest (table 2). It is not clear how many of these nine cases met a narrow definition, or how many were past experiences and how many were in the present and thus occurred only after the onset of bulimia nervosa.

Bulik et al. (19) examined 35 women meeting the *DSM-III* criteria for bulimia who were recruited during an investigation of family environment and psychiatric history. On structured interviewing, 10 (29%) reported childhood sexual abuse that met narrow criteria (table 2); two other subjects came from families in which incest had occurred, but they had not been victims themselves. This study is particularly interesting because it provides diagnoses for the perpetrators in most instances; in at least five of the 10 cases, the perpetrator had a diagnosis of alcohol dependence, bipolar disorder, or both.

Root and Fallon (20) interviewed 172 consecutive female applicants to a bulimia treatment program, all of whom met the *DSM-III* criteria for bulimia. Criteria for sexual abuse were narrow (personal communication from P. Fallon, March 1991). Forty-nine (28%) of the patients were found to have been sexually abused (table 2). An additional 23 subjects reported rape, but it appears that many or all of these subjects were raped as adults. Thus, most rapes probably occurred after the onset of bulimia.

Lacey (21) personally interviewed 112 consecutively referred women who met the *DSM-III-R* criteria for bulimia nervosa. Toward the end of the 3-hour interview, he asked a series of questions regarding childhood sexual abuse. Using rigorous, narrow criteria, he found that eight (7%) reported such experiences (table 2). One, however, did not experience sexual abuse until 1 1/2 years after the onset of her binge eating. Although the prevalence rate found in this study is lower than that reported in other studies, the author argued that it is unlikely that actual cases of sexual abuse were missed, since most patients subsequently entered psychotherapy with female therapists, and no further cases came to light.

One relevant study is not easily classified in the categories we have mentioned. Calam and Slade (22) analyzed the responses of 130 undergraduate college women on the Eating Attitudes Test (23) and a Sexual Events Questionnaire derived from that of Russell (24). It is important to note that the latter instrument contained questions about both childhood and adult sexual events. No significant correlation was found between the number of childhood sexual events (defined as occurring before age 14) and total score on the Eating Attitudes Test or scores on the dieting and bulimia subscales of that test. Answers to five of the six questions about childhood events on the Sexual Events Questionnaire also showed no correlations with total or subscale scores on the Eating Attitudes Test. Only one item, early sexual intercourse against the participant's wishes, showed significant though modest correlations (i.e., with the bulimia subscale scores, r=0.18, which would explain 3% of the variance).

When adult events were added in, several significant correlations did appear, but these are less relevant to the purposes of our review because of the possibility, discussed earlier, that many such events may have occurred after the onset of bulimia nervosa. It should be noted, however, that even with the addition of adult events, there was still no significant association between either total sexual events or intrafamilial sexual events and scores on the bulimia subscale of the Eating Attitudes Test.

Finally, it should be noted that several other studies have assessed sexual abuse in various series of bulimic patients (25–30) or patients displaying bulimic behaviors (31). However, these studies cannot be compared directly with the studies we have summarized because they either have not been published in full or provide insufficient data to permit an estimate of the overall prevalence of sexual abuse in the bulimic groups they examined. Thus, they are acknowledged but not summarized in this review.

## STUDIES OF SEXUAL ABUSE IN THE GENERAL POPULATION

Given that few of the studies of bulimic patients had access to a control group of unselected, nonpatient women, it is instructive to examine for comparison some of the large studies of childhood sexual abuse in the general population. To ensure comparable methods across studies, we sought general population studies of sexual abuse that 1) were published, 2) were conducted in the United States, Canada, or the United Kingdom (the three countries where the bulimia studies we have mentioned were conducted), and 3) assessed the history of sexual abuse in all subjects by personal interview (as did all but three [7, 9, 13] of the bulimia studies we have reviewed). We found four large studies meeting these three criteria.

Russell (24, 32) examined a probability sample of 930 San Francisco women, using trained interviewers to administer a detailed questionnaire devoted to adverse sexual experiences. Remarkably, 357 (38%) of these women reported incestuous and/or extrafamilial sexual abuse involving physical contact before age 18; this figure rose to 504 (54%) when noncontact experiences were included. However, when analysis was restricted to women 18–36 years of age (an age range more closely comparable to that of bulimic patients in most studies), the figures were even higher: 43% for contact experiences and 59% for noncontact experiences (32) (table 2). Strikingly similar findings were subsequently reported by Wyatt (33), who conducted lengthy interviews with a probability sample of 248 African-American and white women, aged 18–36 years, in Los Angeles: 45% reported contact experiences and 62% noncontact experiences (table 2). If one looks exclusively at the data for the 122 white women in this study (a subsample more closely matched to the predominantly white composition of most bulimia groups), the figures are even higher: 51% and 67%, respectively. Bagley and Ramsay (34) studied 377 women representing a probability sample drawn from Calgary, Alta., Canada, as part of the follow-up of a mental health survey. At the end of an extensive interview regarding many aspects of mental health, the interviewers asked several questions about sexual abuse, which was narrowly defined. Of the women under 40 years of age, 28% reported such abuse (table 2). Ten additional women in the study answered "yes" to the initial question regarding "a serious sexual assault by an older person" but were unwilling to elaborate. These individuals were not included in the 28% figure.

Most recently, Finkelhor et al. (35) reported on a national telephone survey of 1,145 men and 1,481 women in the United States in which subjects were asked four specific questions about sexual abuse; the interviewers apparently had no specific training in this area or in psychiatry as a whole. Thus, the prevalence rates generated in this study might again be expected to be lower than would be elicited in face-to-face interviews by trained interviewers, as in the Russell and Wyatt studies. Nevertheless, the rate of sexual abuse elicited was 31% among women 18–39 years of age and remained at about 27% even when noncontact experiences were excluded (table 2).

In summary, then, among randomly chosen women comparable in age to those in groups of bulimic subjects, these four interview studies produced prevalence rates of 27%–51% for narrowly defined childhood sexual abuse by an older perpetrator and 31%–67% if noncontact experiences are included. The two studies that used detailed, face-to-face interviews by trained interviewers produced the highest figures, suggesting that the true prevalence of childhood sexual abuse in the general population may lie closer to the upper end of these ranges. For bulimic patients, as shown in table 2, reported prevalence rates fall well within the same ranges as those for the general population.

Although table 2 shows no differences in the prevalence of childhood sexual abuse between bulimic patients and the general population, it might still be argued that when abuse did occur, it was more severe, more protracted, or occurred at an earlier age in the former group (31, and personal communication from R. Pyle, March 1991). This possibility can be neither accepted nor rejected on the basis of published studies to date. However, given that bulimic patients apparently do not differ from the general population when intermediate or narrow definitions of sexual abuse are used, the burden of proof rests on those who suggest that a difference would nevertheless emerge with use of a very narrow definition, i.e., unusually severe or repeated abuse.

## METHODOLOGIC CONSIDERATIONS

The lack of differences in the prevalence of childhood sexual abuse between bulimic patients and the general population becomes even more impressive when it is considered that there are at least four potential sources of bias in studies of this nature, all of which might be expected to skew the findings in favor of higher abuse rates for bulimic patients than for control subjects. These factors are the following.

1. Detail of the information. Some of the studies of bulimic patients (2, 3, 18) derived information about sexual abuse from multiple interviews over a period of time during treatment, whereas the general population studies we have cited used never more than a single interview (24, 32, 33), and in two studies (34, 35), only a few questions. Given that a patient may not reveal a history of sexual abuse until she or he has formed a trusting relationship with a therapist—sometimes only after years of treatment (18)—it seems that the single-interview population studies might find lower rates of abuse than studies of bulimic patients in treatment, even if the two rates were actually the same.

A corollary consideration is that some individuals might have amnesia or "screen memories" for traumatic experiences of sexual abuse, causing the investigator to miss true cases. However, this source of error would affect individuals in the general population as well as patients with bulimia nervosa, and the latter, through their experience in therapy, might be more successful in retrieving suppressed memories than would untreated control subjects receiving only a single interview.

2. Lack of blind assessment. In only one study to date (19) were bulimic subjects assessed for sexual abuse by an individual blind to the diagnosis of eating disorder. Since most investigators presumably suspected a link between bulimia nervosa and sexual abuse, nonblind conditions leave open the risk that a rater might have unconsciously elicited or scored more sexual abuse for bulimic subjects than for persons known to be control subjects.

3. Effort after meaning. In a so-called "effort after meaning," patients with psychiatric disorders frequently search their past lives for some explanation of their distress (36). In one study, for example, 50% of depressed patients identified a life event or stressor as a cause of their condition, but after detailed clinical evaluation, this stressor was found to be a plausible cause in only 9% of the cases (37). By analogy, bulimic patients, particularly those who become aware of the sexual abuse hypothesis, may be more likely to remember and/or report childhood sexual abuse than control individuals who have less impetus for effort after meaning.

4. Familial psychiatric disorder. Family studies of bulimia nervosa have generally found substantially elevated rates of alcohol abuse and major mood disorders in the relatives of bulimic probands (38–43). Regardless of whether this phenomenon is genetic or environmental in origin, it seems that relatives with alcoholism or mood disorders would be more likely to abuse a child sexually than would relatives without psychiatric disorder. Indeed, in the study by Bulik et al. (19), as mentioned earlier, at least five of the 10 sexually abused bulimic patients were victimized by a relative with alcohol dependence and/or bipolar disorder. Therefore, even if bulimia nervosa were not *caused* by sexual abuse, one would still expect bulimia nervosa to be more frequently *associated* with sexual abuse because of the known association between bulimia nervosa and these familial psychiatric disorders. To argue that sexual abuse causes bulimia nervosa, one would have to demonstrate an elevated prevalence of sexual abuse among bulimic patients even after matching the control subjects for prevalence of familial alcoholism and mood disorder.

In summary, the four methodologic problems we have listed should be considered in the evaluation of any study of sexual abuse among persons with bulimia nervosa, since each would seem likely to bias the results in favor of a higher prevalence of childhood sexual abuse among these persons than among control subjects. Future studies should be designed to address these problems. A prospective study, for example, would almost automatically resolve problems 1–3 and could be constructed to address problem 4 at least partially. Future studies should also attend to the unresolved question, mentioned earlier, of whether particularly severe forms of sexual abuse, more prolonged abuse, or abuse occurring at a younger age might be more prevalent among those who develop bulimia nervosa than among those who do not.

## CONCLUSIONS

For both clinical and theoretical reasons, it is important to assess whether childhood sexual abuse is a risk factor for bulimia nervosa. To address this question, we attempted to review all quantitative studies of childhood sexual abuse among patients with bulimia nervosa, including both controlled and uncontrolled designs. We also reviewed methodologically comparable studies of childhood sexual abuse in the general population in order to compare these results with those for persons with bulimia nervosa.

Of six controlled studies, four found no significantly higher rating on any measure of childhood sexual abuse among bulimic subjects than among control subjects. The fifth study found a significantly higher prevalence of sexual abuse among bulimic patients than among control subjects, but when corrected for sex distribution, this difference also becomes nonsignificant. A sixth study found a significant difference between bulimic patients and normal control subjects, but the rates in the control group in this study were much lower than those in other studies.

Several uncontrolled studies have also reported high rates of childhood sexual abuse for bulimic patients. However, if one examines general population studies that used comparable methods, taking care to match definitions of sexual abuse as closely as possible, it emerges that rates of sexual abuse reported in the various studies of patients with bulimia nervosa compare closely to the range of rates reported in the population at large.

In addition, one must also take into consideration at least four methodologic factors in the designs of available studies which would be expected, if anything, to inflate the rate of childhood sexual abuse among patients with bulimia nervosa relative to that in the general population. Given these factors, the absence of elevated rates of childhood sexual abuse for patients with bulimia nervosa becomes even more striking. Thus, current evidence does not support the hypothesis that childhood sexual abuse is a risk factor for bulimia nervosa.

These conclusions should not be interpreted to mean that childhood sexual abuse is an unimportant issue in the therapy of bulimic patients. Such issues may be very important, but the therapist should be wary of the assumption that the abuse is the cause of bulimia nervosa or that treatment addressing the abuse will necessarily alleviate bulimic symptoms. It may be more profitable, both in therapy and in research, to direct our search toward other potential causes of bulimia nervosa and, perhaps even more urgently, toward understanding the origins of the high levels of childhood sexual abuse that apparently exist in our society as a whole.

# Nicotine Withdrawal Symptoms and Psychiatric Disorders: Findings From an Epidemiologic Study of Young Adults

Naomi Breslau, Ph.D., M. Marlyne Kilbey, Ph.D., and Patricia Andreski, M.A.

*Objective: Earlier, the authors reported on the association of nicotine dependence with major depression and anxiety disorders in a group of young adults. This report describes the occurrence of withdrawal symptoms and their sociodemographic and psychiatric correlates in persons in that group who tried unsuccessfully to abstain from smoking. Method: A random sample of 1,007 members of a health maintenance organization, 21–30 years old, were interviewed with a revised version of the NIMH Diagnostic Interview Schedule. Data on nicotine withdrawal came from a subset of 239 smokers who had tried unsuccessfully to quit or cut down on smoking. Results: With two exceptions, each of the DSM-III-R nicotine withdrawal symptoms was reported by more than one-half of these smokers. Withdrawal symptoms were more severe in white than in black smokers but were unrelated to sex, educational level, or marital status. Persons with histories of major depression or any anxiety disorder reported more severe withdrawal symptoms than persons with neither of these disorders. Severity of withdrawal, or any specific symptom, did not account for the association between major depression and continued smoking. Furthermore, severity of withdrawal was unrelated to continued smoking. Conclusions: While the long-term clinical significance of nicotine withdrawal is unclear, the evidence indicates that in the general population, abstinence from smoking is associated with a variety of disturbances, including a craving for cigarettes, dysphoria, and symptoms of irritability or nervousness. In this study disturbances were more severe in persons with histories of major depression or anxiety disorders.*

(Am J Psychiatry 1992; 149:464–469)

Although the discomfort of withdrawal is presumed to play a role in preventing cessation of drug use (1), the empirical support for this relationship among smokers is inconsistent (2–8). Little is known about factors associated with nicotine withdrawal symptoms in the general population. Studies of clinical samples have provided inconsistent findings on gender differences. While some studies have reported that women have more withdrawal symptoms than men, other studies have found no sex differences in severity of withdrawal (3, 4, 8). No associations have been found between withdrawal symptoms and age, marital status, educational level, or other socioeconomic status indicators (4). In contrast, two recent reports have suggested that smokers with histories of major depression experience more of the defining symptoms of nicotine withdrawal or more psychological distress, anger, and other disturbances that characterize withdrawal (7, 9). The greater withdrawal discomfort observed in persons with histories of major depression has been proposed as

the mechanism that accounts for the higher rates of smoking and lower rates of quitting among persons with depressive symptoms or major depression (7, 10–13).

Recently, we reported on the association of nicotine dependence, as defined in *DSM-III-R,* with major depression and anxiety disorders in an epidemiologic sample of young adults in the Detroit area (13). The study used the National Institute of Mental Health Diagnostic Interview Schedule (DIS) (14), revised according to *DSM-III-R,* to ascertain psychiatric and substance use disorders, smoking histories, and nicotine withdrawal symptoms. Persons with histories of nicotine dependence had higher lifetime rates of major depression and any anxiety disorder than persons who had never been nicotine dependent. Further, a history of major depression increased significantly the likelihood of continued smoking within the year preceding the interview. A history of any anxiety disorder was not associated with the persistence of smoking.

In this report, we examine the association of nicotine withdrawal with major depression and any anxiety disorder in this sample of young adults. The following questions are addressed. 1) What are the rates of individual nicotine withdrawal symptoms in a sample of the general population of young adults? 2) Does severity of withdrawal, defined by number of symptoms, vary by sex, race, educational level, or marital status? 3) Do persons with histories of major depression, an anxiety disorder, or alcohol or illicit drug abuse/dependence report more severe nicotine withdrawal or higher rates of specific withdrawal symptoms? 4) Does severity of withdrawal symptoms account for the association between a history of major depression and continued smoking?

## METHOD

The sample and method of measurement have been described in detail previously (13). Briefly, a random sample of 1,007 members of a large health maintenance organization in the Detroit area, who were 21–30 years old, were interviewed in 1989 with the DIS, revised to cover *DSM-III-R* diagnoses. Of the total sample, 61.7% (N=621) were female, 80.7% (N=813) were white, and 29.3% (N=295) were college graduates. Three hundred ninety-four (39.1%) of the respondents reported that they had smoked daily for a month or more at any time in their lives and were defined as smokers. Smoking daily for a month or more during the year preceding the interview was defined as continued smoking.

Information on withdrawal symptoms was elicited from all smokers who had ever tried unsuccessfully to quit or cut down on smoking. The revised DIS elicits information on the occurrence of 12 symptoms in the first day or so after quitting or cutting down. The list includes the defining symptoms of nicotine (or tobacco) withdrawal in both *DSM-III* and *DSM-III-R*. In addition, two symptoms not included in either *DSM*—tremor and feeling depressed—were included as experimental items.

The associations of a lifetime history of major depression and a lifetime history of any anxiety disorder with severity of withdrawal, measured by total number of withdrawal symptoms, were tested by using multiple regression analyses in which alcohol abuse/dependence and drug abuse/dependence were included as covariates. The unstandardized regression coefficients estimate the increase in withdrawal symptoms associated with each disorder independent of the other disorder and these covariates.

To examine whether nicotine withdrawal symptoms accounted for the association between major depression and continued smoking, a hierarchical multivariable logistic regression analysis was used. Two successive regressions were calculated. The first regression estimates the logistic odds for continued smoking associated with major depression, controlling for any anxiety disorder. The second regression adds the number of withdrawal symptoms to the equation and recalculates the logistic odds for continued smoking associated with major depression. A comparison of the coefficients of major depression in the first and second regressions can show whether withdrawal symptoms act as an intervening mechanism between major depression and continued smoking. Specifically, a marked reduction in the coefficient of major depression from the first to the second regression would support the proposition that withdrawal symptoms explain why those who have histories of major depression are more likely to continue to smoke than those without such histories. The exponential transformation of the logistic odds, calculated in the logistic regression, yields the odds ratio. The odds ratio estimates the multiplicative factor by which the dependent variable (i.e., continued smoking) is increased in persons with the suspected risk factor (i.e., history of major depression). An odds ratio greater than 1 indicates a greater rate of continued smoking among smokers with histories of major depression than among smokers with no prior history of major depression.

## RESULTS

Of the 394 persons who had ever smoked daily for a month or more, 241 (61.2%) reported that they had tried unsuccessfully at least once to quit or cut down on smoking. Information on the occurrence of each of 12 symptoms in the first day after quitting or cutting down on the number of cigarettes appears in table 1. (The analysis is for the 239 respondents for whom there were complete data on the relevant variables.) The rates of symptoms ranged from less than 10% (decreased heart rate, upset stomach) to 82% (craving for cigarettes). Of the seven symptoms that define nicotine withdrawal in *DSM-III-R,* that is, symptoms 1–7 in table 1, five were reported by more than 50% of the smokers who had tried unsuccessfully at least once to quit or cut down. In contrast, trouble concentrating was reported by 27.2%

and decreased heart rate by 9.6%. Although symptoms not included in *DSM-III-R* were generally less common, they were not rare. For example, feeling depressed was reported by 22.6%, and tremor and headache were reported by 16.3% and 18%, respectively.

The mean number of withdrawal symptoms reported by smokers who had ever tried unsuccessfully to quit or cut down was 3.9 (SD=1.9). Heavy smokers, that is, persons who smoked more than 20 cigarettes daily, reported more withdrawal symptoms than light smokers: 4.5 (SD=1.9) and 3.5 (SD=1.8), respectively (t=4.006, df=237, p=0.0001). Table 2 shows the number of withdrawal symptoms—an indicator of severity of nicotine withdrawal— reported by the smokers who had tried to quit, according to sex, race, educational level, and marital status. Severity of nicotine withdrawal was unrelated to sex, educational level, or marital status (p>0.05). It was, however, greater in white persons than in black persons.

Smokers with histories of major depression, any anxiety disorder, or alcohol or illicit drug abuse/dependence reported, on the average, more symptoms after abstinence than smokers with no history of psychiatric disorders (table 3). Because of the high rates of co-occurrence among these disorders, we used multiple regression analysis to test and estimate the association of major depression and any anxiety disorder with severity of withdrawal, holding constant other disorders. The results appear in table 4, where ordinary least squares unstandardized partial regression coefficients are presented. As can be seen in table 4, a history of major depression and a history of any anxiety disorder were associated with more severe withdrawal. Specifically, each disorder, independent of the other disorder and of alcohol or illicit drug use disorders, was associated with an increase of nearly one withdrawal symptom. Alcohol and illicit drug abuse or dependence were unrelated to severity of withdrawal when major depression and any anxiety disorder were held constant. There were no significant two-way interactions among these variables, nor did the addition to the model of sex and of other psychiatric disorders ascertained in the study (specifically, mania and dysthymia) alter these results or enhance the prediction of withdrawal severity.

To examine whether there were specific symptom patterns, apart from more severe withdrawal overall, associated with a history of major depression or any anxiety disorder, we examined the prevalence of individual symptoms in persons with histories of major depression only, any anxiety disorder only, both disorders, and neither disorder (table 5). Compared to persons with neither of the two disorders, persons with histories of major depression only, but not those with histories of anxiety only or both disorders, reported higher frequencies of decreased heart rate and drowsiness. In addition, the rates of trouble concentrating and feeling depressed following attempts to quit were higher among persons who had histories of major depression than among any other subset of smokers. Per-

| Feeling depressed | 19 | 16.7 | 5 | 33.3 | 18 | 27.3 | 12 | 27.3 |

sons with histories of anxiety only or anxiety plus major depression reported higher rates of irritability, nervousness, and restlessness than smokers with histories of major depression only or smokers with neither anxiety nor major depression. Persons with histories of both anxiety and major depression had the highest rates of craving for cigarettes, increased appetite, headache, upset stomach, and tremor, in addition to irritability and restlessness.

Although the differences were not significant in multiple tests of each subset against each of the other subsets, the data suggest the possibility that patterns of withdrawal symptoms might vary among smokers with histories of major depression and those with anxiety only or anxiety and major depression. A history of major depression only might dispose toward dysphoria and depressive symptoms such as concentration problems and feeling unaroused, whereas a history of anxiety might dispose to nervousness and restlessness.

Of the total subset of 239 smokers who reported ever having tried unsuccessfully to quit or cut down, 206 had continued to smoke in the year preceding the interview; the remaining 33 had not. Table 6 shows results from a hierarchical logistic regression analysis, with continued versus discontinued smoking as the dependent variable. In the first regression, it can be seen that when any anxiety disorder was controlled, major depression was associated with continued smoking. The odds ratio for continued smoking was 3.22 (95% confidence interval=1.04–9.94), indicating that smokers with histories of major depression were more than three times as likely to have continued smoking as smokers with no history of major depression. Any anxiety disorder was unrelated to continued smoking when major depression was controlled. The addition of severity of withdrawal symptoms in the second regression did not reduce materially the association between a history of major depression and continued smoking, as can be seen from a comparison of the coefficients for major depression in the first and second regressions. Further, severity of withdrawal symptoms was unrelated to continued smoking according to these results. A comparison of the number of withdrawal symptoms of those who continued to smoke and those who did not yielded similar results. The mean number of withdrawal symptoms was 4.3 (SD=2.2) among those who continued to smoke and 4.1 (SD=2.3) among those who did not, a nonsignificant difference.

| Any anxiety disorder | –0.523 | 0.392 | 0.18 | –0.555 | 0.400 | 0.17 |
| Withdrawal symptoms | | | | 0.037 | 0.092 | 0.69 |

We also examined whether feeling depressed after quitting or cutting down accounted for the association between major depression and continued smoking, but we found no evidence of an intervening role for this disturbance or for the cluster of withdrawal symptoms that was reported more frequently by persons who had histories of major depression, namely, feeling depressed, trouble concentrating, decreased heart rate, and drowsiness.

## DISCUSSION

The key findings of this analysis were the following. 1) The rates of withdrawal symptoms varied between 82% (craving for cigarettes) and 8.8% (upset stomach). 2) Symptoms not included in *DSM-III-R*, although generally less common than *DSM-III-R* withdrawal symptoms, were not rare, ranging in prevalence from 22.6% (feeling depressed) to 8.8% (upset stomach). 3) Severity of nicotine dependence, defined by the total number of withdrawal symptoms, was higher in white than in black persons but was unrelated to sex, educational level, or marital status. 4) Persons with histories of major depression or any anxiety disorder reported more severe nicotine withdrawal than persons with neither major depression nor any anxiety disorder. 5) There was no strong evidence that a history of major depression or any anxiety disorder was associated with distinct patterns of withdrawal symptoms, although the data suggest some trends. 6) Severity of withdrawal was unrelated to the continuation of smoking and did not emerge as the mechanism that might explain the greater persistence of smoking by persons with histories of major depression.

The interpretation of these findings should take into account the nature of the epidemiologic data on which they are based. Information was elicited on nicotine withdrawal experienced at any time, rather than in close temporal proximity to its occurrence, as in studies of clinical samples. The accuracy of these reports might therefore have been influenced by differences in lag time among respondents. Nonetheless, several important strengths should be emphasized. This is the first general population study of nicotine withdrawal symptoms and their relationships with psychiatric disorders. Previous studies have reported more severe withdrawal and lower rates of quitting among smokers with dysphoric symptoms or major depression (7, 9–13, 15). Our study has the advantage of a comprehensive coverage of these widely distributed phenomena, which, until now, have been examined only in selected subsets of the population, chiefly smokers who have sought treatment in specialized medical settings.

With one exception, each of the seven symptoms listed for *DSM-III-R* nicotine withdrawal was reported more frequently than any of the non-*DSM-III-R* symptoms. The exception was decreased heart rate, with a prevalence of 9.6%. Of the subset of 239 smokers who had ever attempted unsuccessfully to quit or cut down, 50.2% (N=120) reported four or more *DSM-III-R* withdrawal symptoms and thus met the criteria for nicotine withdrawal. There are no comparable data on *DSM-III-R* nicotine withdrawal in general population samples. However, Hughes's estimate (16) of the rate of common withdrawal symptoms among smokers who quit on their own—50%—is equal to our observed rate of nicotine withdrawal. Both of these rates are lower than the 68% rate of *DSM-III-R* nicotine withdrawal reported for tobacco-dependent subjects recruited for a clinical trial (4). We found also that persons with histories of major depression and those with any anxiety disorder were more likely than those with neither of these disorders to meet the diagnostic criteria for nicotine withdrawal: 67.8%, 60.9%, and 37%, respectively.

The finding that a history of major depression was associated with more severe withdrawal is consistent with previous reports from clinical samples. In addition, we found that a history of any anxiety disorder, but not a history of alcohol or illicit drug abuse/dependence, was associated with more severe withdrawal. It should be noted that the significant associations with major depression and with any anxiety disorder were each observed independent of the other disorder as well as of coexisting alcohol or illicit drug abuse/dependence. Our results on the relation of major depression to continuation of smoking are in accord with previous reports that a history of depressive symptoms or major depression was associated with smoking and failure to quit (7, 9–12). However, the notion that severity of nicotine withdrawal or the presence of specific withdrawal symptoms, such as depressed mood, accounted for this association was unsupported. Moreover, severity of nicotine withdrawal and rates of individual withdrawal symptoms were unrelated to whether or not smokers (those with histories of major depression and those without) had continued to smoke in the year preceding the interview. It should be noted that in regard to the relation between severity of withdrawal and smoking cessation, previous studies have yielded conflicting results. Associations were reported in some but not all short-term follow-up studies (2–4, 6, 7). If discomfort from withdrawal could be expected to affect smoking behavior only in the short run, that is, 24 hours to 4 weeks, as has been suggested (2, 6), our finding of no association should come as no surprise, since we defined discontinued smoking as abstinence for at least 1 year prior to the interview.

Clearly, the elucidation of the effect of withdrawal symptoms on subsequent smoking behavior requires prospective studies, in which smokers are examined at specified intervals with respect to their quitting and smoking behavior. Although our finding that severity of withdrawal symptoms does not account for continued smoking must be viewed within the limitation of the study design, it suggests that prior experience of nicotine withdrawal has negligible long-term consequences for smoking behavior. This observation is consistent with the conclusions drawn recently from the available data on the process of quitting by oneself (17). According to the evidence, smokers who quit successfully have usually made numerous previous attempts. The number of previous attempts (despite its obvious relation to failed attempts) is unrelated to long-term success in quitting. Thus, even if severity of withdrawal symptoms had an immediate adverse effect on the outcome of a particular attempt to quit, it could not be expected to influence the final outcome of subsequent attempts. The dynamic process of quitting and the independence of withdrawal experiences from long-term smoking behavior might apply to all smokers, including those with histories of major depression, whose withdrawal disturbances are more severe. What, then, might account for the greater liability for persistent smoking in those with histories of major depression? Clinical psychopharmacology studies have reported euphoric, arousing, and antianxiety effects of smoking and nicotine (18–22). We suggest that the greater likelihood of continued smoking among smokers with histories of major depression might be explained by the greater positive reinforcing effects of smoking, chiefly, mood elevation and arousal, rather than the reinforcing effects of nicotine on the relief of withdrawal discomfort (2). To date, there is no empirical evidence bearing on this hypothesis, which clearly merits examination in future research.

# Adrenergic Receptor Genes as Candidate Genes for Panic Disorder: A Linkage Study

Zhe Wu Wang, M.D., Raymond R. Crowe, M.D., and Russell Noyes, Jr., M.D.

*Objective: Several lines of investigation suggest that the noradrenergic neurotransmitter system may be involved in the pathogenesis of panic disorder. Since a mutation in a gene coding for one of the adrenergic receptors could account for both the familial nature and autonomic dysfunction of panic disorder, the authors performed analyses of the linkage between panic disorder and five adrenergic receptor loci. Method: The subjects were 14 multiplex pedigrees with* DSM-III *panic disorder or agoraphobia with panic attacks. The loci tested were the* $\alpha_1/\beta_2$ *pair on chromosome 5q32-q34, the* $\alpha_2/\beta_1$ *pair on chromosome 10q24-q26, and a second* $\alpha_2$ *locus on chromosome 4. Flanking loci were included in the analysis on chromosomes 5 and 10 to increase the informativeness of the adrenergic receptor loci. Results: Lod scores less than –2.0 were found at all five receptor loci. Conclusions: These findings provide strong evidence against the possibility that genetic mutation at any of these loci is responsible for panic disorder in these pedigrees.*

(Am J Psychiatry 1992; 149:470–474)

Noradrenergic dysfunction has been proposed as a mediating mechanism in anxiety and panic (1–4). The locus ceruleus and lateral tegmental noradrenergic afferents and efferents project to and from many areas of the brain that are thought to mediate the physiological and behavioral responses of fear (2, 5). In the monkey, stimulation of the locus ceruleus increases, and ablation reduces, fear-like behavior (6, 7). In humans, the noradrenergic system reaches maximal activity at the age when the incidence of panic disorder peaks (8). Many of the symptoms of panic attacks are suggestive of sympathetic nervous system excitation. Moreover, in patients with panic disorder, pharmacological stimulation of locus ceruleus outflow with yohimbine increases anxiety and norepinephrine turnover (9), and blocking of this outflow with clonidine reduces both (10). The tricyclic and monoamine oxidase inhibitor antidepressants may exert their antipanic effects by increasing available norepinephrine and by down-regulating postsynaptic noradrenergic receptors (11). The significantly lower density and greater affinity of lymphocyte β-adrenergic receptor binding sites (12) and the lower density of platelet $\alpha_2$-adrenergic receptor binding sites (13) in patients with panic disorder than in healthy subjects further implicate noradrenergic dysfunction in panic anxiety.

The actions of the noradrenergic system are mediated through two major classes of receptors, α and β. Two subtypes of each class (i.e., $\alpha_1$ and $\alpha_2$, $\beta_1$ and $\beta_2$) were initially classified on the basis of their pharmacologic properties (14). The $\alpha_2$, $\beta_1$, and $\beta_2$ receptors are coupled to the adenylate cyclase/cyclic AMP second messenger system. The $\beta_1$ and $\beta_2$ receptors stimulate adenylate cyclase and facilitate noradrenergic transmission, while $\alpha_2$ receptors act presynaptically to inhibit adenylate cyclase (14) and, through a major regulatory mechanism, reduce noradrenergic transmission (15). The $\alpha_1$ receptor acts through phospholipase C, primarily as a regulator of vascular tone (16). A recently identified $\beta_3$ receptor acts primarily to mediate the metabolic effects of catecholamines (17).

The adrenergic receptor genes are candidate genes for panic disorder because a genetic mutation could account for both the familial nature of panic disorder (18) and the evidence of noradrenergic dysfunction (1–4). This hypothesis can be tested by studying DNA probes for the adrenergic receptor genes as linkage markers in multiplex pedigrees of panic disorder. If the hypothesis is correct, it should be confirmed by a lod score supporting linkage, since genetic recombination between the disease and the gene responsible for it would not be expected to occur. Conversely, a negative lod score and the presence of obligate recombinants (i.e., affected individuals in the same family who do not share an allele at the candidate gene locus) would be strong evidence against the candidate gene hypothesis.

DNA probes for five adrenergic receptor loci were included in the study: the $\alpha_1$ locus (*ADRA1*), an $\alpha_2$ locus on chromosome 10 (*ADRA2*) and one on chromosome 4 (*ADRA2L2*), $\beta_1$ (*ADRB1*), and $\beta_2$ (*ADRB2*). The $\alpha_1$ and $\beta_2$ loci map to chromosome 5q32-q34, where physical mapping places them 300 kilobases apart, and $\beta_1$ and an $\alpha_2$ locus map to chromosome 10q24-q26 within a 250-kilobase region (19).

DNA markers for four additional loci were included in the analyses: *D10S20* and *D10S27,* which flank the $\alpha_2$ and $\beta_1$ loci on chromosome 10 (20 and unpublished 1989 study by M.R. Hoehe et al.), and *D5S70* and *D5S36,* which flank the $\alpha_1$ and $\beta_2$ loci on chromosome 5 (20, 21, and personal communication from M.R. Hoehe). These loci were added to increase the informativeness of the adrenergic receptor probes on those two chromosomes. Not included in the study was a $\beta_3$ locus (17) and a third $\alpha_2$ locus on chromosome 2 (22). The action of the former is thought to be limited to the metabolic effects of catecholamines (17), and the latter is not expressed in brain (23); therefore, neither gene is a candidate for panic disorder.

## METHOD

### *Clinical Methods*

Fourteen pedigrees with panic disorder were ascertained on the basis of 1) a *DSM-III* diagnosis of panic disorder (N=2) or agoraphobia with panic attacks (N=12) in the proband, 2) at least three family members affected with panic disorder, definite or probable, or agoraphobia with panic attacks, and 3) unilateral disease transmission. The mean age of the 14 probands was 34.7 years (range=14–55), and 11 of the 14 were female. The mean age at onset was 23.4 years (range=8–35). These pedigrees have been reported on previously (24), but new family members have been added since that report.

Interviews were done by experienced clinicians (psychiatrists or senior residents) using the Schedule for Affective Disorders and Schizophrenia—Lifetime Version (SADS-L) (25) for eight pedigrees and the Structured Clinical Interview for DSM-III (SCID) (26) for six. The structured interview was supplemented by a narrative summary and medical records when available. All of the subjects who were phenotyped and thus contributed to the lod scores of the linkage analyses were personally interviewed. Uninterviewed relatives who served as connecting links within the pedigrees were diagnosed through family history, as described elsewhere (24). These individuals did not contribute to the lod scores. Written informed consent was obtained from all participants.

Diagnoses were made by two of us (R.R.C. and R.N.) with *DSM-III* criteria after the interviews and narratives were reviewed, as described elsewhere (24). In addition, diagnoses of probable panic disorder were made for subjects who reported panic attacks but lacked a sufficient number of criterion symptoms or frequency of attacks to meet the criteria for a definite diagnosis. Similarly, diagnoses of probable agoraphobia were made for those with phobic symptoms but insufficient avoidance to meet the criteria for that diagnosis. All of the subjects with agoraphobia, definite and probable, had panic attacks. Clinical assessments were made blind to the genetic marker phenotypes.

We entered 186 individuals in the 14 pedigrees into the linkage analysis. DNA was typed for 154 pedigree members, 68 of whom were classified as affected: 21 with panic disorder (14 definite and seven probable) and 47 with agoraphobia with panic attacks (42 definite and five probable). Subjects who had the following additional primary diagnoses in the anxiety/affective disorders spectrum were coded as unaffected in the linkage analyses: major depression (N=8), alcohol abuse (N=8), substance use disorder (N=1), social phobia (N=2), obsessive-compulsive disorder (N=1), generalized anxiety disorder (N=1), atypical anxiety disorder (N=1), dysthymic disorder (N=1), and bipolar affective disorder (N=1).

### *Laboratory Methods*

DNA was extracted from buffy coats or lymphoblastoid cell lines by phenol-chloroform extraction and digested with restriction enzymes according to the recommendations of the manufacturer (Bethesda Research Labs, Inc., Bethesda, Md.). The digested samples were electrophoresed in 0.8% agarose gels in 1 X TPE (0.09 M Tris-phosphate, 0.002 M EDTA) and transferred to charged nylon membranes (Zetabind; AMF Cuno, Inc., Meriden, Conn.) according to the recommendations of the manufacturer. Probes were labelled with [$\alpha$-$^{32}$P]dCTP by using the random primer method and a commercial kit (Amersham, Inc., Arlington Heights, Ill.) and were hybridized with the membranes for 24 hours according to the recommendations of the manufacturer (AMF Cuno, Inc.). The membranes were washed with three 5-minute low-stringency washes (2 X standard saline citrate [SSC], 0.1% sodium dodecyl sulfate [SDS]) and one 20-minute high-stringency wash (0.1 X SSC, 0.1% SDS, 55 °C) and exposed to Kodak XAR-5 film (Eastman Kodak, Rochester, N.Y.) for 48 hours with image intensifier screens.

Five adrenergic receptor clones were provided by Dr. Robert Lefkowitz, Howard Hughes Medical Institute, Duke University Medical Center. The $\alpha_2$ chromosome 4 probe (pADRA2RL2) detects a two-allele *Bsu*36I RFLP (restriction fragment length polymorphism) (27), the $\alpha_2$ chromosome 10 probe (HPalpha2GEN) detects a two-allele *Dra*I RFLP (28), a $\beta_1$ clone (clone 11) detects a two-allele *Bgl*I RFLP (29), and the $\beta_2$ clone (pTF3) detects a two-allele *Ban*I RFLP (30). No RFLPs have been detected with the $\alpha_1$ clone (ARalpha).

Three of the four probes for the flanking loci were from the American Type Culture Collection, Rockville, Md. The *D5S70* probe (pTP5E) detects a two-allele *Taq*I RFLP; the *D5S36* probe (JO157E-A) detects a two-allele *Msp*I RFLP; the *D10S20* probe (OS-3) detects a three-allele *Taq*I RFLP, and the *D10S27* probe (cTBQ4, Howard Hughes Medical Institute, University

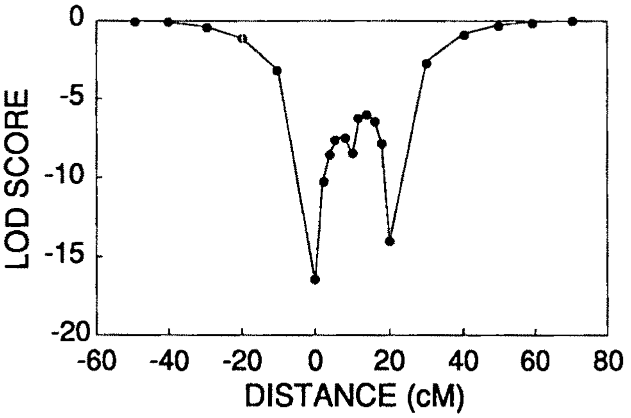
[a] Lod scores calculated with program LIPED (IBM PC/AT version, 1988). Genetic model included subjects with both definite and probable diagnoses of *DSM-III* panic disorder or agoraphobia with panic attacks and assumed a disease allele frequency of 0.014 and penetrance from 0 at age 10 increasing to a maximum of 0.80 at age 40 in females and half that at each respective age in males. The $\alpha_1$ locus is not polymorphic and does not appear here.

[b] Chromosome 4 locus.

[c] Chromosome 10 locus.

**FIGURE 1. Lod Scores for Linkage Between Panic Attacks and Three Loci on Chromosome 10q24-q26 in 14 Pedigrees[a]**



[a] The *D10S20* locus is arbitrarily set at 0 centimorgans (cM), $\alpha_2$ at 10 cM, and *D10S27* at 20 cM. Physical mapping data would place $\beta_1$ at approximately 10 cM. The genetic model included subjects with both definite and probable diagnoses of *DSM-III* panic disorder or agoraphobia with panic attacks and assumed a disease allele frequency of 0.014 and penetrance from 0 at age 10 increasing to a maximum of 0.80 at age 40 in females and half that at each respective age in males. The female-to-male recombination ratio is 2:1. The graph is a composite of two three-point analyses of panic disorder/agoraphobia with each successive pair of loci.

of Utah Medical Center) detects a two-allele *Msp*I RFLP. The DNA phenotypes were interpreted without knowledge of the diagnoses.

### *Statistical Methods*

Lod scores for linkage were computed with the program LIPED (IBM PC/AT version, 1988) for two-point analysis and the LINKMAP program of LINKAGE (version 5.04) for multipoint analysis. The female-to-male recombination ratio was set as 2:1 on chromosome 10 ($\alpha_2$ and $\beta_1$) and 5:1 on chromosome 5 ($\alpha_1$ and $\beta_2$) (20). The genetic model assumed an autosomal dominant disease allele with age- and sex-dependent penetrance and was informed by a segregation analysis of panic disorder in the Iowa population (31). Five variations of this model were tested.

Model 1 assumed subjects with both definite and probable cases of panic disorder or agoraphobia to be affected, a disease allele frequency of 0.014, and penetrance of 0 at age 10 increasing to a maximum of 0.80 at age 40 in females and half that at each respective age in males.

Model 2 used the same conditions as model 1 but included only definite cases of panic disorder and agoraphobia.

Models 3, 4, and 5 assumed the maximum penetrance to be 0.99, 0.60, and 0.01, respectively. These models, together with model 1, examined the effect of varying penetrance from 60% to 99% on the lod score to determine how robust the findings were to assumptions about penetrance. Model 5 based the lod score on affected individuals, eliminating assumptions about penetrance from the results.

## RESULTS

The results of the linkage analyses are presented in table 1 under genetic model 1. Since the adrenergic receptor loci were tested as candidate genes, the lod scores at the recombination fraction of 0.00 reflected the likelihood of linkage at each locus. The $\alpha_2$ locus on chromosome 4 resulted in a lod score of –6.04. The lod score at the $\alpha_2$ locus on chromosome 10 was –3.68. The $\beta_1$ locus was essentially uninformative, with a lod score of –0.65.

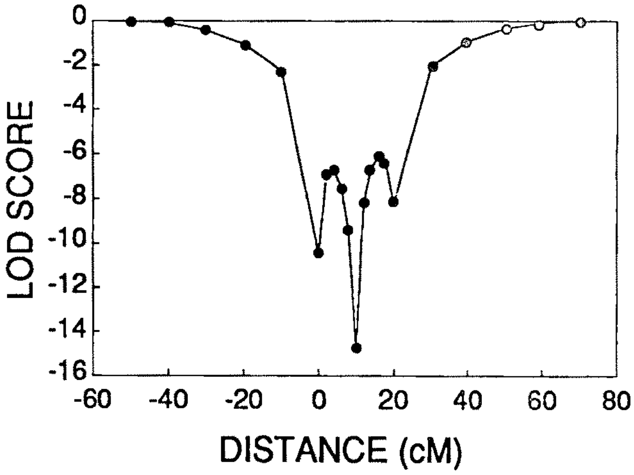
However, the $\beta_1$ locus is only 225 kilobases from the chromosome 10 $\alpha_2$ locus, and both loci lie between the *D10S20* and the *D10S27* loci. Therefore, multipoint analyses of these loci were performed to increase the informativeness of the $\beta_1$ locus. The two flanking markers were placed 20 centimorgans (cM) apart, and the $\alpha_2$/$\beta_1$ pair was arbitrarily set 10 cM from each flanking locus (20 and unpublished study by M.R. Hoehe et al.). The genetic model was model 1, and the female-to-male recombination ratio was assumed to be 2:1 (20). Figure 1 shows a lod score graph of two three-point analyses (panic disorder, *D10S20*, $\alpha_2$; and panic disorder, *D10S27*, $\alpha_2$). Lod scores less than –5.0 were obtained across the entire region in which the $\alpha_2$ and $\beta_1$ loci are located.

Similarly, a multipoint analysis was performed across the $\alpha_1$ and $\beta_2$ loci on chromosome 5 because the $\alpha_1$ clone is not informative for linkage. The $\alpha_1$ and $\beta_2$ loci are 300 kilobases apart and are flanked by the *D5S36* and *D5S70* loci, which lie 20 cM apart (20, 21). The $\beta_2$ locus is tightly linked to the probe cKK5.19 (M.R. Hoehe, personal communication), which lies between *D5S36* and *D5S70* (21). Therefore, we set *D5S36* and *D5S70* at 0 and 20 cM, respectively, and arbitrarily placed the $\alpha_1$ and $\beta_2$ loci at 10 cM on the map. Two three-point analyses were performed (panic disorder, *D5S36*, $\beta_2$; and panic disorder, *D5S70*, $\beta_2$). The genetic model was model 1, and the female-to-male recombination ratio was assumed to be 5:1 (20). The results are shown graphically in figure 2, and it can be seen that lod scores less than –6.0 were obtained across the entire region in which the $\alpha_1$ and $\beta_2$ loci are found.

The influence of assumptions about penetrance on the results was tested with four additional sets of analyses by varying penetrance from 0.01 to 0.99. All four resulted in negative lod scores at all four loci tested. The least informative model was the one that assumed a penetrance of 0.01, since this analysis discounted information on unaffected pedigree members. It resulted in the following lod scores at a recombination distance of 0.00: –2.53 at the $\alpha_2$ chromosome 4 locus, –2.18 at the $\alpha_2$ chromosome 10 locus, –6.77 at the $\beta_2$ locus, and –0.59 at the $\beta_1$ locus. The last analysis considered only subjects with definite diagnoses of panic disorder or agoraphobia as affected and classified subjects with probable diagnoses as unaffected. Lod scores at the four respective loci were –4.57, –2.86, –10.10, and –0.67. With the flanking markers, lod scores less than –2.0 were obtained at all four loci in both sets of analyses. These results indicate that the lod scores obtained in the primary analysis were not dependent on assumptions about clinical phenotype or gene penetrance.

The data were not tested for heterogeneity because there was no evidence of it on inspection of the lod scores by pedigree. At the $\alpha_2$ and $\beta_1$ loci on chromosome 10 all informative lod scores were negative. At the $\alpha_2$ locus on chromosome 4 one pedigree had a lod score of +0.76 and two had lod scores of +0.15. At the $\beta_2$ and $\alpha_1$ loci on chromosome 5 one pedigree had a lod score of +0.25. While linkage cannot be excluded in these pedigrees, lod scores of this magnitude are well within the bounds of chance.

**FIGURE 2. Lod Scores for Linkage Between Panic Attacks and Three Loci on Chromosome 5q32-q34 in 14 Pedigrees**[a]



[a]The *D5S36* locus is arbitrarily set at 0 centimorgans (cM), $\beta_2$ at 10 cM, and *D5S70* at 20 cM. Physical mapping data would place $\alpha_1$ at approximately 10 cM. The genetic model included subjects with both definite and probable diagnoses of *DSM-III* panic disorder or agoraphobia with panic attacks and assumed a disease allele frequency of 0.014 and penetrance from 0 at age 10 increasing to a maximum of 0.80 at age 40 in females and half that at each respective age in males. The female-to-male recombination ratio is 5:1. The graph is a composite of two three-point analyses of panic disorder/agoraphobia with each successive pair of loci.

## DISCUSSION

We found strong evidence against linkage between panic disorder and any of the five adrenergic receptor loci tested. This conclusion holds true regardless of whether panic disorder is defined broadly, to include borderline cases, or narrowly, to include only definite diagnoses. The findings also remain valid across a variety of genetic models, varying penetrance from 0.01 to 0.99. Obligate recombinants, i.e., two or more affected individuals in the same family who share neither allele at the candidate gene locus, were noted at all three informative loci: $\alpha_2$ on chromosome 10, $\alpha_2$ on chromosome 4, and $\beta_2$. Since these individuals were all affected, the apparent recombination could not have resulted from incorrect classification due to incomplete penetrance. While obligate recombinants constitute strong evidence against linkage to a candidate gene, this evidence rests on the assumption that only one disease allele is segregating in each pedigree.

While the results argue against mutation of any of these adrenergic receptors as a cause of panic disorder, several considerations should be kept in mind when interpreting the results in light of the noradrenergic hypothesis of panic disorder. Receptors represent only one link in the chain of neurotransmission. Defects in cell signaling occurring before the receptor or in second messenger systems after the receptor could still be at fault. Up- or down-regulation of receptors resulting from differences in gene expression could also be involved in the modulation of anxiety, and such abnormalities in gene regulation would not be detectable through linkage.

Another consideration is the broad heterogeneity of receptor subtypes in the CNS (32). In addition to the five adrenergic receptor loci tested, a $\beta_3$ receptor has been reported (17), as well as an additional $\alpha_2$ sequence on chromosome 2 (22). While neither of these genes appears to be a reasonable candidate for mediating behavior, other receptor subtypes that are candidates may yet be identified.

A third consideration is the possibility that panic disorder is etiologically heterogeneous. If a genetic mutation in an adrenergic receptor gene were a rare cause of panic disorder, this would be difficult to detect by linkage because the detection of linkage typically requires pooling data across pedigrees. For this reason the lod scores from the individual pedigrees at each locus tested were examined, and no evidence of linkage in any pedigree was found.

# Comorbidity of Parental Anxiety Disorders as Risk for Childhood-Onset Anxiety in Inhibited Children

Jerrold F. Rosenbaum, M.D., Joseph Biederman, M.D., Elizabeth A. Bolduc, B.A., Dina R. Hirshfeld, M.A., Stephen V. Faraone, Ph.D., and Jerome Kagan, Ph.D.

*Objective: Previous work suggested that children of parents with panic disorder and agoraphobia were likely to be classified as behaviorally inhibited and that behaviorally inhibited children were likely to develop anxiety disorders. However, the factors determining which inhibited children were at risk for childhood onset of anxiety disorders remained unknown. The authors of this study hypothesized that greater anxiety loading in parents would increase the risk for anxiety disorders in children with behavioral inhibition. Method: Using* DSM-III *structured interviews, the authors examined patterns of aggregation of anxiety disorders in parents of two existing cohorts of children, one cross-sectional and clinically derived (31 children, 60 parents) and the other epidemiologically derived and longitudinal (40 children, 75 parents). Within each cohort, parents were stratified into three groups based on the presence (behavioral inhibition and anxiety) or absence (behavioral inhibition only, no behavioral inhibition and no anxiety) of behavioral inhibition and two or more anxiety disorders in their child. Results: Parents of children with behavioral inhibition and anxiety, from both the clinical and nonclinical cohorts, had significantly higher rates of two or more anxiety disorders than did parents of children with behavioral inhibition only and parents of children with no behavioral inhibition and no anxiety. Conclusions: These results indicate that the presence of parental loading for anxiety disorders may help to identify the subgroup of inhibited children at very high risk for developing childhood-onset anxiety disorders.*

(Am J Psychiatry 1992; 149:475–481)

In a recent report from the Institute of Medicine (1), the identification of early risk factors for childhood psychopathology was deemed a high priority for psychiatry research. One potential risk factor is temperamental differences among young children. A well-characterized temperamental construct is that termed by Jerome Kagan and colleagues of the Harvard Infant Study Laboratory as "behavioral inhibition to the unfamiliar" (2, 3). This laboratory-based temperamental construct is characterized by the consistent tendency to display fear and withdrawal in situations that are novel or unfamiliar (4). Behavioral inhibition can be identified at an early age; for example, in a recent report (5), behavioral inhibition at 14 months of age was predicted by responses to stimuli in children as young as 4 months of age.

Rosenbaum et al. (6) previously reported high rates of behavioral inhibition in young children of parents with panic disorder and agoraphobia. Further (7), they found that parents of behaviorally inhibited children from a nonclinical cohort studied by Kagan et al. (4) were also at greater risk for anxiety disorders, mainly social phobia. Biederman et al. (8) reported that children of parents with panic disorder and agoraphobia were also at greater risk for childhood anxiety disorders. These findings, taken together, are consistent with the literature implicating family-genetic risk factors in the development of anxiety disorders (9–17). Biederman et al. (18) showed that the risk for pathological anxiety, particularly when strictly defined by the presence of two or more anxiety disorders in the child, fell exclusively among those with behavioral inhibition and not among those without behavioral inhibition (20% versus 0%), regardless of whether the children were from a clinical or nonclinical population. Overall, these findings point to behavioral inhibition as a reflection of

the familial risk for anxiety, but the factors that determine the development of anxiety disorders in inhibited children require further investigation.

We reasoned that if inhibited children who already manifest anxiety disorders have a more severe anxiety diathesis, they may have greater familial loading for anxiety risk factors than those who manifest behavioral inhibition alone. Following a model of familial transmission proposed by Reich (19, 20), a more severe phenotype (i.e., behavioral inhibition and anxiety disorders) would require more familial etiological factors for its expression than would the less severe form (i.e., behavioral inhibition alone). Since anxiety disorders tend to manifest themselves concomitantly, greater familial loading for anxiety disorders could express itself as two or more anxiety disorders in the parents. Thus, it is plausible that inhibited children with anxiety disorders will have greater loading for an anxiety diathesis, manifested by the presence of two or more anxiety disorders in the parents, than will children with behavioral inhibition alone. This research question remains unanswered.

## METHOD

We examined patterns of childhood- and adult-onset psychiatric disorders in parents of two independently ascertained, previously described, and preexisting cohorts of children. One cohort was cross-sectional and clinically derived (a general hospital at-risk cohort) (18), and the other was epidemiologically derived and longitudinal (Kagan et al. longitudinal cohort) (18). Detailed methodology of the ascertainment of the groups has been described in earlier reports (4, 6–8, 18). All parents signed informed consent forms for participation in this study.

### *At-Risk Cohort*

The at-risk group consisted of children (2 to 7 years) of outpatient parents with panic disorder and agoraphobia treated at the department of psychiatry of a general hospital and children with relatives without panic disorder and agoraphobia treated at the same outpatient clinic. Only those children who were assessed for behavioral inhibition and who were old enough to be assessed for psychopathology (4 years or older) (index children: N=31, parents: N=60) are included in this analysis. Before the assessment of behavioral inhibition, these eligible children were matched for age, socioeconomic status, and ordinal position with the comparison group of children who had relatives with other psychiatric disorders.

Assessments of behavioral inhibition were conducted at a university infant study laboratory. The evaluation consisted of a series of age-appropriate cognitive tasks following protocols that had been developed and used in other studies of behavioral inhibition (2, 4, 21–23). These protocols were designed to obtain an index of each child's behavior with an unfamiliar examiner under mild cognitive stress. The observations of the protocol sessions were videotaped and scored by coders who had no knowledge of parental diagnosis. On the basis of these observations, children were dichotomized into two mutually exclusive categories, inhibited and not inhibited. Children were assigned to the inhibited and not inhibited groups by an investigator who was blind to the assessment of psychopathology in the children and in their parents.

### *Longitudinal Cohort*

The longitudinal cohort is a well-described (2, 4, 21–23), preexisting cohort consisting of 40 index children between the ages of 7 and 8 years at the time of the assessment of psychopathology (parents: N=75). These children had been selected originally at age 21 months from a larger group of 305 Caucasian children born in local hospitals whose mothers, responding to questions in a telephone interview, had described their children as tending to be either inhibited (manifesting withdrawal) or uninhibited (displaying approach) in a range of situations. On the basis of these interviews, 117 children came to a laboratory where their behavior was observed and quantified in a variety of unfamiliar settings. The children who consistently displayed the major behavioral signs of inhibition (i.e., long latencies to interact with unfamiliar adults and cessation of play or vocalization), as well as those who consistently did not, were selected to form groups of the most inhibited (inhibited) and the most uninhibited (uninhibited) children. Each group represented about 10% to 15% of the original cohort. The children we assessed were all of those who had been studied longitudinally through the age of 7.5 years by Kagan and colleagues since their initial assessment and assignment to the inhibited and uninhibited groups at 21 months. We did not have access to those children who did not continue to be studied longitudinally.

### *Assessment of Psychopathology*

As described in earlier reports (6–8, 18), all children 4 years of age and older were assessed by interviews with the mothers that used the Diagnostic Interview for Children and Adolescents, Parent Version (24–26), a structured instrument that is based on diagnostic criteria from *DSM-III*. Rated *DSM-III* childhood anxiety disorders were separation anxiety disorder, overanxious disorder, avoidant disorder, and phobic disorders.

Assessments of parents were based on direct interviews that used the National Institute of Mental Health Diagnostic Interview Schedule (DIS) (27) to assess anxiety disorders (panic disorder, agoraphobia, social phobia, simple phobia, and obsessive-compulsive disorder) and major depressive disorder. An addition from the Diagnostic Interview for Children and Adolescents (24) was included to assess past childhood anxiety diagnoses (separation anxiety disorder, overanxious disorder, and avoidant disorder) in the parents.

All interviews were conducted by specially trained raters with graduate or undergraduate degrees in psychology and with established interrater reliability (overall kappa=0.88, SD=0.04). The training consisted of familiarization with the study design and objectives, psychiatric nosology of *DSM-III,* and the structured interviews used (the Diagnostic Interview for Children and Adolescents, Parent Version, and the DIS). Raters in training first observed interviews carried out by experienced raters and clinicians and subsequently conducted at least two interviews while being observed by senior raters before they started to rate subjects independently. Raters were supervised by the two senior investigators (J.F.R. and J.B.). Interviews were audiotaped for random review and reliability assessments. Raters were blind to the temperamental classification of the children and final diagnoses of the parents. Raters were not blind to ascertainment site. Before final diagnostic assignment, all diagnostic information was reviewed by the first two authors, who also were blind to the temperamental classification of the children. Only definite diagnoses were used to determine rates of disorders. Rates of disorders presented reflect lifetime prevalences.

Since meeting criteria for a single anxiety disorder in a structured interview that assesses multiple disorders may sacrifice specificity for sensitivity and thus may not reflect serious and clinically applicable psychopathology, and since the anxiety disorders tend to occur concomitantly (28, 29), we have previously proposed that a more clinically meaningful variable would be defined by the presence of two or more concomitant anxiety disorders, termed multiple anxiety disorders (6–8, 18). Thus, in parents we assessed multiple anxiety disorders (in adult or childhood), multiple adult anxiety disorders, and multiple childhood anxiety disorders, and in children we assessed multiple childhood anxiety disorders. We also examined the presence of multiple anxiety disorders in parents from a developmental perspective as expressed by the manifestation of a childhood-onset anxiety disorder followed by an adult-onset anxiety disorder in the same person, termed continuing anxiety disorder.

### *Data Analysis*

Data were analyzed separately for each ascertainment group (at-risk cohort and longitudinal cohort). At each site, we stratified children into the following three groups on the basis of the presence or absence of behavioral inhibition and multiple (two or more) anxiety disorders (hereafter termed anxiety): 1) behavioral inhibition and anxiety, 2) behavioral inhibition only, and 3) no behavioral inhibition and no anxiety. There were no children in either cohort who were not inhibited and who met criteria for multiple anxiety disorders (anxiety only).

Statistical analyses were made among groups within each ascertainment cohort (at-risk cohort and the longitudinal cohort). For categorical data, 3×2 chi-square comparisons were made, followed by 2×2 comparisons using Fisher's exact test. For overall group comparisons involving continuous data, the nonparametric Kruskal-Wallis analysis was used. In cases where this overall comparison was significant, the Mann-Whitney U test was used for pairwise comparisons among groups. All analyses were two-tailed, and results were considered statistically significant if the p value was less than 0.05.

**TABLE 1. Hypothesized Risk for Anxiety Disorders and Behavioral Inhibition in Children of Parents With Multiple[a] Anxiety Disorders**

| | Hypothesized Risk in Children[b] | | |
|---|---|---|---|
| Parental History of Multiple[a] Anxiety Disorders | Behavioral Inhibition and Multiple[a] Anxiety Disorders | Behavioral Inhibition Only[c] | Neither |
| Any | ++ | + | — |
| Childhood | ++ | + | — |
| Adult | ++ | + | — |
| Childhood and adult | ++ | + | — |

[a] Two or more.

[b] ++=Very high risk, +=high risk, —=low risk.

[c] No multiple anxiety disorders.

### *Study Hypothesis*

We predicted that behaviorally inhibited children with anxiety would have greater loading than behaviorally inhibited children without anxiety for an anxiety diathesis, manifested by the presence of multiple anxiety disorders in the parents (table 1). Accordingly, we also expected parents of children with behavioral inhibition but no early onset of anxiety to be at intermediate risk between those with behavioral inhibition and anxiety and those with neither behavioral inhibition nor anxiety.

## RESULTS

### *At-Risk Cohort*

The sociodemographic characteristics of the parents and children in this cohort are displayed in table 2. There were no significant differences in age or sex among the children in each of the three groups. In addition, there were no differences in age, socioeconomic status, sex, and marital status among the parents of these three groups.

Three-way comparisons among parents of children with behavioral inhibition and anxiety, behavioral inhibition only, and no behavioral inhibition and no anxiety revealed statistically significant differences in the rates of two or more anxiety disorders (87.5% versus 32.1% versus 20.8%; $\chi^2$=11.91, df=2, p=0.003), two or more adulthood anxiety disorders (75.0% versus 28.6% versus 8.3%; $\chi^2$=13.74, df=2, p=0.001) (table 3), panic disorder with agoraphobia (75.0% versus 28.6% versus 12.5%; $\chi^2$=10.91, df=2, p=0.004), and the comorbid condition of panic disorder and agoraphobia with major depressive disorder (50.0% versus 10.7% versus 12.5%; $\chi^2$=7.41, df=2, p=0.025). Follow-up pairwise comparisons revealed that these findings were accounted for by the higher

[a] Two or more.
[b] Significant difference between cohorts (longitudinal: $\chi^2$=7.88, at risk: $\chi^2$=11.91, df=2, p<0.05).
[c] Significant difference within the longitudinal sample ($\chi^2$=9.24, df=2, p<0.05).
[d] Significant difference between cohorts (longitudinal: $\chi^2$=6.86, at risk: $\chi^2$=13.73, df=2, p<0.05).
[e] Significantly different from two other groups in the cohort (p<0.05, Fisher's exact test).
[f] No multiple anxiety disorders.
[g] Significantly different from same cohort group with no behavioral inhibition or multiple anxiety disorders (p<0.05, Fisher's exact test).

rate of these disorders in the parents of children with behavioral inhibition and anxiety than in the parents of children with behavioral inhibition only and no behavioral inhibition and no anxiety. Although parents of the children with behavioral inhibition only had substantially (1.5 to 3.5 times) higher rates of all multiple anxiety disorders than the parents of the children with no behavioral inhibition and no anxiety, these differences failed to attain statistical significance. The differences among the groups appear to be specific to anxiety disorders, since the rates of major depressive disorder did not differ among the three groups (50.0% versus 39.3% versus 33.3%; p>0.05).

### *Longitudinal Cohort*

The sociodemographic characteristics of the parents and children in this cohort are displayed in table 2. There were no significant differences in age or sex among the children in each of the three groups. Although there were small but statistically significant differences for socioeconomic status in parents, there were also no differences in age, sex, or marital status among the three groups of parents. The difference in socioeconomic status was accounted for by the higher socioeconomic status in the behavioral inhibition and anxiety group than in the group with behavioral inhibition only.

Three-way comparisons among parents of children with behavioral inhibition and anxiety, behavioral inhibition only, and no behavioral inhibition and no anxiety revealed statistically significant differences in the rates of two or more anxiety disorders (50.0% versus 18.8% versus 8.6%; $\chi^2$=7.88, df=2, p=0.02), two or more childhood anxiety disorders (37.5% versus 9.4% versus 2.9%; $\chi^2$=9.24, df=2, p=0.009), two or more adulthood anxiety disorders (25.0% versus 3.1% versus 2.9%; $\chi^2$=6.86,

[c] Significant difference among groups ($\chi^2$=21.78, df=2, p<0.05).
[d] Significant difference among groups ($\chi^2$=10.04, df=2, p<0.05).
[e] Significantly different from other two groups (p<0.05, Fisher's exact test).
[f] Significantly different from group with no behavioral inhibition or multiple anxiety disorders (p<0.05, Fisher's exact test).
[g] No multiple anxiety disorders.

df=2, p=0.03), continuing anxiety disorder (37.5% versus 18.8% versus 5.7%; $\chi^2$=6.00, df=2, p=0.05) (table 3), social phobia (50.0% versus 9.4% versus 0%; $\chi^2$=19.24, df=2, p<0.001), and the comorbid condition of social phobia and major depressive disorder (12.5% versus 0% versus 0%; $\chi^2$=8.49, df=2, p=0.02). Follow-up pairwise comparisons revealed that these findings were accounted for by the higher rate of these disorders in the parents of children with behavioral inhibition and anxiety than in the parents of children with behavioral inhibition only and/or no behavioral inhibition and no anxiety. As in the at-risk cohort, although parents of the children with behavioral inhibition only had substantially (2.2 to 3.2 times) higher rates of all multiple anxiety disorders than parents of children with no behavioral inhibition and no anxiety, these differences failed to attain statistical significance. The differences among the groups appear to be specific to the anxiety disorders, since the rate of major depressive disorder did not differ among the three groups (12.5% versus 18.8% versus 14.3%, p>0.05).

### *Exploratory Data Analysis*

Because of the similarities in the findings in both cohorts, and despite methodologic limitations to such an approach, an exploratory analysis of pooled data from both cohorts was conducted to obtain an overview of the findings with improved power (table 4). With enhanced statistical power, the pooled data comparing behavioral inhibition only to no behavioral inhibition and no anxiety were statistically significant. In the pooled cohort, the rates of social phobia (10.0% versus 0%; p=0.01, Fisher's exact test) and continuing anxiety disorder (21.7% versus 6.8%; p=0.03, Fisher's exact test) were statistically higher in parents of children with behavioral inhibition only than in parents of children with no behavioral inhibition and no anxiety.

## DISCUSSION

We have previously hypothesized that the presence of behavioral inhibition in a child may be a marker or precursor of risk for development of an anxiety disorder in childhood, adulthood, or both. Previous work suggested that young children of parents with panic disorder and agoraphobia were likely to be classified as behaviorally inhibited (6) and that behaviorally inhibited children from both clinical and nonclinical cohorts were likely to develop anxiety disorders (18). While parental panic disorder and possibly social phobia are associated with behavioral inhibition in offspring (6, 7) and while behavioral inhibition is associated with a greater risk for childhood anxiety disorders (18), the factors determining which inhibited children were at risk for childhood onset of anxiety disorders were unknown. The findings reported here indicate that the inhibited children whose anxiety disorders were reported by their mothers were those with the greatest familial loading for anxiety disorders, manifested in the form of multiple anxiety disorders in the parent. These results support the hypothesis that behavioral inhibition and anxiety may be a more severe form of an "anxiety-prone" diathesis. These findings appear to be specific for anxiety disorders, since the rate of major depressive disorder did not differ among the groups.

While our hypothesis predicts that differences in parental anxiety disorders should be found in the comparisons between the groups with behavioral inhibition only and no behavioral inhibition and no anxiety (table 1), that could not be statistically established because of limited statistical power. However, in both the at-risk and longitudinal cohorts, although the rates of grouped anxiety disorders (table 3) in the group with behavioral inhibition only were 1.5 to 3.5 times higher than those in the group with no behavioral inhibition and no anxiety, these differences failed to attain statistical significance. Although tentative in nature, results of the exploratory analysis of pooled findings did reveal statistically significant differences between the groups with behavioral inhibition only and no behavioral inhibition and no anxiety groups for continuing anxiety disorder and social phobia, as well as a trend for two or more adult anxiety disorders (p=0.07). These pooled data more clearly illustrate a progression in the risk for anxiety disorders in parents of children with no behavioral inhibition and no anxiety, behavioral inhibition only, and behavioral inhibition and anxiety. These findings suggest that while the presence of behavioral inhibition in a child may be a risk factor in the development of anxiety disorders, their manifestation is more likely in the presence of high familial loading, expressed as multiple anxiety disorders in the parent.

There are likely to be multiple factors influencing the development of manifest anxiety disorders in children with behavioral inhibition, including, for example, adverse environmental influences in general and the specific interaction of inhibited temperament with developmental adversity. The latter may include exposure to a parent with greater psychopathology.

For example, Eisenberg, observing separation anxiety in young children, suggested that the perception by the child of dependency needs (and anxiety) in the mother accounted for the inability to separate and attend school (avoidant behavior) (30). Moreover, agoraphobic parents have been described as either overprotective or unavailable to the child, thereby interfering with the normative process of separation and individuation.

While our findings cannot discern the relative importance of genetically versus environmentally transmitted risk factors, the recognition of parental risk factors in inhibited children enhances early identification of children at greatest risk and the possibility of developing early interventions to minimize the progression of psychopathology and associated distress and impairment.

The findings in this study should be viewed in light of their methodologic limitations. The cohort sizes of individual subgroups were relatively small to evaluate fully the nature of the association between behavioral inhibition and anxiety disorders. Despite limited power, significant differences in the expected direction were found. While the small cohort size reduces the precision of our estimates of rates of disorders and the power to detect differences, only a robust finding should have achieved significance in a small cohort.

Since psychometric data are available only for rating children 6 years or older, another concern is that the assessment of psychopathology in children younger than 6 years may be less certain than that of older children; nonetheless, we elected to include children younger than 6 years since the purpose of this pilot study was to obtain psychopathological data on as many children as possible. As has been recently reviewed by Weissman (29), a lower age limit of 4 years has been used for assessments of children in other high-risk and epidemiologic studies (31).

The assessment of psychopathology in the children was based on interviews with the mothers, which may have led to ascertainment bias and misrepresentation of psychopathology in the children. However, the same method was used to evaluate all groups of children. Some parents were known to have psychiatric disorders, and this may have affected the reported rates of childhood symptoms, since psychiatric patients may exaggerate symptoms in their children (32); alternatively, normal mothers may have a tendency to underreport problem behaviors (33). Nevertheless, high rates of anxiety disorders, similar to those found in the at-risk cohort, were found in the longitudinal cohort in which ascertainment of behavioral inhibition was not based on parental psychopathology (18).

In summary, our results indicate that while children of parents with anxiety disorders have a greater risk for manifesting behavioral inhibition, parental loading for anxiety disorders may account for the early onset of anxiety syndromes in these children. If confirmed, this finding may help identify the subgroup of inhibited children at very high risk for developing childhood-onset anxiety disorders.

# Antisocial Behavior of Intravenous Drug Abusers: Implications for Diagnosis of Antisocial Personality Disorder

Robert K. Brooner, Ph.D., Chester W. Schmidt, M.D.,
Linda J. Felch, M.A., and George E. Bigelow, Ph.D.

*Objective: A pattern of chronic adult antisocial behavior is not sufficient for the* DSM-III-R *diagnosis of antisocial personality disorder unless the early-onset criteria are satisfied, even if the adult criteria are met. The utility of the early-onset requirement for the diagnosis was examined in intravenous drug abusers, a population known to have high rates of irresponsible, aggressive, and criminal behavior. Method: The subjects were 237 drug abusers who had volunteered for an outpatient study of psychopathology and HIV risk behavior and infection. They completed a structured psychiatric interview as part of their participation in that study. The adult antisocial behavior of the group that met both the early-onset and the adult criteria for antisocial personality disorder, the group that met only the adult criteria, and the group that met neither the early-onset nor the adult criteria was then compared. Results: Antisocial personality disorder (meeting the early-onset and adult criteria) was diagnosed in 44% of the sample; an additional 24% met only the adult criteria. The group with the diagnosis of antisocial personality disorder reported a more pervasive and more serious pattern of adult antisocial behavior than did the other groups, although antisocial behavior was commonplace in all three groups. Conclusions: Early onset of multiple antisocial behaviors identified a subset of drug abusers with important differences in the extent and severity of their adult antisocial behavior. The antisocial behavior of the group that met only the adult criteria suggests the possibility of a late-onset and less severe form of antisocial personality disorder.*

(Am J Psychiatry 1992; 149:482–487)

Antisocial behavior is strongly linked to drug abuse (1–3). Ball et al. (3) interviewed 354 drug abusers regarding their day-to-day criminal activities. All subjects reported a history of adult antisocial behavior, including the illegal sale of drugs, illegal gambling, theft, and other criminal offenses. Despite the fact that adult antisocial behavior is commonplace among drug abusers, previous research indicates that most of these persons fail to satisfy the diagnostic criteria for antisocial personality disorder. For example, the prevalence of this disorder in drug abusers when the *DSM-III* (or *DSM-III-R*) definition is used has ranged from 35% (4) to a high of 54% (5), with an average prevalence rate of about 40% (6, 7).

What accounts for the fact that most drug abusers fail to meet the diagnostic criteria for antisocial personality disorder? One potential explanation may be related to how *DSM-III* and *DSM-III-R* operationalize the disorder. Each of these systems uses definitions with a strong behavioral framework that require early onset (before the age of 15) of multiple antisocial behaviors for a patient to become eligible for the adult diagnosis. Thus, to be classified as having antisocial personality disorder, a person must have fulfilled at least three of 12 specific antisocial criteria (e.g., truancy, chronic lying, aggressiveness, and criminality) prior to the age of 15 and fulfill at least four of the adult criteria (e.g., unstable work history, chronic lying, aggressiveness, criminality). As a result of the requirement for early onset, persons with high rates of adult antisocial behavior (including those who may satisfy the adult criteria for antisocial personality disorder) would not be diagnosed as having the disorder unless they also meet the early-onset criteria.

This aspect of the current definition of the disorder has been criticized by Hare (8) and was discussed recently in a review by Gerstley et al. (6). These criticisms

raise important questions about the clinical utility of the early-onset requirement for the diagnosis of antisocial personality disorder, particularly for drug abusers, who typically report high rates of adult criminality, aggressiveness, irresponsibility, and unemployment. To examine this issue further, we compared the rates of specific adult antisocial behaviors among intravenous drug abusers to determine whether there were meaningful differences between those who satisfied both the early-onset and adult criteria for antisocial personality disorder, those who satisfied the adult criteria but not the early-onset criteria, and those who satisfied neither the adult nor the early-onset requirements for the disorder.

## METHOD

The 237 subjects presented in this report were intravenous drug abusers participating in a longitudinal study of psychopathology and HIV high-risk drug use and sexual behavior. The sample included subjects who were in a hospital-based methadone treatment program (N=128) and subjects who were not in methadone treatment at the time of enrollment in the study (community sample, N=109). All subjects who were in treatment met the *DSM-III-R* criteria for current opioid dependence, and many also had at least one additional substance use disorder, primarily related to cocaine use (68%, N=87). These subjects had been in methadone treatment for at least 3 months and had been recruited by advertisements posted in the treatment clinic. Community subjects were eligible for inclusion in the study if they reported intravenous drug use within the 3 months before study enrollment, had a lifetime history of intravenous drug abuse for more than 3 continuous months, and had less than 12 months of cumulative methadone treatment in the 4 years before entering the study. Nearly all of the community subjects satisfied current diagnostic criteria for an opioid (N=89) and cocaine (N=104) use disorder. They were recruited by advertisements in selected health and research agencies and by chain-referral techniques. Each subject was paid $10 per hour for completing the intake assessment instruments, for a total of approximately 6 hours ($60). Informed consent was obtained from each subject after study procedures were fully described. Given the sensitive nature of these data, a confidentiality certificate was obtained for the project from the National Institute on Drug Abuse, which would protect the data from subpoena.

The mean age of the subjects was 36.0 years (SD=6.6, range=23–63); 70% (N=165) were male. Forty percent (N=95) of the subjects were white, 59% (N=140) were black, and less than 1% (N=2) were Hispanic or Native American. The mean educational level was 11.0 years (SD=1.9, range=5–19); 67% (N=159) were unemployed. Forty-six percent (N=109) had never married, 14% (N=33) were married, 35% (N=83) were separated/divorced, and 5% (N=12) were widowed. They reported onset of recurring life problems associated with any substance use at a mean age of 18.8 years (SD=4.9, range=11–45) and an average of 33.2 months (SD=50.0, range=0–240) of cumulative (lifetime) methadone maintenance. Subjects who were in treatment were more likely to be white (66%, N=84, versus 9%, N=10; $\chi^2=76.05$, df=1, $p<0.001$) and married (19%, N=24, versus 6%, N=7; $\chi^2=7.58$, df=1, $p<0.01$). More of the community subjects were male (83%, N=90, versus 59%, N=75; $\chi^2=14.89$, df=1, $p<0.001$).

The diagnoses of antisocial personality and substance use disorders followed *DSM-III-R* guidelines and were made from a modified version of the Alcohol Research Center Intake Interview, a semistructured diagnostic interview with good reliability and procedural validity (9). This interview was derived from both the Schedule for Affective Disorders and Schizophrenia—Lifetime version (10) and the National Institute of Mental Health Diagnostic Interview Schedule (11). The Alcohol Research Center Intake Interview covers the major substance use disorders (excluding nicotine and caffeine) and other psychiatric conditions most prevalent among alcohol and drug abusers (e.g., major depression and antisocial personality disorder), including several categories with low prevalence but high morbidity (e.g., schizophrenia and bipolar disorder).

All interviews were conducted by trained research interviewers with master's degrees in social work or clinical/counseling psychology. Clinical interviewers were required to complete a minimum of 4 hours of didactic training on the interview, to rate a minimum of five consecutive interviews that agreed with an expert interviewer's diagnostic ratings of the subject, and then to conduct a minimum of five subject interviews that agreed with the ratings of an expert interviewer.

The data concerning specific behaviors before and after the age of 15 were derived from items in the demographic and antisocial personality sections of the diagnostic interview. All subjects were interviewed on each of these items, with continuous measures formatted to provide quantitative data on the frequencies of these behaviors. Illegal activities (and formal charges) directly involving drugs and alcohol (e.g., possession and sale of illicit drugs, driving while intoxicated, public intoxication) were not included in the number of misdemeanors or felonies reported by subjects, although no attempt was made to exclude behaviors that may have been motivated by drug abuse (e.g., chronic lying, prostitution, theft, assault). In addition, subjects were compared on a summary measure of more serious adult criminality and physically aggressive behavior that was constructed from a subset of the interview questions. This composite measure of severe antisocial behavior was derived by calculating the sum of the number of times since the age of 15 that subjects had used weapons in fights, been arrested for felonies, and committed felonies that did not result in arrest.

Demographic and treatment history variables for the group that met neither the early-onset nor the adult criteria for antisocial personality disorder, the group that met the adult criteria only, and the group that met both

[c] Subjects meeting neither the early-onset nor the adult criteria for antisocial personality disorder.

sets of criteria were compared by analysis of variance or chi-square tests. Analyses of the percentages of subjects who had engaged in the various childhood and adult antisocial behaviors were done by means of chi-square tests (with continuity correction) with post hoc testing of group differences by the Tukey-Kramer method. The frequencies of specific childhood and adult antisocial behaviors were compared for the three groups by means of analysis of covariance and Tukey's post hoc test; age at onset of recurring life problems associated with drug use was used as a covariate because groups were significantly different on this variable. While it would have also been appropriate to include gender as a grouping factor in this analysis, the resulting cell sizes would have been too small for meaningful interpretation of the results. All analyses were conducted with the SPSS (12), and results were considered significant if the p value was less than 0.05.

## RESULTS

Of the 237 subjects, 44% (N=104) were classified as having antisocial personality disorder, since they met both the early-onset and the adult criteria (Both), 24% (N=56) met only the adult criteria (Adult Only), and 25% (N=60) satisfied neither the early-onset nor the adult criteria (Neither). An additional 7% (N=17) met the early-onset requirement but failed to meet the adult criteria for the disorder. This last group was too small to permit meaningful statistical comparisons and was omitted from the analyses. Thus, all statistical comparisons were made between subjects in the three remaining groups (N=220).

More of the subjects in the Both and the Adult Only groups than in the Neither group were male (79.8%, 71.4%, and 51.7%, respectively; $\chi^2$=14.42, df=2, p=0.001), and more of the subjects in the Neither group than in the Both and the Adult Only groups were married (21.7%, 9.6%, and 5.4%, respectively; $\chi^2$=8.31, df=2, p=0.02). Those in the Both group also reported a significantly earlier age at onset of recurring life problems associated with substance use than those in the Adult Only and the Neither groups (17.4, 20.1, and 20.7 years, respectively; F=10.99, df=2, 215, p<0.001). There were no significant differences between the three groups on age, ethnicity, years of education, employment status, cumulative (lifetime months) of methadone treatment, or methadone treatment status (treatment or no treatment) at the time of study enrollment.

The patterns of antisocial behavior in the three groups were evaluated in two ways: first, by comparing the percentages of subjects reporting any involvement in each of the behaviors, and second, where possible, by comparing their frequencies of occurrence.

Table 1 shows the percentages of subjects in the three groups who reported prior involvement in each of the childhood and adult antisocial behaviors covered by the

[a] Subjects meeting both the early-onset and the adult criteria for antisocial personality disorder.
[b] Subjects meeting only the adult criteria for antisocial personality disorder.
[c] Subjects meeting neither the early-onset nor the adult criteria for antisocial personality disorder.

interview. As expected, significantly more of the subjects in the Both group than in the Adult Only and Neither groups had been involved in each of the childhood behaviors, including having been placed in reform school. There were no significant differences between the percentages of subjects in the Adult Only and the Neither groups who had been involved in these early life behaviors, with the exception that more of the Adult Only group had engaged in "other illegal acts."

On measures of adult antisocial behavior, there were also consistent differences between the Both and the Neither groups (table 1). With the exception of current unemployment, a greater percentage of subjects in the Both group had been involved in each of the adult behaviors. In contrast, comparisons between subjects in the Both and the Adult Only groups yielded mixed results. Similar percentages of subjects in the Both and the Adult Only groups reported employment problems, difficulty maintaining a monogamous relationship, homelessness, and misdemeanor arrests. However, compared to the Both group, significantly fewer subjects in the Adult Only group had been arrested for a felony, committed a felony not resulting in arrest, committed a misdemeanor not resulting in arrest, used weapons in fights, or developed a pattern of chronic lying. It is interesting that significantly more subjects in the Adult Only group than in the Neither group had been involved in each of the adult behaviors, with the exception of felony arrest and of unemployment at the time of study entry. In short, subjects in the Adult Only group appeared to be behaviorally different from and intermediate between those in the Both and the Neither groups.

Table 2 shows the comparison of the three groups with respect to the number of times subjects reported committing specific antisocial acts. These comparisons were restricted to those questions which provided data on the number of times a specific behavior occurred (e.g., number of times arrested, number of times weapons were used in fights). As would be expected, the group with antisocial personality disorder (Both) reported significantly higher frequencies on each of the measures of childhood antisocial behavior than did the Adult Only and the Neither groups. Importantly, the Adult Only and Neither groups did not differ significantly on the frequency of any of these early life behaviors.

The relationships were notably different with respect to the adult behavior of these groups. Although the Both group reported uniformly higher frequencies than the Neither group on all of the antisocial behaviors (including fewer years of monogamy), comparisons between the Both and the Adult Only groups produced more variable results. In general, the antisocial behavior of the Adult Only group was intermediate between that of the Both and Neither groups and most often did not differ significantly from that of either group. Compared to the Both group, the Adult Only group reported a significantly lower number of felony arrests ($q=4.69$, $df=3, 216$, $p=0.01$) and felonies not resulting in arrest ($q=3.23$, $df=3, 216$, $p=0.05$) and more continuous years of monogamy ($q=4.30$, $df=3, 216$, $p=0.01$). In contrast, the two groups did not differ significantly on number of misdemeanor arrests, misdemeanors not resulting in arrest, or number of different employers since the age of 18 years.

Although subjects in the Adult Only group were more likely than the Neither group to be involved in most measures of adult antisocial behavior (table 1), they did not typically differ from each other in the frequencies of these behaviors (table 2). The one exception to this general finding was that subjects in the Adult Only group used weapons more frequently in fights than did those in the Neither group (q=3.73, df=3, 216, p=0.05).

Finally, the three groups were compared on the previously described summary measure of severe criminality and physical aggressiveness. The Both group obtained a significantly higher mean score (48.13) than that of the Adult Only group (20.18) (q=3.47, df=3, 216, $p<0.05$) and that of the Neither group (2.37) (q=5.81, df=3, 216, $p<0.01$). Perhaps more important, the mean score for the Adult Only group was not significantly different from that for the Neither group (q=1.97, df=3, 216, n.s.).

## DISCUSSION

It is interesting that many drug abusers fail to satisfy requirements for the *DSM-III* (and *DSM-III-R*) definition of antisocial personality despite their high rate of antisocial behavior. In this study only 44% of the subjects were classified as having antisocial personality disorder even though most reported chronic adult antisocial problems. Importantly, 42% (N=56) of those not diagnosed as having antisocial personality disorder met the adult criteria for the disorder. Although there were some similarities in adult antisocial behavior across the three groups, the general conclusion drawn from this study is that the early-onset requirement for the diagnosis of antisocial personality disorder is important. For the subjects who met this diagnostic requirement, adult antisocial behavior was more probable and more frequent than for subjects who did not. This relationship is shown most clearly in the comparison of the group of adult intravenous drug abusers who fulfilled both the early-onset and the adult criteria with the group who fulfilled neither set of criteria. There, within a population that was homogeneous with respect to involvement in an antisocial adult lifestyle (intravenous drug abuse), drug abusers diagnosed as having antisocial personality disorder displayed significantly more pervasive and more severe adult antisocial behavior. The relationship is also seen, though less strongly, in the comparison of the group that fulfilled both sets of criteria with the group that fulfilled only the adult criteria. There, the populations compared were even more homogeneous, all engaging in sufficient numbers and frequencies of antisocial behaviors to satisfy the requirements for adult antisocial personality disorder. Still, the various adult antisocial behaviors assessed were more likely to occur, and the composite severity index of these behaviors was higher, for those who met the full criteria for the disorder by having also engaged in multiple chronic antisocial behaviors prior to age 15.

While the adult antisocial behavior of the group who fulfilled both sets of criteria was more pervasive and more frequent than that of the group who met only the adult criteria, subjects in the latter group did report high levels of adult antisocial behavior. This finding raises several possibilities. First, the subjects who met only the adult criteria may constitute a subset of antisocial patients with late onset and a less severe form of the disorder who simply avoided many of the problems measured by the early-life criteria. Second, the high rate of antisocial behavior reported by this group may be associated with their chronic drug abuse. This is partially supported by the fact that even subjects in the group that fulfilled neither set of criteria had histories of recurring adult antisocial behavior, including chronic unemployment, criminal misdemeanors, and felony arrests. It is relatively well established that antisocial behavior is a frequent consequence of drug abuse (13, 14). In the present study, the subjects who fulfilled the adult criteria only and the subjects who fulfilled neither set of criteria had onset of recurring life problems associated with their use of drugs at about 20 years of age. The onset of problem drug use in these subjects was concurrent with their self-reported increase in pervasive antisocial behavior. The severe antisocial lifestyle of the group diagnosed as having antisocial personality disorder may also have been exacerbated by their chronic drug abuse (13, 14).

At minimum, these data supporting the importance of the early-onset requirement in the diagnosis of antisocial personality disorder confirm previous studies reporting a strong association between multiple antisocial behaviors early in life and more severe adult antisocial problems (15, 16). In addition, the greater extent and severity of adult antisocial problems reported by the group with antisocial personality disorder may also be associated with previous findings on a subset (N=100) of these patients that strongly linked antisocial personality disorder to higher rates of HIV high-risk drug use behaviors (7) and with other studies reporting that the disorder is often associated with poor drug abuse treatment outcome (17, 18).

There are several caveats associated with this study. Data were obtained by self-report without the benefit of additional informants or arrest records. However, Maisto et al. (19) found that drug abusers typically provide valid information about illegal and drug use activities when no contingencies (positive or negative) are associated with their reports. Also, Zimmerman et al. (20) reported that the use of other informants did not improve the diagnosis of antisocial personality disorder made on the basis of subjects' self-reports.

Another concern is that approximately 50% of the subjects in our study were not in treatment at the time they completed the interview. The fact that they were not in treatment may have resulted in higher rates of adult antisocial behavior. However, there were no significant differences in the numbers of treatment and community subjects in each of the three subject groups. Further, there were no significant differences between groups in the numbers of cumulative lifetime months of methadone treatment. The demographic and drug use characteristics (i.e., intravenous opioid and cocaine use) of the sample may restrict generalizability of these data to other intravenous narcotic and cocaine abusers demographically similar to those in the present study.

Finally, the study was limited to a retrospective examination of group differences on a restricted range of antisocial behaviors. The inclusion of other measures of personality and antisocial behavior in the study could have provided a more comprehensive view of the differences between the group that met the criteria for antisocial personality disorder and the group that met the adult criteria only. Such work is currently underway at this center with another sample of drug abusers newly admitted to an outpatient drug treatment program.

## CONCLUSIONS

The clinical utility of the *DSM-III-R* early-onset criteria in the definition of antisocial personality disorder represents an important issue in the diagnosis of this disorder. This issue may be especially important in the assessment of drug abusers, given the potential of classifying most as having the disorder if the early-onset requirement is ignored. The present study supported the importance of an early onset of pervasive antisocial behaviors for the diagnosis of antisocial personality disorder in drug abusers. The current definition of antisocial personality disorder, including the early-onset requirement, clearly does not detect all individuals who will engage in extensive antisocial behavior as adults, as shown by the behavior of the Adult Only group. However, the data from this study indicate that adult intravenous drug abusers who do meet the early-onset criteria are, on average, more deviant and more impaired.

# Sensory Gating Deficits in Schizophrenia: New Results

Lewis L. Judd, M.D., LouAnn McAdams, Ph.D.,
Byron Budnick, B.A., and David L. Braff, M.D.

*Objective: It has been widely hypothesized that sensory gating failures and sensory overload occur in schizophrenic patients compared to normal subjects. The authors of this study sought to confirm and extend results of earlier studies that showed specific sensory gating deficits in schizophrenic patients. Method: Age- and sex-matched schizophrenic patients (N=20) and normal subjects (N=20) were tested using electrophysiologically recorded P50 event-related potentials to assess the overall competence of the subjects' central sensory inhibitory capacity by measuring sensory filtering or gating. P50 area responses to two 75-dB (conditioning and test) click stimuli of 0.04-msec duration, averaged over 60 trials, were recorded for each subject. Normally, the first (conditioning) click stimulus induces gating mechanisms that result in diminished or gated P50 event-related potentials in response to the second click stimulus. Results: The schizophrenic subjects manifested a significant sensory gating deficit at frontal, central, and parietal electrode placement sites, with a nonsignificant tendency for the deficit to be most prominent in the frontal areas of the brain. Conclusions: These data reflect a regionally diffuse loss of normal sensory gating in schizophrenic patients.*

(Am J Psychiatry 1992; 149:488–493)

Since the time of Kraepelin and Bleuler, abnormalities of attention and information processing have been identified among patients with diagnoses in the schizophrenic spectrum of disorders. In recent years, investigators have used information-processing paradigms in studies of both humans and animals to specify the time course of information-processing deficits and the possible underlying neuroanatomical and neurophysiological abnormalities that evoke these deficits (1). Earlier, McGhie and Chapman (2) discussed "disorders of attention and perception in early schizophrenia" and noted that organisms integrate sensory data by utilizing a buffer capacity that allows for perceptual constancy by reduction of the "otherwise chaotic flow of information reaching consciousness." This is very similar to Venables' view (3) that in some schizophrenic individuals there is stimulus "flooding" through sensory overload based on a failure of normal filtering and gating mechanisms. Still, theories of sensory gating abnormalities in schizophrenia are often confusing and difficult to operationalize. This led Neale and Cromwell (4) to call for "refined behavioral techniques utilizing relevant behavioral cues" in gating studies.

In more recent years, a number of investigators have used innovative techniques to specify the sensory gating deficits and corresponding sensory overload and inundation that occur in some schizophrenic spectrum patients. Gottschalk et al. (5) used a novel paradigm to illustrate that sensory overload (or LSD treatment) could induce changes in normal subjects' scores on social alienation-personal disorganization and cognitive-intellectual impairment scales that are similar to the test results of schizophrenic patients. Specifically, Gottschalk et al. subjected normal control subjects to sensory overload by using an "overload apparatus" that consisted of a geodesic dome into which cacophonous sounds and fragmenting, bizarre, and complex visual images were projected. The results were consistent with sensory gating deficit theories, since cognitive fragmentation occurred when individuals experienced sensory overload.

Other studies of sensory overload and sensory gating deficits in patients with schizophrenic disorders have been reported in which cortically based event-related potentials were used. Braff et al. (6) used a self-stimulation paradigm in which the subject uses a key release to initiate a stimulus that elicits event-related potentials. The P300 wave component of event-related potentials reflects the amount of novel or unanticipated informa-

tion delivered by a stimulus. Thus, the P300 component is diminished when the subject has elicited the stimulus (in contrast to a randomly generated stimulus), and this diminution is greatest at brief intervals (e.g., 100 msec) between key release and stimulus onset, when the subject is aware that the stimulus is about to "arrive." Schizophrenic subjects, however, show a paradoxically decreased P300 amplitude in the 250–500-msec interval, indicating a diminution of the normal inhibitory mechanisms that operate in this time frame.

In a related series of studies, Freedman, Adler, Siegel, and associates found that medicated (7) and unmedicated (8) schizophrenic patients, as well as relatives of schizophrenic patients (9), showed deficits in a sensory gating study in which a two-stimulus (conditioning and test) event-related potentials paradigm was used. Both of the stimuli used in this paradigm evoke P50 waves that occur in the epoch about 50 msec after stimulus onset. The second stimulus usually evokes a P50 wave that is inhibited or gated by the effect of the first stimulus. Schizophrenic patients exhibit a lack of this normal inhibitory influence and thus show a larger than normal P50 wave elicited by the second stimulus that could reflect a deficit in sensory gating. This deficit is not an artifact of antipsychotic medications, since unmedicated schizophrenic patients and family members of schizophrenic patients show similar deficits. Kathmann and Engel (10) reported that this loss of P50 gating in schizophrenic patients was not reproduced in their study. It is noteworthy, however, that the click stimulus they used in their study was many times more powerful than that used by Freedman and associates because of its longer duration (1.5 msec versus 0.04 msec). In related work with animals, Adler et al. (11) proposed that these deficits are caused by a state of hyperarousal, with hyperexcitable neurons causing a defect in normal cortical and subcortical inhibitory mechanisms. The existence of this viable animal model allows for novel and enlightening studies of the mechanisms underlying gating failures in schizophrenic patients.

Since their initial reports (7, 8), there has not been independent confirmation in another laboratory of Freedman and associates' observations of sensory gating deficits in schizophrenic patients compared with normal or patient control subjects. The only report from another laboratory (10) failed to confirm Freedman and associates' basic finding. Our study was designed to use the P50 event-related potentials paradigm to replicate and extend Freedman and associates' findings of sensory gating deficits in schizophrenic patients.

## METHOD

The subjects were 20 medicated schizophrenic patients recruited from the inpatient psychiatry service of a university medical center. The patients were between 18 and 55 years of age and met the *DSM-III* criteria for schizophrenia. In addition, the patients were administered the Schedule for Affective Disorders and Schizophrenia—Lifetime Version (SADS-L) (12), and patients meeting the Research Diagnostic Criteria (RDC) (13) for schizophrenia were included in the study. The Brief Psychiatric Rating Scale (14) and the Global Assessment Scale (15) were also administered to all patients.

The mean age of the schizophrenic patients (15 male and five female) was 28.8 years (SD=8.49, range=18–53 years). Their average dose of antipsychotic medications was 1996 mg/day of chlorpromazine equivalents. Eighteen of the patients were right-handed and two were left-handed. Potential subjects who had current or recent histories of alcoholism, drug abuse, dementia, or ECT were excluded, as in our previous method (16).

Twenty normal subjects (14 male and six female) with no active psychopathology or family history of schizophrenia were recruited from advertisements in local papers and from among the medical center staff. All were administered the SADS-L. Only subjects who were medically healthy and met the RDC for "never mentally ill" were included in the normal group. The mean age for this group was 27.9 years (SD=5.99, range=18–39 years). Seventeen of these subjects were right-handed and three were left-handed.

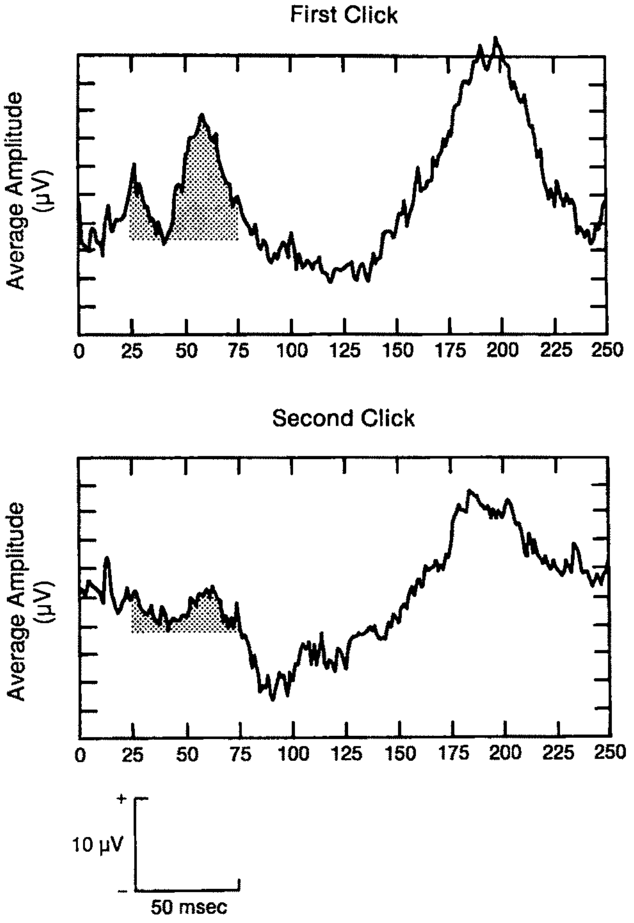
Informed consent was obtained from all subjects.

All recordings were performed in the electrophysiology laboratory of one of us (L.L.J.) in a shielded chamber with a DEC-MINC computer and Grass amplifiers. Recordings were made from gold cup electrodes (resistances less than 5 Ω) placed at the midline frontal, central, and parietal sites according to the 10/20 system. Electrodes were referenced to linked ear electrodes. In general, the recording methods closely followed those published by Freedman and associates (7–9), so that the results would be comparable to their published data. One difference, however, was that we used 60 pairs of stimuli in these experiments, whereas Adler et al. (7) used 32 pairs.

Electrical activity was amplified 20,000 times by a 1-MΩ impedance amplifier with band pass filters (–3 dB) at 0 and 1500 Hz. The EEG was monitored on an oscilloscope, and acquisition of data was interrupted when voltage exceeded 100 μV or when there was evidence of artificial muscle activity. Data were digitized at a rate of 1000 Hz for on-line averaging, and simultaneous averages were recorded from lateral canthus electro-oculography (EOG) electrodes and monitored in order to exclude EOG contribution to the data. The artifact rejection was automated by computer program and preset to exclude any sweep that was larger than 90% of the A-to-D capacity for amplitude and that exceeded 15% of the entire sweep for duration. With these exclusion parameters it was felt that EOG artifact as well as other artifacts (e.g., swallowing, minor muscular movement) would be fully removed. Grass S-88 stimulator-generated clicks of 0.04-msec duration were amplified within a band width of 20–10,000 Hz and delivered through earphones with a mean intensity of 75 dB, as measured by a sound meter at the earphone.

Stimuli were presented as a series of paired conditioning and testing stimuli. As described by Freedman et al. (8), the interval between the pairs of stimuli was kept

**FIGURE 1. Representative Data for One Normal Subject on P50 Area Responses to Two Click Stimuli Averaged Over 60 Trials[a]**



[a] Robust sensory gating is indicated by the large decrement in the area of the P50 wave following the second click relative to that following the first click.

constant at 10 seconds, and the interval between the conditioning and test pulses was kept constant at 500 msec in order to test the previously identified interval of maximal differences between schizophrenic and normal subjects in this paradigm. Sixty pairs of responses were averaged. The P50 response data were analyzed as follows. Averaged evoked potentials were measured for peak amplitude and area of the P50 wave. The P50 peak was defined as the maximal positive activity occurring between 25 and 75 msec after the stimulus and corresponds to peak amplitude data. Both amplitudes and areas were measured by two methods: 1) from prestimulus baseline to peak and 2) from trough to peak by using the segments of potential immediately preceding and following the P50 peak to construct the local baseline. This second method was used in order to avoid all possible problems caused by a small P50 peak riding on a large, long-lasting negative potential and those associated with using a short interval between conditioning and test stimuli (i.e., 500 msec). Analyses of peak amplitude and area measurements of absolute and relative change scores yielded similar results. Therefore, only area data are reported.

Three specific prospective hypotheses for P50 area responses were formulated. 1) A gating effect would be observed across both groups of subjects and all electrode positions and would be evidenced by a decrement in average P50 response to the second click relative to that of the conditioning first click stimulus. 2) If schizophrenic patients lack robust gating, then the overall decrement in the P50 wave from the response to the first click stimulus to the response to the second click stimulus would be larger in the normal group than in the schizophrenic group (the Diagnosis by Gating interaction). 3) The hypothesized "hypofrontality" in schizophrenic subjects led to the prediction that regional differences between the two groups would be found. Specifically, the magnitude of the differences in P50 responses between normal and schizophrenic subjects would vary among electrode positions, being largest at the frontal electrode position and smallest at the parietal position (the Electrode Position by Diagnosis by Gating interaction).

A three-way repeated measures multivariate analysis of variance (MANOVA) was conducted using BMDP software (17, 18). The MANOVA included a factor for diagnosis (normal or schizophrenic subjects), a repeated measures factor for the stimulus presentations (stimulus 1, the conditioning click; and stimulus 2, the test click), and a factor for the repeated measures at the three electrode positions (frontal, central, and parietal). A square root transformation of P50 area data was used to preserve assumptions of homogeneity of variance and normality.

## RESULTS

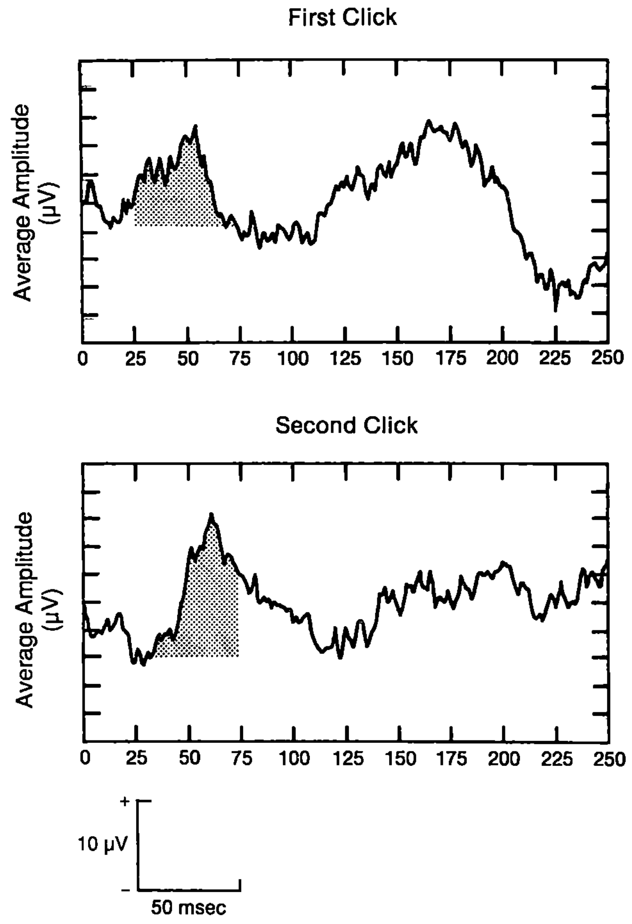
Figures 1 and 2 show averaged P50 area responses to the first and second clicks for one representative subject from the normal group and one from the schizophrenic group, respectively.

### *Primary Analysis*

A significant gating effect was observed in the P50 area response. Across both groups and all three electrode positions, the mean P50 area response to the experimental second click was significantly diminished from that of the conditioning first click (gating effect, $F=176.98$, $df=1, 38$, $p<0.0001$). The mean absolute change scores for the square root of P50 area responses are shown in table 1. The mean relative P50 change score was also significant ($F=281.83$, $df=1, 38$, $p<0.0001$).

A Diagnosis by Gating interaction was evident in the P50 area response. Across all electrode positions the schizophrenic group had a smaller change in the P50 area response from the first to the second click than did the normal group (Diagnosis by Gating interaction, $F=73.33$, $df=1, 38$, $p<0.0001$). It is interesting to note that these significant differences in the decrements can be

**FIGURE 2. Representative Data for One Schizophrenic Subject on P50 Area Responses to Two Click Stimuli Averaged Over 60 Trials[a]**



[a] Loss of normal sensory gating is reflected in the large P50 wave after the second click.

attributed to two separate differences between the two subject groups. That is, the schizophrenic group had a smaller mean P50 area response to the conditioning first click than did the normal group (F=4.34. df=1, 38, p<0.05). The schizophrenic group also had a significantly larger mean P50 area response to the experimental second click than did the normal group (F=21.20, df=1, 38, p<0.0001). Overall, the magnitude of differences between the two groups was fivefold or greater, depending on the electrode placement examined.

There was no significant Electrode Position by Diagnosis by Gating interaction. A multivariate approach to repeated measures was adopted, and since electrode placement was a repeated measures factor with more than two levels (i.e., frontal, central, and parietal), the test for significance for electrode placement effects used in this analysis was Hotelling's $T^2$ test (19). The overall Diagnosis by Gating by Electrode Position interaction was not significant ($T^2$=2.08; F=1.01, df=2, 37, p=0.37). There was a trend in the normal group for the differences between the P50 area responses to the first and second clicks to lessen progressively from the frontal to the parietal electrode positions (i.e., more gating frontally). The opposite trend was noted in the schizophrenic group: the difference between the P50 area responses to the first and second clicks increased progressively from the frontal to the parietal electrode positions (i.e., less gating frontally), as reflected in figure 3.

**TABLE 1. P50 Wave Area Responses of Normal and Schizophrenic Subjects to Two Click Stimuli**

| | P50 Response (μV)[a] | | | |
|---|---|---|---|---|
| | Normal Subjects (N=20) | | Schizophrenic Subjects (N=20) | |
| Stimulus and Electrode Placement | Mean | SE | Mean | SE |
| Conditioning (first click) | | | | |
| Frontal | 13.26 | 0.83 | 10.92 | 0.59 |
| Central | 12.43 | 0.77 | 10.28 | 0.63 |
| Parietal | 11.59 | 0.86 | 10.22 | 0.76 |
| Test (second click) | | | | |
| Frontal | 5.76 | 0.54 | 9.68 | 0.70 |
| Central | 5.17 | 0.53 | 8.68 | 0.70 |
| Parietal | 5.09 | 0.51 | 8.45 | 0.75 |
| Absolute change from conditioning to test | | | | |
| Frontal | –7.50 | 0.70 | –1.24 | 0.57 |
| Central | –7.26 | 0.53 | –1.60 | 0.53 |
| Parietal | –6.50 | 0.62 | –1.77 | 0.53 |

[a] With square root transformation.

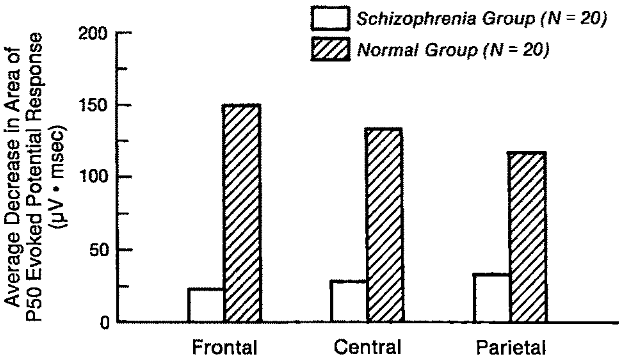
### *Secondary Analyses*

There was a significant difference in mean level of education between the two groups. The mean was 16.20 years (SD=2.75) for the normal subjects and 12.45 years (SD=1.23) for the schizophrenic subjects. However, statistical controls for this difference, using analyses of variance with education levels as covariates, did not change the pattern of results, nor has level of education been reported to affect sensory gating, especially at this observed order of magnitude.

Electrode position affected the magnitude of P50 area response. Across both study groups and both stimulus clicks, the effect of electrode position on the P50 area response was largest at the frontal electrode and smallest at the parietal electrode. This same trend was observed for each combination of subject group and stimulus. The remaining effects—the main effect of diagnosis, the Diagnosis by Electrode Position interaction, and the Gating by Electrode Position interaction—were all nonsignificant.

Sex and age were factors in gating. None of the effects on P50 area tested in the three-way MANOVA changed their significant or nonsignificant status when tested in the five-way MANOVA. However, there were three additional significant effects. The age effect was significant (F=8.59, df=1, 32, p<0.01), with older subjects having larger P50 area responses than younger subjects. The Age by Sex interaction was significant (F=8.57, df= 1, 32, p<0.01). Among younger subjects, males had slightly larger P50 area responses than females (young

**FIGURE 3. Robust Sensory Gating of Normal Subjects and Impaired Gating of Schizophrenic Patients at Frontal, Central, and Parietal Electrode Placement Sites**



males, mean=8.9 μV, SD=1.9; young females, mean= 7.6 μV, SD=1.8); among older subjects, females had larger P50 area responses than males (older females, mean=12.2 μV, SD=1.7; older males, mean=9.1 μV, SD=2.8). The Age by Gating by Electrode Position interaction was significant ($T^2$=13.48; F=6.53, df=2, 31, $p<0.005$). Whereas some details of the difference in P50 area response pattern between younger and older subjects depended on whether the decrement from the first to the second click was measured in absolute square root of P50 area response or in relative change in square root of P50 area response, a consistent finding was that older subjects had their largest mean decrement at the parietal electrode position, and younger subjects had their smallest mean decrement at the parietal electrode position.

## DISCUSSION

The finding that schizophrenic subjects show impaired gating when the P50 conditioning test paradigm is used confirms observations of Freedman and associates (7–9). The normal subjects in this study showed robust sensory gating, whereas the schizophrenic patients showed impaired gating at the frontal, central, and parietal electrode sites. This group difference requires continued scrutiny in larger samples in order to assess the contributions of paradigmatic manipulations, intelligence, education, age, sex, medications, neurotransmitter concentrations, psychological states, and other relevant factors. Also, the relation of sensory gating failures to other information-processing deficits and clinical state and trait variables needs clarification. The functional significance of gating deficits in schizophrenic patients remains speculative. The most common assumption is that the individual is subject to sensory overload when normal gating mechanisms fail, which leads to cognitive fragmentation (1, 20, 21) and may result in the secondary formation of psychotic symptoms (22), although the exact sequencing of these events remains ambiguous and in need of experimental identification.

Potential mechanisms underlying the deficits in sensory gating have been investigated using animal models. Adler et al. (11) invoked the concept of hyperexcitable neuronal systems as a general construct. Swerdlow et al. (23) used the prepulse inhibition or sensorimotor gating of the startle response and found that nucleus accumbens dopamine overactivity induces sensorimotor gating failures parallel to those seen in schizophrenic patients (16). Further, direct infusion of dopamine into the nucleus accumbens (24) and systemic administration of $D_2$ but not $D_1$ agonists (25) produce similar losses of sensorimotor gating. It is possible that such increased subcortical dopamine tone is correlated with the inhibition of frontal brain activity, known as hypofrontality (26, 27), which may be related to gating failures. Supporting this view, the types of stimulus interactions used in our study ("proactive interference") have recently been interpreted as frontal-lobe-based functions (28). In a recent preliminary report, Butler et al. (29) found that paranoid schizophrenic patients with the greatest number of perseverative responses on the Wisconsin Card Sorting Test also showed the greatest loss of tactile but not auditory sensorimotor gating. Since the perseverative response measure of the Wisconsin Card Sorting Test has been reported to be correlated with frontal lobe damage (30), it is possible that both that test and various gating paradigms tap into a common dimension related to hypofrontality, perhaps associated with increased subcortical dopamine activity. Although the evidence in support of hypofrontality is mixed, increased subcortical dopamine activity is consistent with positron emission tomography findings that the mean metabolic centroid is more ventral and caudal in schizophrenic patients than it is in control subjects (31).

Last, it is important to note that the power difference between a 1.5-msec and a 0.04-msec click is so profound (i.e., 37.5 times) that differences between schizophrenic and control subjects could easily have been eliminated in the Kathmann and Engel study (10) by this difference alone. Our own results, with the use of a 0.04-msec click duration, seem to confirm that the increased click power played a role in eliminating the schizophrenia-related P50 gating deficits in that study, perhaps through mechanisms related to suprathreshold stimuli yielding asymptotic data for all groups tested. Future studies may usefully explore multiple click durations among the same subjects in order to clarify fully this issue. In human (20) and animal (32) studies of prepulse inhibition, subtle-appearing paradigmatic manipulations of stimulus intensity and background noise can have profound effects on sensorimotor gating. We have previously pointed out (20) that these information-processing functions often operate at threshold values, where minor experimental paradigmatic changes yield major differences. Thus, it is not surprising that Kathmann and Engel did not reproduce Freedman and associates' finding (7–9) of decreased gating in schizophrenic as compared to normal subjects when the power of the click stimulus was increased manyfold.

In this study, we observed a nonsignificant trend for the schizophrenia-linked gating deficits to be more pronounced in the frontal than in the posterior loci, and this trend needs further examination to see whether a specific subgroup of schizophrenic patients accounts for the gating deficit. Extensions of this research should evaluate the influence of the number of trials used and various interstimulus intervals. Importantly, the relation between reported decreases in regional cerebral blood flow in frontal and temporal lobes in schizophrenic patients (33) and event-related potentials responses in sensory gating paradigms needs to be clarified, as do the contributions of many other factors, including generalized and specific symptoms, neurotransmitter binders, and schizophrenic subtypes. Despite these residual issues, our study strongly confirms the finding of Freedman and associates that compared with normal subjects, schizophrenic patients show a loss of normal sensory gating.

# Bizarre Delusions and *DSM-III-R* Schizophrenia

Dodi Goldman, M.A., M.M.H., Denise A. Hien, M.S., Gretchen L. Haas, Ph.D., John A. Sweeney, Ph.D., and Allen J. Frances, M.D.

Objective: *Bizarre delusions are assigned greater weight relative to other delusions in the* DSM-III-R *diagnosis of schizophrenia. The decision to emphasize bizarre delusions was based largely on historical tradition rather than empirical evidence. This study examined 1) the extent to which a history of bizarre delusions contributes to the diagnosis of schizophrenia and 2) whether schizophrenic patients with bizarre delusions constitute a clinically distinguishable subgroup.* Method: *Two hundred fourteen consecutively admitted psychotic inpatients were assessed for bizarre delusions according to the* DSM-III-R *criteria. Clinical and demographic correlates of bizarre delusions were examined in subsets of patients diagnosed as schizophrenic according to* DSM-III-R *who also received CT scans and neuropsychological testing.* Results: *With the base prevalence rate for schizophrenia of 0.71, bizarre delusions had a sensitivity of 0.79, a specificity of 0.56, and a positive predictive power of 0.82 for the diagnosis of schizophrenia (N=152) relative to other psychotic disorders (N=62). Clinical, neurobehavioral, CT scan, and premorbid adjustment data on the schizophrenic patients indicated that beyond manifesting more severe positive symptoms, patients with bizarre delusions did not otherwise constitute a clinically distinguishable subgroup.* Conclusions: *The data suggest that criterion A for the diagnosis of schizophrenia in* DSM-IV *could be improved by removing the special emphasis that was placed on bizarre delusions in* DSM-III-R.

(Am J Psychiatry 1992; 149:494–499)

For decades clinicians and researchers have been seeking disease-specific or pathognomonic indicators of schizophrenia. The markedly strange, fantastic, and idiosyncratic content of certain delusions has been thought by some to be a unique hallmark of schizophrenia. Despite the absence of empirical evidence, these so-called bizarre delusions (defined in *DSM-III-R* as delusions "involving a phenomenon that the person's culture would regard as totally implausible") were given greater weight relative to nonbizarre delusions in the *DSM-III-R* criteria for schizophrenia. As part of the effort to validate symptom criteria for inclusion in *DSM-IV,* there is a need for systematic investigation of the value of giving special significance to bizarre delusions in the criteria for the diagnosis of schizophrenia.

According to *DSM-III-R,* the presence of bizarre delusions is by itself sufficient to meet the psychotic symptoms requirement that constitutes criterion A for the diagnosis of schizophrenia. If delusions are not bizarre, the patient must demonstrate at least one additional psychotic symptom to meet this criterion. For some psychotic patients, therefore, the differential diagnosis of delusional disorder versus schizophrenia depends on whether their delusions are judged to be bizarre (1, 2).

From a historical perspective, the concept of bizarre delusions is a vestige of Schneider's (3) first-rank symptoms, which included delusions of being controlled, thought broadcasting, and thought insertion or withdrawal. Although Schneider suggested that these symptoms should be considered pathognomonic of schizophrenia, subsequent studies have not supported this notion (4). Carpenter et al. (5) found that first-rank symptoms do appear frequently in schizophrenia but are by no means exclusive to schizophrenia. Moreover, they found that frequent diagnostic errors are made if these symptoms are viewed as pathognomonic. Other investigators have reported findings consistent with this conclusion (6, 7). Although there is some evidence that first-rank symptoms may have some discriminative value in distinguishing among psychotic disorders (8),

[a] Includes *DSM-III-R* schizophrenia, schizophreniform disorder, and schizoaffective disorder.
[b] Manic episode.
[c] Includes brief reactive psychosis (N=2) and psychotic disorder not otherwise specified (N=2).
[d] Significant difference between groups ($\chi^2$=17.18, df=8, p<0.05).

there is considerable variability in estimates of the prevalence of these symptoms in schizophrenia, ranging from as high as 72% (9) to as low as 28% (10). It is important to note, however, that most studies have considered first-rank symptoms collectively, leaving the specific value of the bizarre delusion criterion relatively unexplored.

Findings on the prognostic value of first-rank symptoms have also been contradictory. Taylor (10) and Harrow et al. (11, 12) concluded that schizophrenic patients with first-rank symptoms showed poorer outcome than patients without first-rank symptoms, but Strauss and Carpenter (13) and Hawk et al. (14) found no relation between outcome and the presence or absence of these symptoms. Kendell et al. (15) concluded that Schneider's first-rank symptoms were among the poorest predictors of social and symptomatic outcome when compared to five alternative operational definitions of schizophrenia.

In the present study, we investigated the diagnostic efficiency (16–18) of bizarre delusions and the relation between bizarre delusions and other clinical features of hospitalized schizophrenic patients. In particular, we asked, 1) To what extent does the presence of a history of bizarre delusions contribute to the diagnosis of schizophrenia? and 2) Do schizophrenic patients with bizarre delusions differ from other schizophrenic patients on key demographic and/or clinical features?

## METHOD

Subjects were recruited from among psychotic inpatients consecutively admitted to a psychiatric teaching hospital. Thorough screening of new admissions to the hospital was conducted daily. Patients with histories of neurologic or significant medical illness or substance abuse/dependence disorders that might confound diagnosis or clinical presentation were excluded from the study.

The 214 subjects were aged 18–55 years. On the basis of information gathered with the Structured Clinical Interview for DSM-III-R (SCID) (19), the patients had the following diagnoses: schizophrenia (N=119), schizoaffective disorder (N=26), schizophreniform disorder (N=7), bipolar disorder with psychotic features (N=36), major depression with psychotic features (N=11), delusional disorder (N=11), psychotic disorder not otherwise specified (N=2), and brief reactive psychosis (N=2). The mean age was 31.4 years (SD=8.6) for the 152 patients with schizophrenic disorders, 33.1 years (SD=9.6) for the patients with bipolar disorder, 28.4 years (SD=10.4) for the patients with depression with psychotic features, 33.0 years (SD=8.2) for the patients with delusional disorder, and 29.8 years (SD=8.0) for the four patients with other psychotic disorders. Age and other demographic characteristics were essentially equivalent across diagnostic groups, with the exception of marital status (table 1). A higher percentage of the patients with bipolar and other psychotic disorders were currently or had been previously married.

The lifetime histories of bizarre delusions of the 214 patients were determined using *DSM-III-R* criteria. Three raters, independently and without knowledge of final diagnoses, reviewed written transcripts of relevant data collected in the SCID interviews and determined whether or not each reported delusion qualified as bizarre. The kappa coefficient for the three independent raters was 0.78. For the final data analysis, discrepancies between ratings were resolved through discussion

**TABLE 2. Diagnostic Efficiency[a] of Bizarre Delusions in Differentiating Schizophrenic Disorders From Other Psychotic Disorders**

| Bizarre Delusions | Patients With Schizophrenic Disorders (N=152) | Patients With Other Psychotic Disorders (N=62) | Total (N=214) |
|---|---|---|---|
| Present | 120(a) | 27(b) | 147 |
| Absent | 32(c) | 35(d) | 67 |

[a] For the calculations, patients with delusional disorder (N=11) were included in the group with other psychotic disorders. Base prevalence rate of schizophrenic disorders=number of schizophrenic patients/total number of patients: 152/214=0.71. Sensitivity=a/number of schizophrenic patients: 120/152=0.79. Specificity=d/number of patients with other psychotic disorders: 35/62=0.56. Positive predictive power=a/(a+b): 120/147=0.82. Negative predictive power=d/(c+d): 35/67=0.52. Meehl and Rosen's (16) index of diagnostic efficiency: prevalence (P)/(1–P)>(false positive rate)/(true positive rate): 0.71/(1.0–0.71)>(27/62)/(120/152).

until a consensus judgment was obtained; additional opinions of senior clinicians were used when necessary.

From the group of 119 patients diagnosed as having *DSM-III-R* schizophrenia, a subset of 81 patients was included in an intensive clinical assessment study. These patients were predominantly single (74.1%, N=60), and their mean age was 31.8 years (SD=9.0); 61.7% (N=50) were white, 29.6% (N=24) were black, and 8.6% (N=7) were "other." They came from a broad distribution of socioeconomic strata: 12.3% (N=10) from levels I and II (upper and upper-middle class), 30.9% (N=25) from level III (middle class), 27.2% (N=22) from level IV (lower-middle class), and 29.6% (N=24) from level V (lower class). The following clinical dimensions were assessed: 1) the global level of current functioning, with the Global Assessment Scale (GAS) (20); 2) the severity of general symptoms, with the Brief Psychiatric Rating Scale (BPRS) (21); and 3) the severity of specific positive and negative symptoms, with the Scale for the Assessment of Positive Symptoms (22) and the Scale for the Assessment of Negative Symptoms (23). We also used the Cannon-Spoor Premorbid Adjustment Scale (24) to assess levels of social, sexual, academic, and occupational functioning at various developmental stages prior to the onset of illness. The interviews for this scale were conducted with each of the patients near the time of discharge. When available, family members were interviewed to provide additional information on the patients' premorbid adjustment.

Neurobehavioral tests and CT scans were done on patients (N=65) who qualified for study on the basis of the following criteria: no known systemic or neurologic illness by history and by physical examination, no prior ECT, no history of head trauma or substance dependence, and no significant substance abuse within 1 month before testing (and for eye movement measures, no lithium or benzodiazepines within 2 weeks before testing). Neurobehavioral assessments included 1) a battery of neuropsychological tests (Wisconsin Card Sorting Test, Rey Verbal Learning Test, Block Design, Benton Judgment of Line Orientation, F-A-S Verbal Fluency, Finger Tapping, Trail-Making, and Ammons' IQ test), 2) pursuit eye movement testing, and 3) a CT scan for calculating the ventricle-brain ratio (VBR) of the lateral ventricles and frontal horns, by procedures reported elsewhere (25).

## RESULTS

A history of bizarre delusions was documented for 78.9% (N=120) of the 152 patients with "broad-band" schizophrenic disorders (i.e., schizophrenia, schizoaffective disorder, and schizophreniform disorder) (table 1). Prevalence rates were essentially equivalent for the patients with schizophrenia (79.0%, N=94), schizoaffective disorder (80.8%, N=21), and schizophreniform disorder (71.4%, N=5)($\chi^2$=0.29, df=2, n.s.). A history of bizarre delusions was present in 43.5% (N=27) of the patients with nonschizophrenic psychotic disorders, a significantly lower prevalence rate than that for the group with broad-band schizophrenic disorders ($\chi^2$=24.04, df=1, $p<0.0001$).

Seven of the 214 patients met the *DSM-III-R* psychotic symptom criterion for schizophrenia solely on the basis of the presence of bizarre delusions. Thus, 3.3% of all of the psychotic patients and 4.6% of all of the patients with *DSM-III-R* schizophrenic disorders would have failed to qualify for a diagnosis of schizophrenia if bizarre delusions had not been a "sufficient" psychotic symptom in the *DSM-III-R* criterion A for schizophrenia. If bizarre delusions had not been given special emphasis in the diagnosis of schizophrenia, two of these seven patients would have met the *DSM-III-R* criteria for delusional disorder. They did not show a pattern of bizarre behavior, and although chronically psychotic, they had demonstrated intact functioning until shortly before admission. The remaining five patients would have been assigned to the *DSM-III-R* category of psychotic disorder not otherwise specified. Of the seven patients who would no longer be considered schizophrenic, six had experienced their first psychotic episode within the previous 12 months.

Compared to the base prevalence rate for schizophrenia of 0.71 in this sample (table 2), a history of bizarre delusions had a diagnostic sensitivity of 0.79 and a specificity of 0.56. This symptom showed a relatively high positive predictive power of 0.82, indicating that 82% of the patients with histories of bizarre delusions received the *DSM-III-R* diagnosis of schizophrenia. The negative predictive power of 0.52 indicates that 52% of the patients who did not have this symptom received *DSM-III-R* psychotic disorder diagnoses other than schizophrenia.

As one approach to assessing the diagnostic efficiency of the bizarre delusion symptom, we used Meehl and Rosen's base-rate-corrected evaluation of classification accuracy (16). This index (footnote to table 2) indicates whether a certain symptom or test value improves the classification accuracy above and beyond reliance on the base rate alone. In this sample, the index of diagnostic inaccuracy (the false positive rate [0.44] divided by the true positive rate [0.79], i.e., 0.56) was exceeded by

[b] Significant difference between groups (t=2.55, df=79, p<0.02).

the index of prevalence (the positive base rate of schizophrenia in the sample [0.71] divided by the negative base rate [0.29], which is equivalent to 2.45). This indicates that the accuracy of diagnosis when the presence or absence of a history of bizarre delusions was used exceeded the base rate of the disorder in our sample (footnote to table 2). A z test of the significance of the difference in proportions indicated that the efficiency of diagnosis based on the symptom criterion (0.82) was statistically greater in magnitude than that attained using the base rate alone (0.71) (z=2.38, p<0.009).

Because according to the *DSM-III-R* criteria, a patient with delusional disorder cannot have bizarre delusions, the preceding analyses may have yielded an artificially high estimate of the diagnostic specificity of bizarre delusions. For this reason, a second analysis was conducted in which patients with *DSM-III-R* delusional disorder were excluded from the group with nonschizophrenic psychoses. In this case, bizarre delusions were found in 52.9% of the patients with nonschizophrenic psychoses—still a significantly lower prevalence than for the broad-band schizophrenia group ($\chi^2$=12.93, df=1, p<0.0003). With the revised, now higher, base rate of 0.75 for schizophrenia, the specificity of bizarre delusions dropped from 0.56 to 0.47, and the negative predictive power dropped from 0.52 to 0.43. Using the revised base rate in the computation of the Meehl and Rosen index, we found that the bizarre delusion criterion still added meaningfully to diagnostic classification beyond the base rate alone in identifying cases of *DSM-III-R* schizophrenia.

To determine whether schizophrenic patients with bizarre delusions represent a clinically distinctive subgroup, we examined the demographic and clinical characteristics of 81 of the 119 patients with *DSM-III-R* schizophrenia for whom extensive clinical assessments were available. This group included 64 patients with and 17 patients without histories of bizarre delusions. Comparisons of the demographic characteristics of these two groups showed no significant differences in age, sex, marital status, race, or socioeconomic status.

We determined the relation between a history of bizarre delusions and admission ratings of symptom severity (with the scales for positive and negative symptoms and the BPRS) and global functioning (with the GAS). The results (table 3) indicated that patients with histories of bizarre delusions showed significantly more severe positive symptoms, as measured by the sum of the global ratings from the Scale for the Assessment of Positive Symptoms. Hallucinations and delusions, as assessed on the global scales from that instrument, were significantly more severe among the patients with bizarre delusions (t=4.48, df=78, p<0.001, and t=2.54, df=79, p<0.02, respectively). Patients with histories of bizarre delusions also had more severe general psychopathology on admission (as measured by total BPRS scores) than those who did not have histories of bizarre delusions. At admission no significant differences between groups were found on the negative symptom dimensions of the Scale for the Assessment of Negative Symptoms. Global functioning at admission, as measured by the GAS, was poorer for the patients with histories of bizarre delusions when compared with the other patients.

Results of neurobehavioral assessment revealed that the patients with histories of bizarre delusions had *fewer* perseverative errors on the Wisconsin Card Sorting Test (t=2.03, df=64, p<0.05), a trend for *smaller* VBR of the frontal horns (t=1.93, df=64, p<0.05) but not the body of the lateral ventricles, and higher IQs (t=3.49, df=64, p<0.01). There were no significant differences on other neuropsychological tests or in gain of pursuit eye movements.

Finally, we investigated the relation between a history of bizarre delusions and clinical factors often considered to be prognostic indicators (age at onset, number of previous hospitalizations, duration of illness, premorbid adjustment, and length of stay during the index hospitalization). The results (table 4) indicated no significant differences between the two groups, with a single exception: patients with histories of bizarre delusions had a significantly shorter hospital stay.

## DISCUSSION

The nosological changes introduced by *DSM-III-R* gave greater weight to bizarre delusions than to nonbizarre delusions in the differential diagnosis of schizophrenia. The assessment of lifetime histories of bizarre delusions among patients with psychotic disorders revealed that bizarre delusions are characteristic of a sizable majority (78.9%) of patients with schizophrenic disorders but are also found with relatively high prevalence (43.5%) in patients with other *DSM-III-R* psychotic disorders. These findings are consistent with previous studies that disputed the pathognomonic character of these symptoms on the basis of prevalence data obtained for various psychotic disorders (5–8).

With use of the Meehl and Rosen index of classification accuracy, the bizarre delusion symptom proved more "efficient" than the schizophrenia base rate alone in accurately classifying cases in our sample into the schizophrenia and nonschizophrenia categories. (On the basis of the ratio of false positives to true positives for our sample, Meehl and Rosen's index of classification accuracy indicates that use of the bizarre delusion symptom would yield more accurate classification than that obtained by using the base rate alone in settings with a base rate for schizophrenia, among psychotic disorders, of 36% or more.) This indicates merely that patients with bizarre delusions were more likely to have schizophrenia than any other psychotic disorder, even with a correction for the base rate of the syndrome.

A more stringent criterion of efficiency is reflected by the number of cases in which the diagnosis of the target disorder would change with a change in the presence or absence of the criterion symptom. In the case of the bizarre delusion symptom criterion, we found that elimination of the extra emphasis on bizarre delusions in criterion A of the *DSM-III-R* definition of schizophrenia would result in only a relatively small number of changes in diagnosis (3%–4%) among a heterogeneous group of patients with psychotic disorders. All but one of the patients diagnosed as having schizophrenia on the basis of meeting this criterion were first-hospitalization patients in the early phase of illness. Although bizarre delusions may offer an advantage for earlier detection of schizophrenia, it is not clear whether all such patients would go on to meet the other diagnostic criteria for schizophrenia. Examination of the patients in our sample who had been ill for 5 years or longer and had histories of bizarre delusions revealed that all of them also had histories of other psychotic symptoms. Therefore, it is possible that over the course of the illness, the diagnosis may become less contingent on the presence of bizarre delusions alone. This suggests that, from a nosological point of view, the bizarre delusion symptom criterion could be dropped as a sufficient psychotic symptom without significantly changing clinical diagnostic practice. The possible cost of delaying the diagnosis of schizophrenia in a small percentage of first-episode patients would be offset by the lack of evidence that this diagnosis is suitable for such individuals.

Comparison of the clinical characteristics of patients with and without histories of bizarre delusions revealed that patients with bizarre delusions had more severe psychotic symptoms at the height of the index episode. Several explanations may account for the more severe positive symptoms in these patients. In patients who presented with bizarre delusions during the target hospitalization, the bizarreness of the delusions might have accounted for the severity of the positive symptom ratings. However, global ratings of hallucinations were also higher for patients with histories of bizarre delusions, suggesting that the elevated global positive symptom ratings were not attributable to bizarre delusions alone. This suggests that schizophrenic patients with histories of bizarre delusions tend to become more acutely psychotic during exacerbations of illness.

Other than the more florid positive symptoms during acute exacerbations, there were no significant differences between schizophrenic patients with and without bizarre delusions in demographic characteristics, premorbid adjustment, or age at onset of illness. Patients with histories of bizarre delusions actually stayed fewer days in the hospital. From the neurocognitive assessment data, there was no indication that a history of bizarre delusions was associated with a more severely disabling illness. In fact, trends in the data were for patients with bizarre delusions to manifest fewer neuropsychological and neuroanatomic impairments. Thus, in terms of factors often thought to be associated with a poorer course of illness (such as premorbid adjustment, age at onset, length of hospital stay, negative symptoms, and neuropsychological and neuroanatomic abnormalities), patients with bizarre delusions were not clinically distinguishable from those without bizarre delusions. In sum, these data do not support the notion that a history of bizarre delusions is prognostic of a more severe form of illness.

Another important issue in evaluating the utility of bizarre delusions as a diagnostic criterion for schizophrenia is the extent to which delusions can be reliably classified as bizarre. Many investigators have noted that it is often difficult to reach agreement among even the most experienced of practitioners (26, and personal communication from K. Kendler, 1990). The *DSM-III-R* definition of "bizarre," based as it is on implausibility rather than physical impossibility, was intended to enhance the clarity of the definition and thus to increase potential interrater agreement on its presence or absence. Nonetheless, there still remains some lack of clarity about what constitutes an implausible delusion. For example, a Hispanic patient who reports spirit possession, or a fundamentalist Christian professing to be controlled by Jesus, or an anxious city dweller who avoids use of the subway because he is convinced that exposure to the electromagnetic field is giving him cancer could present problematic determinations for the clinician. Given the diversity of ethnic and cultural belief systems, and advances in modern technology that tend to blur the distinctions between science fiction and physical fact, it is often difficult to come to a categorical determination of the implausibility of a belief. Nevertheless, the relatively high kappa rate obtained in this study (0.78) demonstrates that a reasonable degree of reliability can be achieved with use of the current operational definition. However, it is likely that our interrater reliability estimate approaches an upper limit, because our assessment team met regularly over a period of years and conducted weekly live interviews and consensus reviews of diagnostic data.

In summary, although bizarre delusions are often presented by patients with schizophrenia, psychotic patients in other *DSM-III-R* categories also show a high prevalence of these delusions. Few patients in our sample met the psychotic symptom criterion for schizophrenia solely on the basis of the presence of a history of bizarre delusions. Patients with bizarre delusions showed more severe positive symptoms at admission; however, on demographic, premorbid adjustment, neurocognitive, and all other clinical measures, there was no evidence that the presence of a history of bizarre delusions reflected a more pathological form of illness. Whereas there may be merit in retaining the bizarre delusion symptom in the exclusion criteria for the diagnosis of delusional disorder, retaining it in the inclusion criteria for schizophrenia appears to add an unnecessary level of complexity to the diagnosis of schizophrenia, with little obvious benefit for clinical practice. Taken as a whole, our data suggest that criterion A for *DSM-IV* could be improved by removing the special emphasis that was placed on bizarre delusions in *DSM-III-R*.

# Haloperidol Plasma Levels and Clinical Response: A Therapeutic Window Relationship

Theodore Van Putten, M.D., Stephen R. Marder, M.D., Jim Mintz, Ph.D., and Russell E. Poland, Ph.D.

---

*Objective: The purpose of the study was to assess the relationship between plasma haloperidol and clinical response. Method: Sixty-nine newly admitted drug-free schizophrenic men were randomly assigned to receive haloperidol, 5, 10, or 20 mg daily for 4 weeks, and clinical response was measured at the end of the fixed-dose period. Haloperidol was assayed by a sensitive and specific radioimmunoassay. Results: The authors found a curvilinear relationship between clinical response and plasma haloperidol during fixed-dose treatment, with an apparent optimum between 5 and 12 ng/ml. When plasma levels above 12 ng/ml were lowered to the 5–12 ng/ml range, all patients improved to varying degrees and no patient deteriorated. When plasma levels of nonresponders within this therapeutic window were raised above 12 ng/ml (as in routine practice), they, on balance, deteriorated in that they became more dysphoric. With the 20-mg dose, half the patients had plasma levels above 12 ng/ml. Conclusions: In this sample of newly admitted schizophrenic men, optimal clinical response occurred with a plasma haloperidol range of 5–12 ng/ml.*

(Am J Psychiatry 1992; 149:500–505)

---

To detect a relationship between plasma haloperidol levels and clinical response, patients need to be treated with a fixed dose of haloperidol. Preferably, patients are randomly assigned to a low, moderate, and high dose so that both ends of the therapeutic window (if such exists) are represented. Variable-dose studies tend to produce artifactual therapeutic windows (1).

Four fixed-dose studies with haloperidol suggest a therapeutic window relationship between plasma haloperidol and clinical response. The suggested optimal drug concentrations are 6.5–16 ng/ml (2), 3–11 ng/ml (3), 4–11 ng/ml (4), and 4–22 ng/ml (5). Six fixed-dose studies did not find a therapeutic window relationship, but they were so designed that detection of a therapeutic window relationship (if such exists) was unlikely. Two of the studies (6, 7) used primarily poor neuroleptic responders; three used such low doses—5 versus 10 mg (8), 6 mg (9), and 0.2 mg/kg (10)—that detection of an upper toxic limit was unlikely; and three used doses too high—60 versus 120 mg (7), 0.4 mg/kg (6), and 30 mg (11)—to have plasma levels in the subtherapeutic range. In other words, of the 10 fixed-dose studies with haloperidol, four, in retrospect, were designed properly, and these four found a therapeutic window.

In the four studies (2–5) that suggested a therapeutic range, there were only 26 patients that defined the proposed toxic range, and 17 of these were in Potkin et al.'s investigation (5) of Chinese schizophrenic patients, in which the curvilinear fit explained only 8% of the variance of clinical improvement. Further, these studies failed to discuss the clinical state of patients with high, supraoptimal haloperidol levels. Do such patients appear overmedicated, and, more importantly, do they improve when plasma levels are lowered? This study addresses these issues. The matter is important, for if a therapeutic window relationship exists, it could have significant implications for clinical practice. In particular, the dose would be reduced in some nonresponding patients.

## METHOD

### *Subjects*

The subjects were 82 newly admitted, drug-free (for at least 2 weeks but usually several months) schizophrenic men. They had given informed consent, and

each patient suffered from a schizophrenic disorder (*DSM-III-R*) without significant physical disease or drug or alcohol addiction. Patients with a history of nonresponse to neuroleptic drugs were excluded, as were those who had a history of severe extrapyramidal side effects with high-potency neuroleptics. Those with a history of poor compliance with medication or treatment also were excluded. Patients were observed in a drug-free state (except for chloral hydrate) for at least 3 days, and none started treatment with haloperidol as long as there was an indication of spontaneous improvement.

Characteristics of the 69 patients who completed the study are detailed in table 1. The patients' ages averaged in the early 30s, and the patients averaged four previous hospitalizations. They had all served in the armed forces, had worked for a mean of 4.5 years at some time, were judged markedly ill on a nurses' rating scale, and had scored at least moderate on conceptual disorganization, unusual thought content, or hallucinatory behavior on the Brief Psychiatric Rating Scale (BPRS) (12). In fact, their mean baseline BPRS Schizophrenia factor score was 13 (normal=3, maximum=21), indicating that they were quite psychotic at baseline. Very excited or menacing patients were not included.

[c] Perfect score=3.

### *Procedure*

The 82 patients were assigned to receive haloperidol, 5, 10, or 20 mg daily for 4 weeks. Patients were assigned by cohort. The first 38 eligible patients were given the 10-mg dose, the next 22 eligible patients were given the 5-mg dose, and the next 22 eligible patients were given the 20-mg daily dose. Assignment to dose was independent of the patient's presenting clinical symptoms. Of the 82 patients, haloperidol plasma levels were available for 69 (of the 13 subjects lost from the study, four eloped, four had protocol violations, three refused blood drawing, and all blood samples were lost for two patients). In case of nonresponse, the physician could increase (or decrease) the dose for another 4 weeks according to clinical judgment. Clinical response was measured at baseline, weekly for the first 4 weeks, and at week 8 after the flexible-dose period. Clinical ratings were made by clinicians who were blind to plasma levels.

Clinical status was assessed weekly in semistructured interviews with the first author (T.V.P.), using the BPRS and the Clinical Global Impression (CGI) (13). The rater was not blind to dose. Extrapyramidal side effects were rated with the Involuntary Movement and Extrapyramidal Side Effects Scale (unpublished manuscript; copies available on request from Dr. Van Putten). On this scale akathisia is scored on a 7-point scale and akinesia is rated for decreases in facial expression, gestures, spontaneous movement, and speed of movement.

Haloperidol was assayed by a sensitive and specific radioimmunoassay (14, 15) capable of detecting 0.5 ng/ml of haloperidol with a within-sample variance (standard deviation/mean) of less than 10%. All samples from each subject were analyzed together in the same batch. The maximum intra-assay and interassay coefficient of variation was 12%, as determined by multiple serum pool replicates analyzed repeatedly in all assays. Blood was drawn weekly in the morning, 10 to 12 hours after the last dose.

### *Data Analysis*

Haloperidol plasma levels were averaged during fixed- dose treatment, and clinical change was measured by the change from baseline on the BPRS Psychosis cluster (Thought Disturbance and Hostile Suspiciousness clusters). Mean haloperidol plasma levels had an estimated reliability (intraclass correlation) of 0.83. These data were fit to a theoretical model that proposed the presence of two sigmoidal plasma level-effect functions, one representing positive treatment response (i.e., increasing BPRS Psychosis improvement scores) and the other representing negative effects (i.e., decreasing BPRS Psychosis improvement scores), as suggested by Teicher and Baldessarini (15). In this two-component model, the predicted BPRS change score is obtained by subtracting the negative component from the positive component.

Each of the two hypothesized components is defined by its slope, minimum and maximum values. The full six-parameter model was initially estimated by using nonlinear regression (16). Very high correlations among the parameters, extremely large coefficients of variation, and poor convergence suggested that a simpler model might be better in this data set. A four-parameter model with equal slopes appeared to be optimal, yielding the same pseudo-$R^2$ (0.46) as the full model. In the final model, coefficients of variation ranged from –0.28 to 0.34, and correlations between parameters ranged from –0.86 to 0.54.

FIGURE 1. Two Sigmoidal Functions of Outcome in Relation to Plasma Haloperidol Concentrations in 69 Schizophrenic Men

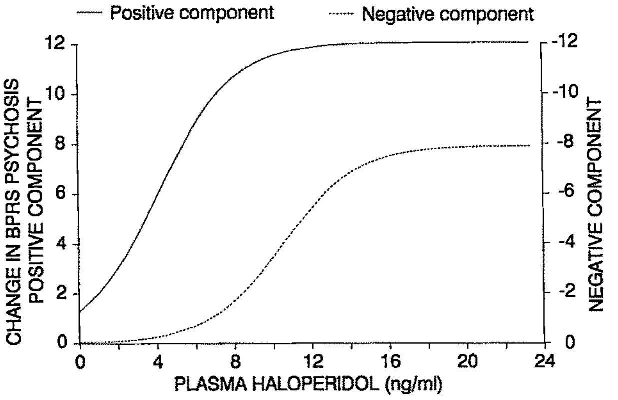

FIGURE 2. Curvilinear Relationship Between Plasma Haloperidol Concentration and Change in BPRS Psychosis Factor for 69 Schizophrenic Men

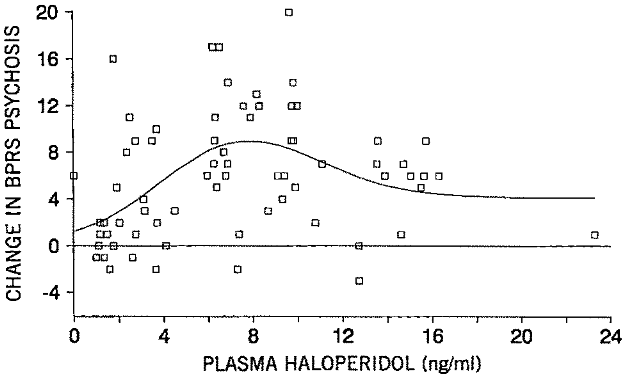

TABLE 2. Scores of 69 Schizophrenic Men on the BPRS Psychosis Factor After Haloperidol Treatment

| Haloperidol Plasma Level Range (ng/ml) | BPRS Psychosis Factor Score |  | N |
|---|---|---|---|
|  | Mean | SD |  |
| Ineffective (<2) | 2.4 | 4.9 | 12 |
| Threshold (2–5) | 4.2 | 4.4 | 14 |
| Optimal (5–12) | 8.8 | 5.0 | 30 |
| Suboptimal (>12) | 4.6 | 3.7 | 13 |

## RESULTS

Figure 1 shows the two sigmoidal dose-effect curves. Negative responses start at about 8 ng/ml and plateau at about 15 ng/ml. Positive treatment response plateaus at about 10 ng/ml. If we subtract the negative from the positive response curve, the resultant curve appears to fit the data rather well (r=0.46, df=66, p=0.001).

Figure 2 shows this two-component model superimposed on the scatterplot of change in the BPRS Psychosis factor versus mean plasma haloperidol. By inspection, it appears reasonable to divide the data into the following nanogram/milliliter ranges: less than 2 (ineffective), 2–5 (threshold), 5–12 (optimal), and more than 12 (suboptimal or toxic). Mean improvement on the BPRS Psychosis factor was significantly greater by t test in the optimal than in the suboptimal range (p=0.004) or the threshold range (p=0.004) (table 2). Mean improvement in the optimal range was roughly twice that in the threshold and suboptimal ranges. The standardized effect sizes were both large (0.95 and 0.90, respectively).

Thirteen patients had mean plasma haloperidol levels above 12 ng/ml at the end of the fixed-dose period. Three insisted on leaving the hospital before a dose adjustment was possible (all had become more paranoid [mean BPRS Paranoia score=–3.5, SD=2.5], and two had become extremely dysphoric). One patient with a mean plasma haloperidol level of 15.6 ng/ml insisted that he required more haloperidol, and his plasma level eventually reached 90 ng/ml (see Discussion). Another patient with a plasma haloperidol level of 14.7 ng/ml was mildly retarded (BPRS Withdrawal-Retardation score=–2) but refused dose reduction. When the plasma haloperidol levels of the remaining eight patients were reduced to less than 12 ng/ml (range=4.0–10.8 ng/ml, mean=7.8), they experienced milder side effects (in particular, a subjective sense of sedation or objective akinesia) and became less psychotic (N=5), less dysphoric (N=3), and less retarded (N=8). No patient deteriorated. Two patients had developed peculiar delusions of bodily destruction, which vanished as the plasma level was lowered. Table 3 summarizes these changes.

In eight relative nonresponders (defined as patients with a global improvement rating of minimally improved or less) with plasma levels in the 2–12 ng/ml range, the plasma level was raised above 12 ng/ml (range=12.9–24 ng/ml, mean=17.8) by increasing mean daily dose from 9.2 mg (SD=2.0) to 23.3 (SD=7.5). Six of eight patients became worse on the global improvement ratings, and, on balance, these six became more dysphoric. Table 4 summarizes the changes.

Figure 2 suggests a threshold limit of 2 ng/ml. If so, patients with plasma levels lower than 2 ng/ml at the end of the fixed-dose period should improve as the plasma level is raised to 2–12 ng/ml. Patients with plasma levels of 1.8, 1.5, 1.6, 1.1, 1.1, and 1.4 ng/ml all improved (with the CGI as the criterion) as their plasma levels rose above 2.0 ng/ml (the plasma levels at which improvement occurred were 2.9, 2.6, 2.1, 2.2, 2.0, and 6.7 ng/ml, respectively). One man with a plasma level of 1.8 ng/ml improved remarkably.

## DISCUSSION

A curvilinear relationship was found between plasma haloperidol and clinical response when patients were given fixed doses of haloperidol. The approximate upper and lower limits of this proposed therapeutic window were 12 and 5 ng/ml, respectively, with 2 ng/ml as a threshold level. When plasma haloperidol levels in relative nonresponders were pushed beyond 12 ng/ml

**TABLE 3. Change in BPRS Scores of Eight Schizophrenic Men When Plasma Haloperidol Levels Were Reduced to Less Than 12 ng/ml**

| | | | Change in BPRS Factor Score From Baseline[a] | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | Haloperidol Level (ng/ml) | | Schizophrenia | | Depression | | Paranoia | | Withdrawal-Retardation | |
| Weeks | Mean | SD | Mean | SD | Mean | SD | Mean | SD | Mean | SD |
| 1–4 | 15.0 | 2.1 | 5.1 | 1.6 | 1.0 | 4.3 | 2.4 | 2.9 | –2.3 | 3.4 |
| 5–8 | 7.8 | 2.1 | 6.4[b] | 2.2 | 2.8 | 3.8 | 3.0[c] | 3.5 | –0.1[d] | 3.8 |

[a] Higher change scores mean more improvement; a negative score means deterioration.

[b] $t=2.76$, df=7, $p<0.05$; paired t test, two-tailed, for all comparisons.

[c] $t=1.93$, df=7, $p<0.10$.

[d] $t=5.34$, df=7, $p<0.01$.

| | | Plasma Level (ng/ml) | | |
|---|---|---|---|---|
| Dose (mg/day) | N | Mean[b] | SD | Range |
| 5 | 21 | 2.2 | 0.9 | 1.0–4.1 |
| 10 | 31 | 7.7 | 3.2 | 0.0–15.6 |
| 20 | 17 | 12.8 | 4.0 | 7.6–23.3 |

[a] Correlation (r) for haloperidol level versus dose=0.78, df=67, $p<0.0001$.

[b] For each patient weekly plasma levels were averaged.

(as in routine clinical practice), they, on balance, worsened. In particular, they became (relative to their status at more moderate plasma levels) more dysphoric (mean BPRS Depression factor score=–2.6, SD=2.8, $p<0.07$) and more withdrawn (mean BPRS Withdrawal-Retardation factor score=1.3, SD=2.6, n.s.) and did not improve in global psychosis ratings (mean Schizophrenia and Paranoia factor score=–0.83, SD=3.4, n.s.).

Similarly, when patients with plasma levels higher than 12 ng/ml had their plasma levels lowered, they, on balance, improved (change in mean BPRS Schizophrenia factor score of 1.25, $p<0.05$; change in mean Withdrawal-Retardation factor of 2.1, $p<0.01$). No patient deteriorated. Some improved in that they no longer appeared overmedicated in terms of a subjective sedation or objective akinesia. Three patients with plasma levels higher than 12 ng/ml had become globally worse, developed a frantic agitation, and insisted on leaving the hospital before plasma levels could be lowered (two of these patients had become profoundly depressed). Finally, two patients had developed delusions of bodily destruction, which disappeared as the plasma level was lowered.

The division of the data into ineffective, threshold, optimal, and suboptimal ranges was by informal estimation and must be regarded as an approximation. For example, the upper limit of the optimal range could well be drawn at 10 ng/ml. Clinically, the most important is the suboptimal or toxic range (higher than 12 ng/ml), which contained only 13 patients. While plasma level reduction into the 5–12 ng/ml range in eight of these 13 patients resulted in improved psychosis ratings, the same or greater improvement in psychosis ratings (but not in withdrawal-retardation ratings) could have occurred had these patients been exposed to another 4 weeks of the same suboptimal plasma level. To confirm a toxic or suboptimal range, half the patients in the toxic range would need to be randomly assigned to the 5–12 ng/ml range, and the other half would need to remain at the toxic level. Therefore, a clear decrease in antipsychotic effect at a haloperidol level above 12 ng/ml has not been demonstrated.

We also do not mean to imply that patients with plasma levels above 12 ng/ml (table 5) do not improve relative to baseline (after all, many schizophrenic patients in the United States are treated with plasma levels above 12 ng/ml). Table 6 dichotomizes patients into very much or much improved versus minimal improvement, no change, or minimally worse. Five of 13 patients were rated improved at plasma levels higher than 12 ng/ml. In addition, some patients tolerated very high plasma levels. One 33-year-old man in the present sample requested more and more haloperidol, claiming that each dosage increase made him feel somewhat better. Finally, at a dose of 90 mg of haloperidol (plasma level=90 ng/ml), he became slightly sedated and developed moderate akathisia and dyskinesia but remained

**TABLE 6. Global Improvement in 68 Schizophrenic Men at End of Fixed-Dose Period of Haloperidol Treatment**

| Haloperidol Plasma Level Range (ng/ml) | Actual Plasma Level (ng/ml) |  | Improvement on CGI[a,b] |  |  |  |  |
|---|---|---|---|---|---|---|---|
|  |  |  | Improved |  | Not Improved |  |  |
|  | Mean | SD | N | % | N | % | Ratio |
| Ineffective(<2) | 1.3 | 0.5 | 1 | 9 | 10 | 91 | 0.10 |
| Threshold (2–5) | 3.2 | 0.7 | 6 | 43 | 8 | 57 | 0.75 |
| Optimal (5–12) | 8.2 | 1.6 | 22 | 73 | 8 | 27 | 2.75 |
| Suboptimal (>12) | 15.2 | 2.7 | 5 | 39 | 8 | 62 | 0.63 |

[a] Improved=very much or much improved; not improved=minimal improvement, no change, or minimally worse.
[b] $\chi^2$=10.75, df=3, p=0.01.

much improved. When his plasma level was decreased to the therapeutic range, he remained improved and had fewer side effects (including dyskinesia).

Since the correlation between dosage and plasma level was high (r=0.78), a plasma level usually does not provide much extra information. On a dose of 10–15 mg/day, nearly all patients would be in the therapeutic window. There are exceptions. For example, Schultz et al. (17) reported a patient who improved with haloperidol at a dose of 5 mg/day, with a surprisingly high plasma haloperidol level of 22 ng/ml; at 15 mg/day, this patient had a plasma level of 64 ng/ml and developed increased psychotic symptoms. When the plasma level was lowered, the psychotic symptoms improved.

Does knowledge of plasma level improve prediction of outcome over and above dose? When a more conventional method of evaluating a curvilinear relationship is used, a curvilinear (quadratic) function of plasma level fits the data better than a quadratic function of dose (plasma: multiple R=0.40, df=2, 66, p=0.003; dose: multiple R=0.28, df=2, 66, p=0.07), and a stepwise multiple regression analysis indicated that plasma level produces a significant increment in multiple R (F=3.75, df=2, 64, p=0.03). Thus, plasma level is the more powerful predictor of outcome.

At a practical level, it would seem prudent to consider dose reduction in any nonresponding patient with a plasma level higher than 12 ng/ml or when doses greater than 20 mg/day are not successful. Similarly, it may also be prudent to measure plasma haloperidol levels in responding patients who are receiving a high dose. If the plasma haloperidol level is higher than 12 ng/ml, a trial of dose reduction may be indicated. Lastly, plasma haloperidol levels may be most informative with drug interactions. For example, carbamazepine is known to reduce plasma haloperidol levels by 50% or more through microsomal enzyme induction (18–21), and other drug interactions are likely to be discovered.

Limitations of this paper are that all patients were men and dose assignment was not done in a blind manner, raising the possibility that knowledge of dose influenced clinical ratings. The relationship between dose and clinical ratings is complicated (22), however, and we do not believe this happened.

The reason why some patients tend not to do as well at plasma levels higher than 12 ng/ml is unknown. It is unclear whether efficacy is lost at high tissue levels or whether adverse effects diminish therapeutic response. Side effects (such as akathisia, akinesia, or confusion) may mimic or worsen psychiatric illness. In our experience, it is difficult to disentangle akinesia from the negative symptoms of schizophrenia or to distinguish between akathisia and psychotic excitement. For example, one patient with a plasma haloperidol level of 14 ng/ml developed the delusion that he had neurosyphilis and would stand motionless in front of the physician's door. When the plasma level was lowered to 7 ng/ml, these symptoms disappeared. We suspect that the catatonic-like behavior was a manifestation of extrapyramidal symptoms, as described by Quitkin et al. (23)—but we cannot prove it because this particular patient had mild akinesia ratings and was judged as having no akathisia. We believe that the rating of neuroleptic side effects is in a primitive state and that the mechanism whereby some patients deteriorate at higher plasma levels is unknown. Finally, in the present sample there was no relationship between plasma haloperidol levels and akathisia or akinesia, whether examined in ranked or unranked order.

A close relationship between haloperidol brain concentrations and effects on dopamine neurons (stimulation of dopa synthesis, elevation of prolactin secretion, blockade of avoidance responses, and antagonism of amphetamine- and apomorphine-induced behavioral stimulation) has been demonstrated in well-controlled animal experiments. It is interesting that optimal brain concentrations for the aforementioned pharmacological effects correspond to plasma concentrations of 8–12 ng/ml in the rat, while threshold concentrations correspond to 2–3 ng/ml (24).

Our proposed estimate of an optimal range of 5 to 12 ng/ml may not apply to chronic, treatment-refractory patients. Certainly, many such patients are managed at plasma levels of haloperidol much greater than 12 ng/ml (25). The fact that such patients, to varying degrees, can tolerate such high levels does not mean that this is their optimal plasma level. Further, the higher plasma levels in some treatment-refractory patients are really used for chemical restraint or result because of our compulsion to do something. Chemical restraint, useful and necessary as this may be, was not a desired endpoint in the present sample; the patients were reasonably cooperative and calm, thought-disordered schizophrenic men, so that these results may not apply to acutely agitated patients.

Our suggested threshold limit of 2.0 ng/ml is similar to the plasma haloperidol level (mean=4.9 ng/ml, SD=2.9) drawn at neuroleptic threshold by McEvoy et al. (26).

# Alprazolam as a Neuroleptic Adjunct in the Emergency Treatment of Schizophrenia

James G. Barbee, M.D., Donna M. Mancuso, M.D.,
Charles R. Freed, M.D., and Alexandre A. Todorov, M.Ed.

---

*Objective: While neuroleptics remain the mainstay of drug intervention in the emergency management of psychosis, a variety of agents have received study as alternatives or adjuncts to these drugs in an attempt to improve the safety and efficacy of acute treatment. The purposes of this study were to investigate the efficacy and safety of alprazolam as a neuroleptic adjunct for schizophrenic patients in psychotic relapse and to clarify the effects of combination treatment on specific aspects of the psychotic process. Method: Twenty-eight acutely psychotic patients with schizophrenia who were admitted to an emergency psychiatric service were randomly assigned to treatment with either haloperidol and alprazolam or haloperidol with placebo under double-blind conditions. Drug administration lasted 72 hours. Results: Both groups improved significantly. The combination-treated group required significantly less medication and had 56% fewer dystonic reactions. The addition of alprazolam was most effective for symptoms of excitement and uncooperativeness, particularly in the initial hours of treatment. Conclusions: The combination of alprazolam and haloperidol seems to be the most effective for agitated patients, particularly in the first 48 hours of treatment. It may also result in fewer dystonic reactions.*

(Am J Psychiatry 1992; 149:506–510)

---

While neuroleptics remain the mainstay of drug intervention in the emergency management of psychosis, a variety of agents have received study as alternatives or adjuncts to these drugs in an attempt to improve the safety and efficacy of acute treatment (1). Benzodiazepines have been the subject of increasing investigation in this regard. To date, a number of reports have focused on the use of benzodiazepines alone or in combination with neuroleptics in the acute treatment of psychotic patients (2–8). In such studies the principal effect of the benzodiazepine as neuroleptic adjunct appeared to be a lowering of the total dose of neuroleptic required, primarily to control agitation as a nonspecific symptom of psychosis. In a recent review article comparing antipsychotics and benzodiazepines as rapid tranquilizing agents, Dubin (9) concluded that benzodiazepines are "very effective" for manic patients in this regard but noted that there is not sufficient evidence to permit a similar conclusion about their use for schizophrenia. According to a recent excellent review on the use of benzodiazepines in psychotic disorders (10), 12 studies have examined the usefulness of benzodiazepines as neuroleptic adjuncts in schizophrenia. Among these studies are reports that when benzodiazepines are used as adjuncts they reduce positive (11, 12) and/or negative (12, 13) symptoms, although these effects may not persist (13). The authors also concluded, however, that there is little evidence of an overall benefit from the use of such combinations, other than in a small number of individuals (10).

Most of these studies were based on weekly ratings and therefore are not applicable to emergency treatment. We are aware of only three prospectively designed acute treatment studies of the efficacy of benzodiazepines (alone or with neuroleptics) in groups of psychotic patients that included schizophrenic patients (4, 5, 8). Cohen and Khan (4) reported significantly greater improvement on two overall outcome measures after 4 days in patients receiving more than 2 mg of lorazepam equivalents in combination with a neuroleptic than in patients receiving less than this amount. This study is the only one of the three which used a study group composed exclusively of schizophrenic patients. Garza-Treviño et al. (5) found several combinations of neuroleptics and sedatives to be very effective in controlling agitation in a group of psychotic patients with a variety of diagnoses. Individual psychotic symptoms were not rated. Finally, Arana et al. (8), studying 14 psychotic

patients (only five of whom were schizophrenic) who were given either lorazepam or lorazepam with haloperidol, found that both treatment groups demonstrated improvements (at 48 hours) on individual ratings of multiple psychotic symptoms, including suspiciousness, hallucinations, unusual thoughts, and conceptual disorganization.

The present study compared the effects of haloperidol alone with those of haloperidol and alprazolam in a group of schizophrenic patients in psychotic relapse, by means of intensive, prospective ratings of psychotic symptoms in the first 72 hours of treatment. Its purpose was twofold: 1) to investigate the efficacy and safety of alprazolam as a neuroleptic adjunct in this clinical population and 2) to clarify the effects of combination treatment on specific psychotic symptoms.

## METHOD

The subjects were recruited from the psychiatric emergency service of a large inner-city hospital. All of the patients in this study were capable of informed consent and entered voluntarily. Each fulfilled the *DSM-III-R* diagnostic criteria for schizophrenia and were actively psychotic at the time of the interview (as evidenced by a minimum score of 12 on an abbreviated version of the Brief Psychiatric Rating Scale, as will be described). All subjects were between the ages of 18 and 60 years and weighed between 100 and 225 lb. Any individual with a coexisting major axis I disorder, significant medical illness, pregnancy, or use of a nonprescription psychoactive drug (including alcohol) within 72 hours before arrival at the hospital was excluded. Urine drug screens for all patients were collected at the initiation of the study, and patients with positive results were also excluded from the analyses. Thirty subjects were originally selected for the study, but two had to be dropped because of positive urine drug screens.

The patients were assessed at baseline with the Scale for the Assessment of Positive Symptoms (SAPS) (14), Scale for the Assessment of Negative Symptoms (SANS) (15), Brief Psychiatric Rating Scale (BPRS) (16), and a subscale consisting of six items in the psychoticism cluster of the BPRS. The six symptoms included in this measure were suspiciousness, conceptual disorganization, hallucinatory behavior, uncooperativeness, unusual thought content, and excitement. The psychoticism subscale was administered every 2 hours for the first 8 hours on day 1 and at 24, 48, and 72 hours by one of the investigators (J.G.B.). The full-scale version of the BPRS was administered by a second investigator (D.M.M.) at baseline and at 24, 48, and 72 hours. This investigator also administered the SAPS and SANS at baseline and a modified version of these two scales at 72 hours. This modified version contained only the items that are based on signs or symptoms assessed during the course of the interview (rather than on prior history) and are therefore sensitive to acute change.

The investigators who administered the scales were blind to each other's ratings, and the latter investigator was blind to the dose and schedule of treatment established on the first day of the protocol. Both investigators were blind to drug assignment. Interrater reliability was found to be very high during a pilot study; interrater reliability estimates varied from 0.76 on the psychoticism subscale of the BPRS to 0.89 on the SANS, as assessed with the intraclass correlation coefficient (17).

The 28 patients were randomly assigned to two treatment conditions under double-blind conditions. One group received 5 mg of haloperidol in oral concentrate form with a 1-mg tablet of alprazolam. The control group received 5 mg of haloperidol with an identically appearing placebo tablet. After each rating interval on day 1, any individual with a score of 12 or higher on the psychoticism subscale of the BPRS was administered a repeat dose of medication. A dose was not administered if the patient's score was less than 12 or if the patient was excessively sedated. The cutoff score of 12 was empirically derived on the basis of pilot work and represents a level of psychopathology at which a patient is relatively stable and additional antipsychotic medication is not indicated. The total dose received on this basis within the first 24 hours was then administered on a b.i.d. basis (if the total dose was even) or t.i.d. basis (if the total dose was odd) on the second and third days. Both groups received their final doses at 8:00 p.m. Each patient received a minimum of two doses within the first 24 hours. After completion of the study, all patients resumed routine neuroleptic treatment (usually haloperidol) without alprazolam.

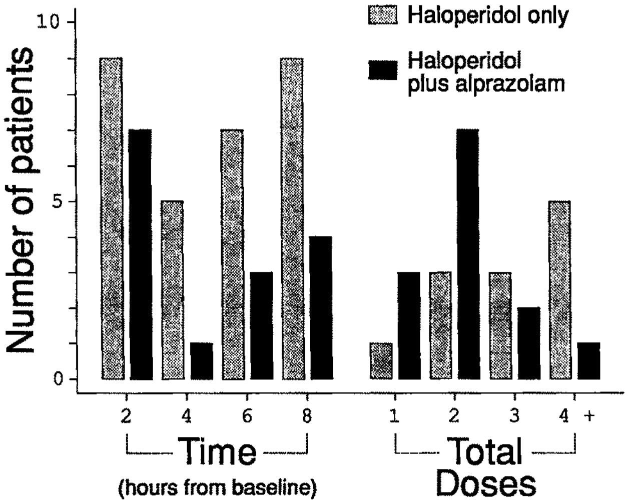
The two groups of 14 subjects each were similar in terms of mean age (haloperidol-only: mean=32.5 years, SD=6.2; combination: mean=33.4 years, SD=5.8), mean weight (haloperidol-only: mean=158 lb, SD=26; combination: mean=158 lb, SD=39), black race (86% and 79%, respectively), and overall level of psychopathology. The proportion of females was higher in the haloperidol-only group (79% versus 43%).

The presence of side effects was assessed with the Simpson-Angus Side Effects Profile (18) and another side effects rating scale (19), which were administered at the completion of the study. The occurrence of dystonic reactions and the frequency with which biperiden was administered to treat these reactions were recorded throughout the study period. A 5-ml sample of blood was drawn between 7:00 and 9:00 a.m. at the conclusion of the study, before institution of routine neuroleptic treatment, in order to measure plasma trough levels of alprazolam and haloperidol. Plasma levels of alprazolam and haloperidol were determined with the gas chromatography techniques described by Greenblatt et al. (20) and Burstein et al. (21).

For humanitarian reasons, patients who had improved sufficiently were discharged from the hospital before the conclusion of the study. In such a case, a final set of ratings (as already described) for the 72-hour assessment were administered before discharge, and these results were included in the analyses.

The test scores were analyzed by using both univari-

**FIGURE 1. Temporal Distribution of Doses and Number of Doses During First Day of Acute Treatment for Schizophrenic Patients Given Haloperidol Only or Haloperidol Plus Alprazolam**[a]



[a] For the haloperidol-only group (N=14), a dose consisted of 5 mg of haloperidol and a placebo tablet; for the combination group (N=14), a dose was 5 mg of haloperidol plus 1 mg of alprazolam. The average total dose was significantly lower in the combination group than in the haloperidol-only group (2.1 versus 3.2 doses; t=2.49, df=19.2, p=0.02).

ate and multivariate techniques, following the guidelines suggested by Looney and Stanley (22). Since the two approaches yielded the same results, only the more familiar univariate results will be reported here. The Greenhouse-Geisser correction was applied in the calculation of p values. Spearman correlations were used to determine the association between the outcome measures and plasma haloperidol level. Spearman correlations were used because these do not assume that the relationship between dose and effect is linear.

## RESULTS

Figure 1 depicts the allocation of doses over the first 8 hours of the study. On day 1, the number of patients in both groups who required medication decreased over hours 0–4 but then increased toward the end of the period. The group that received haloperidol plus alprazolam received significantly fewer doses of medication on day 1.

Scores for each of the measures at each time point are given in table 1. For both groups as a whole the tranquilizing effect (i.e., decrease in score) was found to be significant for the SAPS, the SANS, the BPRS, and the BPRS psychoticism subscale. There were no significant differences between the two groups on any of these measures, at any of the time points, suggesting that the two treatments had similar overall effects. Similar results were found for four of the six items of the psychoticism subscale: suspiciousness, hallucinatory behavior, unusual thought content, and excitement. There were no changes for the group as a whole over the course of the study and no difference between the two groups at any time point on the conceptual disorganization and uncooperativeness subscales.

Nine subjects improved sufficiently to be discharged before the completion of the study (four from the haloperidol-only group and five from the combination group). Those subjects had lower mean baseline scores than the other subjects on the SAPS (t=2.71, df=25, p=0.01) and BPRS psychoticism subscale (t=2.54, df=20.8, p=0.02) but had comparable mean baseline SANS scores. It appears unlikely that their early departure from the study affected the results, as the groups were equally depleted. In addition, the exit ratings, which were completed for all these subjects, were incorporated in the analyses.

The average numbers of side effects were similar in the two groups (an average of about eight). The five most frequent complaints were drowsiness, blurred vision, tremors or shaking, difficulty in concentration, and restlessness. The mean scores on the Simpson-Angus extrapyramidal side effects questionnaire were equivalent.

A total of 16 dystonic reactions occurred in the haloperidol-only group, while only seven occurred in the combination group. The proportion of individuals receiving as-needed medication for dystonic reactions was higher in the haloperidol-only group (64%) than in the combination group (36%). However, there is no statistical evidence to indicate that these differences were significant. This may be because of the small number of subjects.

The plasma alprazolam levels ranged from 0 to 30.1 mg/ml (mean=12.53, SD=7.20). The mean plasma haloperidol level was lower in the haloperidol-only group (mean=2.02 mg/ml, SD=1.5) than in the combination group (mean=3.69 mg/ml, SD=2.6), but the difference was not statistically significant (Wilcoxon test, normal approximation, p=0.12). The mean plasma haloperidol level of the subjects receiving medication on a b.i.d. basis (mean=3.33 mg/ml, SD=2.7) was slightly higher than that of the subjects who received it on a t.i.d. basis (mean=2.27 mg/ml, SD=1.7), but the difference was not statistically significant.

The correlation between the number of doses received and plasma haloperidol level was higher in the combination group (Spearman r=0.63) than in the haloperidol-only group (Spearman r=0.38). Lastly, we were unable to find a significant association between plasma haloperidol level and measures of outcome.

## DISCUSSION

These results demonstrate that both treatment groups improved significantly during the study period and that the patients receiving the combination of haloperidol and alprazolam required significantly less haloperidol to achieve a similar result. The finding that less medication is required in combination therapy for schizophrenic patients supports similar conclusions by previous investigators (7, 8) in retrospective studies of

[a] Significant decrease in scores for both groups (F=62.20, df=1, 22, p).

[b] Significant decrease in scores for both groups (F=52.52, df=1, 22, p).

[c] Significant decrease in scores for both groups (F=31.15, df=3, 48, p).

[d] Significant decrease for both groups in overall scores (F=15.10, df=7, 119, p) and in scores on the items for suspiciousness (F=8.07, df=7, 105, p=0.0001), hallucinatory behavior (F=10.30, df=7, 105, p=0.0001), unusual thought content (F=4.04, df=7, 105, p=0.01), and excitement (F=3.80, df=7, 105, p=0.007) but not for conceptual disorganization (F=2.01, df=7, 105, p=0.12) or uncooperativeness (F=2.31, df=7, 105, p=0.08).

groups of psychotic patients from multiple diagnostic categories. The data in table 1 also indicate that the patients who received the combination treatment tended to improve throughout the first 8 hours of the study, unlike the patients who received haloperidol alone, who had a more fluctuating course. There was no evidence of paradoxical excitation (a side effect that has been reported with benzodiazepines) or of an association between discontinuation of alprazolam at the end of the study and any adverse effects.

This study does not suggest that the addition of alprazolam to haloperidol results in a significantly greater reduction in the core psychotic symptoms of schizophrenia, e.g., suspiciousness, hallucinations, unusual thoughts, and conceptual disorganization. However, the first dose of the combination treatment did result in greater decrements initially in the ratings of excitement (1.25 points versus 0.43 in the haloperidol-only group) and uncooperativeness (0.80 points versus 0.14), although these did not reach statistical significance. Interestingly, the total BPRS score was actually (nonsignificantly) higher in the combination-treated group at 72 hours, perhaps because the combination-treated group received substantially less haloperidol over time. These results suggest that the primary utility of combination treatment in an emergency setting is in the first 48 hours of treatment, predominantly for the control of agitation and increased arousal.

Although the differences in the occurrence of dystonic reactions and the amount of adjunctive medication to treat these reactions did not reach statistical significance, the subjects in the combination-treated group experienced 56% fewer reactions. Such a reduction may represent a significant clinical advantage for combination therapy. It has been estimated that 90% of dystonic reactions occur within the first 5 days of initiation of neuroleptic treatment (23), and such reactions are a common complication of emergency neuroleptic treatment.

Inferences about the effectiveness of alprazolam as an adjunct to haloperidol within our study design are limited by three factors. First, the two groups did not receive equal amounts of haloperidol, which is a proven antipsychotic agent. The observation that plasma levels of haloperidol tended to be higher in the group that also received alprazolam was surprising, since this group received fewer doses of medication. It is possible that alprazolam may interfere with the metabolism of haloperidol, although to our knowledge there have been no such reports with neuroleptics (24). Results with tricyclic antidepressants, however, have been conflicting (25, 26). If there were such interference, the lower number of doses of medication required by the combination group could be due to the pharmacokinetic effects of alprazolam, rather than to its psychotropic effect.

Second, the doses in the two treatment groups were allocated on an as-needed basis and were the lowest amount possible to calm the patients. Prior reviews on the efficacy of the benzodiazepines in schizophrenia (27, 28) have suggested that one of the major reasons for an apparent lack of efficacy in many studies has been inadequate doses. The plasma values of alprazolam we obtained were at the lower end of the range of the values that have been reported to be therapeutic in nonpsychotic anxiety disorders (29). Douyon et al. (12), in their study of alprazolam as a neuroleptic adjunct for outpatient schizophrenic patients treated for 3 weeks, found that individuals with blood levels higher than 23 ng/ml were more likely to show a significant response.

Third, the relatively small number of subjects in the study, as well as the wide variability of the outcome measures, raises the possibility that significant differences between the two treatment groups were missed. In particular, the alprazolam-treated group had a lower mean SAPS score at baseline, although the difference was not statistically significant. Inspection of the other baseline measures reveals only minimal differences between the two groups in psychopathology ratings, thus suggesting that such differences were not a major factor in the outcome. However, because of the large variability in all of the measures, the presence of differences in the baseline status of the two groups cannot be completely ruled out. The number of subjects available for this study was too small for more elaborate statistical methods, which may have helped in the resolution of this issue.

In conclusion, the combination of alprazolam and haloperidol seems to be the most effective for agitated patients. The severity of the psychopathology of the patients included in our study was limited by our decision to obtain informed consent. Had we included more severely disturbed patients in the study, we believe that differences in the outcomes of the two groups would have been more apparent, particularly on measures of arousal and aggression. From our clinical observations, the patients who are the most severely agitated are the most likely to benefit from combination treatment, especially in the initial hours of emergency treatment.

# Prospective Study of Neuroleptic-Induced Dystonia in Mania and Schizophrenia

Rakesh Khanna, M.D., Arunava Das, M.D., and Saji S. Damodaran, D.P.M.

---

*Objective: The authors' goal was to conduct a prospective study comparing the rate of occurrence of neuroleptic-induced dystonia in a group of consecutively admitted manic and schizophrenic patients receiving typical inpatient treatment from several clinicians. Method: All patients met the following criteria: 1) male sex, 2) age between 17 and 45 years, 3) definite diagnosis of mania or schizophrenia according to Research Diagnostic Criteria, 4) no exposure to neuroleptics during the past month, 5) absence of past or family history of a neurodegenerative disorder with extrapyramidal symptoms. All treatment decisions were left to the treating clinicians. Fifty patients with mania and 33 with schizophrenia were included in the study. Most of these patients received high-potency neuroleptics, but the specific neuroleptic used varied in the two groups. Results: Twelve (24%) of the patients with mania and five (15%) of the patients with schizophrenia developed acute dystonia. Manic patients received significantly higher peak doses of neuroleptics during the risk period for dystonia. Stepwise multiple regression analysis revealed that the peak neuroleptic dose and age were most strongly related to the occurrence of dystonia. Conclusions: This prospective study failed to support the retrospective finding of another study that acute dystonia occurred more often in manic patients than in patients with nonparanoid schizophrenia. The authors conclude that there is a need for carefully controlled prospective studies with larger groups of patients.*

(Am J Psychiatry 1992; 149:511–513)

---

Acute dystonic reactions are the most dramatic forms of acute dyskinesias. Some 90% of acute dystonic reactions occur within the first 5 days of neuroleptic treatment (1–3). The reported rates of neuroleptic-induced acute dystonic reactions vary from 2.3% (1) to 63% (4). Risk factors that have been identified include male sex, age younger than 30, higher dose of neuroleptics, and use of high-potency agents (1–9). An analysis of pooled data from nine studies found that the incidence of neuroleptic-induced dystonia without prophylactic anticholinergics was 14.8% in studies using any neuroleptic and 51.2% in studies using only high-potency neuroleptics (10). Drawing from the repeated observations that tardive dyskinesia occurs more often in affective disorders (11–14), Nasrallah et al. (15) hypothesized that acute dystonia may also be more common in affective disorder. In a retrospective study (15) they found a significantly higher incidence of acute dystonia in mania (26.1%) than in nonparanoid schizophrenia (5.9%). Nasrallah et al. included only nonparanoid patients with schizophrenia to eliminate any error due to the possible diagnostic overlap between paranoid schizophrenia and mania with paranoid features. However, Hamra et al. (14) noted a high risk for tardive dyskinesia in both paranoid schizophrenia and affective disorder and, citing Jeste et al. (16), hypothesized that the common denominator could be the "increased noradrenergic activity reported in both conditions, as reflected by low levels of monoamine oxidase and high serum levels of dopamine-β-hyroxylase."

The findings of Nasrallah et al. (15) are interesting. Acknowledging the limitations of their retrospective study, they emphasized the need for prospective studies. We conducted such a study to compare the rate of occurrence of neuroleptic-induced dystonia in a group of consecutively admitted manic and schizophrenic patients receiving typical inpatient treatment from several clinicians.

## METHOD

We included in this study all patients consecutively admitted to our facility who met the following criteria: 1) male sex, 2) age between 17 and 45 years, 3) definite diagnosis of mania or schizophrenia according to Research Diagnostic Criteria, 4) no exposure to neuroleptics

during the past month, 5) absence of past or family history of a neurodegenerative disorder with extrapyramidal symptoms. All treatment decisions were left to the treating clinicians. The general hospital policy is not to use anticholinergics prophylactically. Patients who received anticholinergics during the first week of neuroleptic treatment were excluded from study. This led to the exclusion of 14 patients for whom anticholinergics were prescribed for moderate to severe pseudoparkinsonism, typically on day 4 or 5 of hospitalization. Equal proportions of patients with mania and patients with schizophrenia were excluded on account of this criterion.

Fifty patients with mania and 33 with schizophrenia were finally included in the study. The mean age of the manic patients was 26.34 years (SD=8.34) and that of the schizophrenic patients was 27.39 (SD=6.59). The difference in age between the two groups was not significant (t=1.01, df=81, n.s.). Twenty-one (42%) of the manic patients were experiencing their first episode of mania; the rest were having their second to sixth episode. The duration of illness among patients with schizophrenia varied from 6 months to 5 years; only four schizophrenic patients had clearly episodic courses. Twelve (36%) of the schizophrenic patients had paranoid type and 21 (64%) had nonparanoid type.

Residents and nurses who were blind to the hypothesis of the study were asked to record explicitly all forms of acute dystonia in all newly admitted patients along with the treatment given and the response to treatment. The diagnosis of dystonia was made by the attending resident on the basis of the sudden onset of twisting or sustained movements, acute discomfort of the patient, and rapid resolution of symptoms after parenteral administration of benztropine mesylate.

High-potency neuroleptics were prescribed for most of the patients, but the specific neuroleptic used varied in the two groups. Forty-six of the patients with mania received haloperidol, three received chlorpromazine, and one received pimozide; only five received lithium in addition to neuroleptics. Among the patients with schizophrenia, seven received haloperidol, 13 received trifluoperazine, four received fluphenazine decanoate, three received chlorpromazine, one received thioridazine, and five received a combination of fluphenazine decanoate and trifluoperazine. For the conversion to chlorpromazine equivalents we used the following formula: 100 mg of chlorpromazine=100 mg of thioridazine=5 mg of trifluoperazine=2.5 mg of haloperidol=2 mg of pimozide. One intramuscular injection of 25 mg of fluphenazine decanoate was considered the equivalent of 291.7 mg/day of chlorpromazine. The conversion formula used was based on tables of suggested dose equivalence (17).

## RESULTS

Seventeen (20%) of the 83 patients developed neuroleptic-induced dystonia. More of the patients with mania (12 of 50) than of the patients with schizophrenia (five of 33) developed dystonia, but the difference between the groups was not statistically significant ($\chi^2$=0.96, df=1). In the schizophrenic group there was no significant difference in dystonic reactions between paranoid (two of 12) and nonparanoid (three of 21) patients ($\chi^2$=0.09, df= 1).

In both groups, acute dystonia occurred more often among those who were younger than 30 years (10 of the 12 patients with mania and four of the five patients with schizophrenia who developed dystonia were younger than 30). Dystonia occurred more often in those receiving haloperidol (13 of 53 manic or schizophrenic patients), trifluoperazine (three of 13 schizophrenic patients) and a combination of fluphenazine decanoate and trifluoperazine (one of five schizophrenic patients). None of the seven patients receiving low-potency neuroleptics (chlorpromazine and thioridazine) had dystonia. When the data for only the patients treated with high-potency neuroleptics were analyzed, 12 (26%) of the 47 patients with mania and five (17%) of the 29 patients with schizophrenia had dystonia, which further diminishes the difference ($\chi^2$=0.70, df=1, n.s.). Only one of the five manic patients receiving lithium in addition to neuroleptics developed dystonia.

Fifty-nine percent (N=10) of the 17 patients who developed dystonia, compared with 26% (N=17) of the 66 patients who did not develop dystonia, received a dose of neuroleptics that was higher than 1 g/day. The difference between these groups was significant ($\chi^2$=6.73, df=1, p=0.01). The mean dose of neuroleptics (in chlorpromazine equivalents) for the first week of treatment was 966.23 mg/day (SD=475.43) for the manic group; for the schizophrenic group it was 588.00 mg/day (SD=459.78). The difference between the two groups was highly significant (t=5.65, df=81, p=0.001). Within the manic group those who had dystonia received significantly higher peak doses (1188.00 mg/day [SD=371.43]) of neuroleptics than those who had no dystonia (896.10 mg/day [SD= 482.29]) (t=2.72, df=48, p=0.01). The peak doses of schizophrenic patients who did or did not develop dystonia did not differ significantly (t=0.49, df=31, n.s.).

Because there was no significant difference between patients with mania and patients with schizophrenia, the data for these groups were pooled for a stepwise multiple regression analysis to determine the variables related to dystonia. The independent variables used as predictors of dystonia included diagnosis, age, mean neuroleptic dose, and peak neuroleptic dose. The strongest correlate was peak neuroleptic dose (F=4.53, df=1, 81, p=0.05). The only other significant correlate was age plus peak neuroleptic dose (F=3.29, df=2, 80, p=0.05). The peak neuroleptic dose explained 5.3% of the total variance, and the addition of age to peak neuroleptic dose increased the percentage of variance explained to 7.6%.

## DISCUSSION

Our prospective study failed to support the retrospective findings of Nasrallah et al. (15). Neuroleptic-induced dystonia occurred with almost equal frequency among patients with mania in our study and theirs. More of our schizophrenic patients developed dystonic reactions (15% compared with 5.9%). Both investigations involved only male subjects exposed to a variety of neuroleptics. However, unlike the study of Nasrallah et al., we included paranoid patients with schizophrenia in our sample and did not find the occurrence of dystonia to differ between paranoid and nonparanoid subtypes. In keeping with the literature, dystonia in our sample occurred more often among patients younger than 30 and those receiving high doses of high-potency neuroleptics. Stepwise multiple regression analysis of the pooled data found that only peak neuroleptic dose made a significant independent contribution to the development of dystonia. The addition of age to peak neuroleptic dose was the only other significant contributor. Thus, the majority of the variance in risk for dystonia was still unaccounted for.

The study by Nasrallah et al. (15) found no significant difference between the mean neuroleptic dose prescribed for the manic and the schizophrenic groups. In our study, manic patients received significantly higher doses of neuroleptics than did patients with schizophrenia. Simpson and Singh (18) suggested that the peak or maximum dose of neuroleptics used may be more informative than the total mean dose. Patients with mania more often receive higher initial doses of neuroleptics that are later reduced as therapeutic levels of lithium are reached and/or the acute symptoms subside. For patients with schizophrenia, however, it is usual to start with relatively smaller doses of neuroleptics that are raised depending on the response. Thus, the total mean dose may conceal the real difference in the dose of neuroleptics used during the risk period for dystonia. It is also possible that there were more young patients with schizophrenia in our study group (mean age=27.39 years) than among the subjects of Nasrallah et al. (age was not reported).

There are two important limitations of this study: the small number of subjects and the substantial difference in the type of neuroleptic used in the two patient groups. However, under typical inpatient treatment conditions, diagnosis was not found to be an important risk factor for neuroleptic-induced dystonia. Peak neuroleptic dose emerged as the single most significant risk factor for dystonia. The estimation of the peak neuroleptic dose was based on a table of suggested dose equivalence, however, and such data are crude at best (19). Thus, there is a need for carefully controlled prospective studies with larger groups of patients.

# Fatigue, Sleep Disturbance, Disability, and Indices of Progression of HIV Infection

Denis F. Darko, M.D., J. Allen McCutchan, M.D., Daniel F. Kripke, M.D.,
J. Christian Gillin, M.D., and Shahrokh Golshan, Ph.D.

*Objective: The authors' objective was to test the hypothesis that fatigue affects the activities and employment of subjects with HIV infection and that indices of immunosuppression and inflammation may have statistical utility in predicting fatigue and sleep disturbance. Method: The authors prospectively asked 112 homosexual men (62 HIV-seropositive subjects and 50 HIV-seronegative comparison subjects) to complete a questionnaire on fatigue and sleep disturbance. In addition, hematocrit, WBC count, CD4+ cell number, lactate dehydrogenase, albumin, and total globulin were measured. Results: For HIV-seropositive patients fatigue was significantly more of a problem and interfered more with important activities such as employment and driving than with seronegative comparison subjects. The HIV-infected patients were significantly more likely to be unemployed, to feel fatigued through more hours of the day, to sleep more, to nap more, and to have diminished midmorning alertness. The medical variables could be used to statistically predict fatigue, its interference with daily activities, and employment. Conclusions: Fatigue and sleep disturbances contribute to morbidity and disability in HIV-infected homosexual men, especially those in CDC stage IV (AIDS-related complex or AIDS). Correlation with measures of immunosuppression and inflammation and comparison between fatigued versus nonfatigued groups suggest the possibility of statistical prediction of fatigue by using these measures. Further study is needed to examine the possibility of eventual specific intervention to clinically treat HIV-related fatigue, sleepiness, and sleep disturbance.*

(Am J Psychiatry 1992; 149:514–520)

Fatigue has been associated with the syndrome of HIV infection in all early clinical descriptions (1). In an early case report, tiredness was the chief complaint (2). In acute HIV infection, fatigue is prominent, with lethargy and malaise being reported in 66.7% of homosexual men who became HIV positive (3, 4).

In chronic HIV infection, unexplained fatigue is a prominent persistent symptom (5). Fatigue as measured by the score on the 5-item scale in the Profile of Mood States (POMS) was reported to be significantly higher in a group of 13 patients with AIDS-related complex (ARC) than in 17 HIV-positive subjects with minimal symptoms, 11 seronegative homosexual men, and 22 heterosexual men (6). Fifteen patients with AIDS also had more fatigue than did control subjects, but the difference did not reach statistical significance.

Fatigue may be a uniquely important symptom in HIV infection. In addition to the anguished complaints of HIV patients about this draining fatigue, the impact on public funding may be large. Fatigue can be the overriding symptom that causes individuals to discontinue employment. When they are unable to continue to work, they must turn to public support for subsistence. With loss of employment also comes loss of health insurance coverage in almost all cases. The individuals must then also rely on public funds for health care of this illness, with its prolonged, slowly progressive deterioration.

To test the hypothesis that fatigue affects the activities and employment of HIV-seropositive subjects, fatigue, sleepiness, and disturbances of sleep were prospectively measured and their influence on the morbidity and disability caused by HIV infection was examined. Within this general hypothesis, we further tested whether differences in life disruption existed between

the CDC stage III and stage IV patients and the comparison subjects. In addition, we examined multiple laboratory indices of disease activity as correlates of fatigue and as statistical predictors of fatigue, sleep disturbance, and employment status. The symptoms that we evaluated, fatigue and sleepiness, are complex and difficult to define. Subjective complaints of fatigue and sleepiness may be a more sensitive measure of CNS impairment than objective, behavioral sleep activities. No standard, objective psychometric instruments exist for the assessment of fatigue and sleepiness, especially their assessment in the context of chronic HIV infection, as will be discussed later. We developed a questionnaire to specifically address problems of subjective fatigue in HIV-positive patients.

## METHOD

Subjects were recruited for this study from a cohort of men in a longitudinal study of over 200 homosexual men. All subjects in the cohort had given informed consent after the nature of the study had been fully explained. A total of 112 homosexual men arriving for consecutive appointments for a scheduled study visit were asked to participate. Of the 112 men, 50 were HIV-negative comparison subjects and 62 were HIV-positive patients. Each of the subjects completed the questionnaire that we developed to evaluate fatigue, sleepiness, and sleep habits in HIV-positive subjects. (The questionnaire is available from Dr. Darko.) In addition, blood samples were drawn to measure hematocrit, WBC count, number of CD4+ cells, lactate dehydrogenase, albumin, and total globulin (defined as total protein minus albumin).

For the purposes of analysis, 108 of the subjects were first divided into three groups on the basis of diagnosis. Group 1 (N=14) consisted of subjects with ARC or AIDS (CDC stage IV) (7). Group 2 (N=44) consisted of HIV-seropositive subjects without symptoms or signs except lymphadenopathy (CDC stage III). Group 3 (N=50) contained the comparison homosexual men who were seronegative for HIV antibodies. (The remaining four HIV-seropositive subjects were without symptoms or lymphadenopathy.) All statistical analyses were performed with standard statistical programs (8, 9). Initially an among-groups comparison (three groups) was performed. Following this comparison, three between-groups comparisons were performed with analysis of variance (ANOVA) (CDC stage IV group versus comparison group, CDC stage III group versus comparison group, and CDC stage IV versus stage III group). Statistical comparisons of the categorical data were made by using the nonparametric chi-square statistic (likelihood ratio), with Yates's correction when appropriate. For brevity of data presentation, multiple-choice items were interpreted dichotomously on the basis of whether the response was positive or negative. There is occasional missing data in the fatigue questionnaire because not all subjects answered all questions. In table 1 the missing data are reflected in subject numbers that are smaller than the total number of subjects in the group. Comparisons of continuous data were made with ANOVA.

To examine the question of which medical indices may be associated with or underlie fatigue and sleep difficulties, Pearson's correlation coefficients were calculated between the continuous fatigue/sleep variables and the six medical indices (hematocrit, WBC, CD4+ cells, lactate dehydrogenase, albumin, and total globulin). The continuous fatigue/sleep variables were question 6 (hours of fatigue felt daily) and question 8 (hours slept at night). In addition, questions 2 (does fatigue interfere with daily activities) and 3 (employment status) (categorical variables) were used as grouping parameters to define new subject groups, and the between-groups differences were examined for the six medical indices by using ANOVA. Further, a discriminant analysis involving canonical discriminant functions used the six medical variables to predict group membership as defined by questions 1 (is fatigue a problem), 2, and 3.

Finally, to examine whether fatigue, sleep, and peripheral blood measures are related independently to the stage of HIV infection, we performed multiple regression on the CDC stage III and IV groups individually. Specifically, laboratory variables were used to statistically predict responses on the fatigue/sleep questions, using discriminant analysis on the CDC stage III and IV groups separately. This technique allowed us to control for factors such as concurrent opportunistic infection, tumor, fever, and zidovudine therapy, which may increase as HIV infection progresses through CDC stages.

## RESULTS

The three groups, patients with ARC or AIDS (CDC stage IV), patients with only lymphadenopathy (CDC stage III), and the HIV-negative comparison subjects, were not statistically different in age (CDC stage IV: mean=36 years, SD=4; CDC stage III: mean=38, SD=6; comparison subjects: mean=38, SD= 10; F=0.31, df=2, 109, p=0.62).

CDC stage IV patients clearly differed from uninfected comparison subjects on fatigue and sleep disturbance, with significant among- and between-group differences on most of the areas examined. Over half of the CDC stage IV patients had problematic fatigue, compared to only 10% of the comparison subjects (table 1, question 1). Half of the CDC stage IV subjects, but none of the comparison subjects, said that fatigue interfered with their daily activities (question 2). Most of the CDC stage IV subjects were not working, compared with less than one in 10 of the comparison subjects (question 3). One in five unemployed CDC stage IV subjects, but none of the unemployed comparison subjects, said that fatigue was largely responsible for the need to stop working (question 5). The CDC stage IV subjects were fatigued through more hours of the day than comparison subjects (question 6). CDC stage

| Alert to relaxed | 4 | 29 | | | 35 | 79 | | | 42 | 84 | | |
| Foggy or worse | 10 | 71 | | | 9 | 21 | | | 8 | 16 | | |
| 17. How many cups of coffee and tea or cans of cola do you drink per day? | | | | | | | | | | | | |
| Less than three | 13 | 93 | | | 33 | 75 | | | 40 | 80 | | |
| Three or more | 1 | 7 | | | 11 | 25 | | | 10 | 20 | | |

[a] For chi-square comparisons among three groups, df=2; for chi-square comparisons between two groups, df=1. For all comparisons, significance was defined as p≤0.05.

[b] Cannot be calculated; the result reflects no difference.

IV subjects slept longer each night than comparison subjects (question 8). Over one-third of the CDC stage IV subjects had frequent early morning awakening, compared to almost none of the comparison subjects (question 13). Fully half of the CDC stage IV patients napped frequently, compared to only 12% of the comparison

subjects (question 14). Only one-third of CDC stage IV patients felt alert during the morning hours, compared to most of the comparison subjects (question 16).

A statistically significant difference between CDC stage III patients and comparison subjects existed for two questions: fatigue interfering with daily activities and sleepiness while driving (question 12). One of 10 patients said that fatigue interfered with daily activities and one of five experienced sleepiness while driving, compared with none or almost none, respectively, of the comparison subjects (table 1).

The relationship of fatigue to markers of immunosuppression, inflammation, and anemia were pursued by correlational analyses. Patients with lower numbers of CD4+ cells (i.e., those more ill with HIV infection) experienced more hours of daily fatigue (r=–0.19, p=0.05) and required more hours of sleep during the night (r=–0.34, p<0.0009). Higher lactate dehydrogenase levels correlated with more hours of fatigue felt daily (r=0.25, p=0.009) and with more hours slept during the night (r=0.26, p=0.009). Lower hematocrit levels correlated with more hours slept during the night (r=–0.29, p<0.002).

The 112 subjects were next divided on the basis of their response to question 2. The group in whom fatigue did interfere with daily activities had significantly lower numbers of CD4+ cells, significantly higher total globulin, and significantly lower hematocrit than the group in whom fatigue did not interfere with daily activities (table 2).

To assess the relationship between laboratory variables and employment, subjects were divided on the basis of their response to question 3 (employed versus unemployed). The unemployed group had significantly lower hematocrit, significantly lower numbers of CD4+ cells, significantly higher lactate dehydrogenase, significantly lower albumin, and significantly higher total globulin (table 3).

Next, three discriminant analyses were performed by using the medical variables to predict group membership, as defined by the response to fatigue questionnaire questions 1, 2, and 3. For question 1, number of CD4+ cells contributed the most to this grouping, followed in rank order by WBC, total globulin, hematocrit, and lactate dehydrogenase. The membership in the "fatigue not a problem" group was correctly predicted for 75.0% of the patients and membership in the "fatigue a problem" group was correctly predicted for 52.6% of the patients; overall, 71.2% of the patients were correctly classified.

For question 2, group membership was predicted better than for question 1, with CD4+ number being the strongest predictor, followed by WBC, total globulin, hematocrit, and lactate dehydrogenase. Membership in the "fatigue not interfering with daily activities" group was correctly predicted for 74.0% of the patients, and membership in the "fatigue interfering with daily activities" group for 81.8% of the patients; overall, group membership of 74.8% of the patients was correctly classified.

The best prediction of group membership existed for question 3 (employment). Total globulin was the strongest predictor, followed by hematocrit, WBC, CD4+, and lactate dehydrogenase. Membership in the employed group was predicted correctly for 84.9% of

the patients, and membership in the unemployed group for 77.8% of the patients; overall, 83.1% of the patients were correctly classified.

Finally, a further question needed to be resolved. Were these predictions possible simply because the fatigue, sleep, and laboratory measures all worsen independently with worsening stages of HIV infection? To answer this question, we performed multiple regression on the CDC stage III and IV groups individually in order to determine whether the blood measures would predict responses on the fatigue/sleep questions within each CDC stage and discriminant analysis on the CDC stage III and IV groups individually to predict membership in sets as defined by the response to fatigue questionnaire items 1, 2, 3, 12, and 14 within each CDC stage.

When multiple regression of the CDC stage III group was used alone, hematocrit (p=0.008) did significantly predict the number of hours slept at night. On discriminant analyses, the five medical variables did predict group membership as defined by questions 1, 2, and 3, with 72% to 96% correct classification of patients.

When multiple regression on the CDC stage IV group was used alone, WBC (p=0.03) and CD4+ (p=0.01) did significantly predict the number of hours slept at night. On discriminant analyses of the CDC stage IV group alone, the five medical variables did predict group membership as defined by questions 1, 2, 12, and 14, with 83% to 100% correct classification of patients.

## DISCUSSION

This prospective study confirms the previously undocumented clinical impression that fatigue and sleep disturbance are frequent symptoms of advanced HIV infection, contributing to morbidity and disability. When subjects with ARC or AIDS (CDC stage IV) were contrasted with comparison subjects, the difficulties caused by fatigue were dramatically demonstrated. The differences among the three groups were due primarily to the differences between the CDC stage IV (AIDS/ARC) group and the comparison group. Fatigue did interfere with daily activities, and sleepiness interfered with driving, significantly more in the CDC stage III patients than in comparison subjects. It is possible that CDC stage IV patients are no longer driving as much and thus do not notice that fatigue interferes with driving because they do not place themselves at risk. Given the imposed physical immobility and the monotony of the effort, driving may be a relatively sensitive indicator of sleepiness. As expected, the patients with more advanced HIV infection, as evidenced by lower hematocrit and CD4+ cell number and higher lactate dehydrogenase, were troubled by fatigue throughout the day and slept more.

We have tried, using several statistical methodologies, to convince ourselves and the reader that the draining fatigue of which HIV patients complain is a real problem related to the infection. We realize that such statistical associations do not imply causality, and we have planned continuing studies, as described later, to investigate this question and its mechanism. It may be possible to construct statistical models to predict disability based on early changes in medical indices. In a multivariate model, five of the medical variables (CD4+, WBC, total globulin, hematocrit, and lactate dehydrogenase) predicted reasonably well whether or not subjects were troubled by fatigue, whether or not fatigue interfered with their daily activities, and employment status. The role of total globulin in predicting employment status is especially interesting in light of the association of hypergammaglobulinemia and polyclonal B cell activation (10).

The results of analyses in the CDC stage III and IV groups alone demonstrate that the medical variables are not merely independently associated with advancing HIV infection. Instead, within CDC groups, the medical variables remain predictive of the presence of fatigue and its interference with daily activities.

The need for developing a fatigue and sleep questionnaire is worthy of discussion. The POMS does allow the calculation of a fatigue subscore, but it is based on only five items and represents a limited range of aspects of fatigue. The Stanford Sleepiness Scale, meant to be used in conjunction with the polysomnographic Multiple Sleep Latency Test (11, 12), measures only tendency toward sleepiness at the time the scale is administered. The Pittsburgh Sleep Quality Index (13) is intended as a screening instrument for insomnia and does not address fatigue or hypersomnia, such as are found in HIV infection. No instrument existed to survey the fatigue of HIV infection, its effect on daily activities such as work and driving, and possible sleep disturbances that may underlie the fatigue. A revision of this questionnaire is now being used at our HIV Neurobehavioral Research Center (funded by the National Institute of Mental Health [NIMH]) and will allow data collection for standardization, sensitivity, validity, and reliability.

Each of the peripheral blood tests chosen is medically nonspecific in itself and is suggestive of conditions associated with fatigue or sleepiness. For example, elevations of lactate dehydrogenase have been clearly associated with pneumocystis carinii pneumonia, hepatitis, or hemolytic anemias. However, for these indices to have clinical utility in predicting fatigue, it is not necessary that this be independent of predictive utility for medical illness with which fatigue is known to be associated.

A direction for future studies is the examination of specific humoral mediators of fatigue and sleep disturbance in HIV-positive individuals. A convergence of data suggests that HIV-related excess of interferon, tumor necrosis factor, or interleukin-1 may be a cause of the fatigue of HIV infection. Elevated acid-labile interferon-α was one of the first abnormalities described in AIDS (14) and may be a marker for AIDS (15). Interferon-α-2 has been demonstrated to be somnogenic in an animal model (16). Tumor necrosis factor is elevated in sera of CDC stage IV subjects (17–19), and cells from HIV-positive subjects produce increased amounts of tumor necrosis factor (20–23). Elevated levels of interleukin-1 (24) and interleukin-1 inhibitor (25) have been described in the plasma of AIDS patients. Interleukin-1 has been demonstrated in brain tissue and may be produced by astroglial cells (25, 26).

Interferon, tumor necrosis factor, and interleukin-1 are each somnogenic and affect sleep physiology by enhancing slow-wave sleep (26, 27). Interleukin-1 is thought to mediate the induction of slow-wave sleep and fever in animals by muramyl dipeptide (28, 29), a constituent of the slow-wave sleep-enhancing, sleep-promoting factor, Factor S (30). Interleukin-1 has been shown to promote slow-wave sleep and fever in two animal models (31, 32), with the sleep effect persisting when the febrile response was blocked by an antipyretic agent (31). There is evidence that these three cytokines elicit their somnogenic actions through a common regulatory mechanism involving serotonin and glial cells (27). In healthy male control subjects, increased plasma interleukin-1 occurs during sleep, particularly after sleep deprivation (33). This raises the question of whether sleep disturbance could be cause rather than effect.

Disturbed sleep physiology in HIV-infected patients has been reported (34). The seropositive subjects had a higher percentage of slow-wave sleep in the second half of the night and more movements and awakenings than the control subjects. Further data (35, 36) suggest increased slow-wave (percent of delta wave activity) sleep in asymptomatic HIV-seropositive patients, including four patients studied again after 11 to 15 months. In a group of four CDC stage III patients, all had fragments of delta sleep in the last half of the night, which is unusual. Such alterations in sleep architecture may reflect early CNS disease in HIV-infected patients and provide a marker for prognosis or monitoring response to treatment (34). We have begun a 5-year NIMH-funded study to examine the role of elevated somnogenic cytokines in the fatigue and sleep disturbance of HIV infection. The study will involve three nights of polysomnographically recorded sleep, blood sampling throughout the night, objective testing with the Multiple Sleep Latency Test of the daytime tendency to fall asleep, computerized daytime testing of attention, continuous core temperature recording throughout the 24-hour day with an ingested temperature probe, and spectral analysis of the sleep records.

Because we did not collect data on depression in our subjects, we cannot directly assess the contributions of depression to sleepiness, fatigue, and sleep disturbance. There were group differences in early morning awakening, which would be consistent with depression. However, there were no group differences reported in difficulty falling asleep and awakenings during sleep, which are often associated with depression and may be expected if the groups differed in presence or severity of depression. Given these observations, along with our impressions from working directly with these patients, we believe that we can exclude concurrent major depression as a confounding factor in this study.

Fatigue and sleep disruption may be important features of HIV infection, have obvious implications in terms of disability and quality of life, and should be further evaluated in replications of this study, using the revised Fatigue and Sleep Questionnaire, the Stanford Sleepiness Scale, the Pittsburgh Sleep Quality Index, polysomnographically recorded sleep studies, and the Multiple Sleep Latency Test (37, 38). The importance goes beyond simplistic concepts that sick people often get tired. If the specific humoral mediators can be identified, it may be possible to treat these disabling symptoms with specific clinical interventions. This augmentation in their clinical care would be a welcome improvement to HIV-infected patients.

# Training Directors' Opinions About the Psychiatry Resident In-Training Examination (PRITE)

Lynn C. Webb, Ed.D., Sandra Sexson, M.D., James Scully, M.D.,
Charles F. Reynolds III, M.D., and Miles F. Shore, M.D.

*Objective: The American College of Psychiatrists conducted research to validate the content outline of the Psychiatry Resident In-Training Examination (PRITE) and to assess what residency training directors think about the examination. Method: A mail survey was sent to the 218 psychiatry residency training directors who subscribe to the PRITE. Results: The survey response rate was 70%. A majority of the respondents indicated agreement with the relative emphasis given to each content area in the PRITE (range=52%–80% agreement). Eighty-one percent of the respondents were strongly in favor of continuing the practice of releasing the examination and the correct responses each year after the examinations have been scored. The majority of the respondents use results on the PRITE for individual resident evaluation and program evaluation (90% and 94%, respectively). Very few respondents use the PRITE results as the sole measure for assessing residents' cognitive competence or use it for marketing their residency programs. Conclusions: The survey provided strong support for the content areas covered in the PRITE and their relative emphases. The current practice of releasing PRITE items and answers (a main difference between the PRITE and the certification examination of the American Board of Psychiatry and Neurology) was well supported by the survey results. The stated purpose of the PRITE, to provide educationally useful feedback for individuals and groups in the form of comparisons with peers in specific areas of knowledge, was supported by a large majority of the respondents.*

(Am J Psychiatry 1992; 149:521–524)

The popularity of in-training examinations within medical specialties has grown greatly in the past 25 years. The first written, multiple-choice in-training examination was developed in 1964 in response to concern regarding the high failure rate on the certification examination given by the American Board of Neurological Surgery. An in-training examination was developed to determine weaknesses in trainees or programs (1). Many specialty boards have seen the benefits of formative evaluation provided by in-training examinations.

The American College of Psychiatrists' Psychiatry Resident In-Training Examination (PRITE) has been administered annually since 1979 (2). The 300-item, multiple-choice examination is administered on a voluntary basis by psychiatry residency training directors who wish to provide an educational experience for their residents. More than 5,800 psychiatry residents completed the 1991 PRITE. Following the scoring of the examination, the PRITE items and correct answers are given to the residents, along with references for verification of item material. Through a comprehensive reporting system, residency training directors can also compare the performance of their residents with the performance of those in other programs. The PRITE is taken by residents in all stages of training, allowing comparison of residents to peers over time.

The American College of Psychiatrists' primary objective for the PRITE is to provide educationally useful feedback for individuals and groups in the form of comparisons with peers in specific areas of knowledge (3). The specific areas of knowledge and their relative emphases are delineated in the content outline for the examination. This outline serves as a blueprint and communicates to test users what the test measures. It also presents the content domains being measured, so that item writers can generate items that are functionally homogeneous. Content outlines should be revised periodically to ensure that they reflect changes occurring in the field over time; the process of test planning is an iterative one (4). Content outlines that are developed or updated through empirical research provide a sound starting point for the development of an examination.

The American College of Psychiatrists conducted research in consultation with American College Testing

**TABLE 1. Preferences of 153 Residency Training Directors for Emphasis Given to Content Areas in the Content Outline of the Psychiatry Resident In-Training Examination (PRITE)**

| | Agree With Emphasis | | More Emphasis | | Less Emphasis | | No Response | |
|---|---|---|---|---|---|---|---|---|
| Content Area | N | % | N | % | N | % | N | % |
| Neurology and neurosciences | 106 | 69.3 | 25 | 16.3 | 15 | 9.8 | 7 | 4.6 |
| Psychiatry | 100 | 65.4 | 12 | 7.8 | 19 | 12.4 | 22 | 14.4 |
| Growth and development | 93 | 60.8 | 29 | 19.0 | 21 | 13.7 | 10 | 6.5 |
| Adult psychopathology | 104 | 68.0 | 32 | 20.9 | 11 | 7.2 | 6 | 3.9 |
| Emergency psychiatry | 120 | 78.4 | 18 | 11.8 | 8 | 5.2 | 7 | 4.6 |
| Behavioral science | 92 | 60.1 | 6 | 3.9 | 48 | 31.4 | 7 | 4.6 |
| Psychosocial therapies | 79 | 51.6 | 51 | 33.3 | 16 | 10.5 | 7 | 4.6 |
| Somatic treatment methods | 109 | 71.2 | 13 | 8.5 | 25 | 16.3 | 6 | 3.9 |
| Patient evaluation | 110 | 71.9 | 24 | 15.7 | 15 | 9.8 | 4 | 2.6 |
| Consultation-liaison psychiatry | 116 | 75.8 | 17 | 11.1 | 14 | 9.2 | 6 | 3.9 |
| Child psychiatry | 99 | 64.7 | 22 | 14.4 | 26 | 17.0 | 6 | 3.9 |
| Alcoholism and substance abuse | 104 | 68.0 | 12 | 7.8 | 28 | 18.3 | 9 | 5.9 |
| Miscellaneous (forensic, ethics, etc.) | 122 | 79.7 | 12 | 7.8 | 11 | 7.2 | 8 | 5.2 |

to study the current content outline for the PRITE. A confidential written survey of the 218 PRITE residency training directors was conducted to validate the outline empirically or to indicate support for changes. The results of the survey are the focus of this article.

## METHOD

The survey instrument was developed by a task force appointed by The American College of Psychiatrists in consultation with American College Testing through a series of teleconferences. The task force consisted of two members of the American Association of Directors of Psychiatry Residency Training and two members of The American College of Psychiatrists.

The current PRITE content outline is composed of two major areas: neurology and neurosciences (18%) and psychiatry (82%). The area of psychiatry contains 11 separate content domains. The primary section of the survey focused on residency training directors' preferences for the relative emphasis given to each specific content area.

In addition to collecting information regarding the PRITE content outline, the survey was designed also to assess 1) support for the practice of releasing PRITE items and answers, 2) how residency training directors use the PRITE results, 3) which textbooks are appropriate for PRITE item writing and referencing, 4) whether journals are appropriate for item writing and referencing, and 5) how programs prepare residents for the examination. In this way, the survey would provide valuable information about the PRITE that would extend beyond the issue of the validation of the content outline.

The content outline for Part I of the American Board of Psychiatry and Neurology (ABPN) examination was included in the survey instrument for comparison with the PRITE content outline. The inclusion of the content outline was authorized by the ABPN with the understanding that it would be distributed only to residency training directors subscribing to the PRITE.

One week before the survey questionnaires were mailed, each residency training director who subscribed to the PRITE was sent a letter describing the research project. The letter was intended to stimulate interest in the research and was sent from The American College of Psychiatrists with the signatures of the president of The American College of Psychiatrists and the PRITE editor-in-chief. The survey instruments were mailed by The American College of Psychiatrists in October 1990. Return envelopes addressed to American College Testing were included. The survey questionnaires were coded to facilitate follow-up correspondence with nonrespondents.

By mid-November 1990, American College Testing had received 94 responses to the survey, a 43% response rate. A second copy of the survey questionnaire with a letter and return envelope was mailed by American College Testing to the 124 residency training directors whose materials had not been received. The letter included directions to disregard the second copy if the two copies had crossed in the mail.

A total of 153 responses were received, which corresponds to a 70% response rate for the study. Survey instruments received after Dec. 7, 1990, were not included in the data analysis. Late responses did not differ significantly from those received on time.

A 70% response rate is considered quite good for written survey research. The American College of Psychiatrists did not feel that it was necessary to encourage further the training directors who had not yet responded, as nonresponding programs were not systematically different from responding programs.

## RESULTS

The results of the survey showed strong support for the current PRITE content outline. A majority of the respondents indicated agreement with the relative emphasis given to each content area, and a majority did not indicate any content areas that should be added or deleted. The preferences of survey respondents are shown in table 1. The percentages of respondents indicating agreement ranged from 51.6% to 79.7% for the various content areas.

Only 23 respondents (15.0%) indicated additional areas that should be included in the PRITE content outline. Geriatric psychiatry was listed by eight respondents; the other areas indicated were varied. Only nine respondents (5.9%) indicated content areas for deletion; these areas also were varied.

The residency training directors were asked to indicate their feelings about maintaining the educational aspect of the PRITE by releasing the examination and correct responses each year. This represents the major difference between the PRITE (as an educational tool) and Part I of the ABPN certification examination. A 5-point Likert-type rating scale was used for responses: 5=strongly in favor of and 1=strongly opposed to releasing PRITE items and answers to residents. The mean of the ratings was 4.65. Eighty-one percent (N=124) of the respondents were strongly in favor of maintaining the educational aspect of the PRITE by releasing the examination and correct responses each year; no respondents were strongly opposed.

On the item asking whether they would be in favor of *stopping* the practice of releasing the PRITE items and answers to establish greater similarity to Part I of the ABPN examination, 7.2% (N=11) of the respondents answered yes and 89.5% (N=137) answered no (3.3%, N=5, did not answer). It is interesting to note that this question elicited the greatest consensus within the survey.

The residency training directors were asked to respond to a list of possible uses that could be made of PRITE results by indicating the ones applicable to their programs. The majority of the respondents indicated more than one use, most frequently choosing the categories of program evaluation and individual resident evaluation (table 2).

The training directors were also asked to indicate any additional uses of PRITE results that their programs make. Additional uses were indicated by 21 respondents (13.7%). Counseling of residents was listed by eight respondents, and practice for the ABPN examination was listed by seven. The other uses were varied.

In the comparison of the ABPN Part I content outline and the PRITE content outline, about one-half of the respondents could see advantages in using the ABPN Part I content outline for the PRITE, and about one-half could see disadvantages in doing so. With respect to advantages, 45.8% (N=70) could not see any advantages, while 49.0% (N=75) indicated that they could see advantages (5.2%, N=8, did not respond to this item). Explanations of advantages were listed by 72 respondents. Almost one-half of these indicated an element of practice/preparation for the ABPN Part I examination, and approximately one-third indicated a preference for some content area or the total format of the ABPN content outline rather than the one used for the PRITE. Several respondents listed the possibility of better predictive power of results on the ABPN Part I examination; other responses were varied.

With respect to the disadvantages of using the ABPN Part I content outline, 43.8% (N=67) of the respondents indicated that they did not see any disadvantages, while 45.8% (N=70) indicated that they saw disadvantages (10.5%, N=16, did not respond to this item). Explanations of disadvantages were listed by 68 respondents. More than one-half of these respondents indicated that neurology was given too much emphasis in the ABPN Part I content outline to be appropriate for the PRITE. Approximately one-fourth indicated a preference for maintaining child psychiatry and consultation-liaison psychiatry as separate content areas. Several respondents listed a more global indication of preference for the PRITE content outline; other responses were varied.

**TABLE 2. Responses of 153 Residency Training Directors Regarding Use of Results on the Psychiatry Resident In-Training Examination (PRITE)**

| Use | N | %[a] |
|---|---|---|
| Program evaluation | | |
| Comparing program's mean scores to the national percentiles | 142 | 92.8 |
| Evaluating specific content areas to identify program strengths and weaknesses | 144 | 94.1 |
| Modifying curriculum | 116 | 75.8 |
| Individual resident evaluation | | |
| Identifying residents' weaknesses so as to focus future training better | 138 | 90.2 |
| Use in conjunction with other measures for assessing residents' cognitive competence so as to determine progress in training | 102 | 66.7 |
| Use as sole measure for assessing residents' cognitive competence so as to determine progress in training | 2 | 1.3 |
| Marketing residency program (distributing program results to residency applicants) | 8 | 5.2 |

[a] Percentages do not total 100 because respondents were directed to select as many categories as applied to their programs.

The texts currently in the PRITE library that are available to writers and reviewers of PRITE items were listed in the survey instrument. Training directors were asked to check "yes" for each text they recommended to be used for the PRITE and "no" for each text they did not recommend. The majority of respondents indicated support for nearly all of the texts. There were no texts for which the majority of respondents indicated "no." A higher percentage of nonresponse was seen for this section of the survey, possibly indicating that some respondents were not comfortable evaluating all the texts listed.

For the question about whether or not journal articles should be used for PRITE item writing and referencing, 69.3% (N=106) indicated yes, and 28.1% (N=43) indicated that journals should not be used (2.6%, N=4, did not respond).

The training directors were asked to indicate, on a list of possible approaches to preparing residents for the PRITE, the ones that were applicable to their programs. A majority of the respondents indicated that no specific recommendations are given to residents. The percentages of respondents who selected each approach are presented in table 3.

In response to the item asking whether all programs should be required to adopt uniform practices to pre-

**TABLE 3. Approaches Taken by 153 Residency Training Directors to Prepare Residents for the Psychiatry Resident In-Training Examination (PRITE)**

| Approach | N | %[a] |
|---|---|---|
| No specific recommendations are given to residents | 90 | 58.8 |
| Residents are encouraged to take the examination without any preparation | 46 | 30.1 |
| Residents are encouraged to study for the examination | 29 | 19.0 |
| Residents are encouraged to form study groups | 12 | 7.8 |
| Study sessions are scheduled for residents | 8 | 5.2 |
| Practice examinations are administered to residents | 5 | 3.3 |
| Residents are relieved of on-call responsibilities in order to prepare for the examination | 8 | 5.2 |

[a] Percentages do not total 100 because respondents were directed to select as many categories as applied to their programs.

pare residents to take the PRITE, 79.7% (N=122) of the respondents indicated no, and 17.6% (N=27) indicated yes (2.6%, N=4, did not answer). Several respondents included an unsolicited comment indicating that enforcement of uniformity would be problematic.

## DISCUSSION

A majority of the residency training directors indicated agreement with the relative emphasis given to each content area of the PRITE, and only a small percentage of respondents listed content areas that should be added or deleted. There was strong support for continuing the practice of releasing the examination and the correct responses. It is this practice that clearly differentiates the in-training examination from the next examination in the career path, the certification examination. Residency training directors indicated that they use PRITE results for program evaluation and individual resident evaluation. Only very small percentages indicated that they use PRITE results for marketing a residency program or as the sole measure for assessing residents' cognitive competence so as to determine progress in training.

The responses also indicated that the hypothetical question regarding the appropriateness of adopting the ABPN Part I content outline for the PRITE is a complex issue. About one-half of the residency training directors saw advantages for doing so, and one-half saw disadvantages. Key areas for comparison of the two tests' content outlines are the emphasis given to neurology and neurosciences and the distribution of items in the areas of child psychiatry and consultation-liaison psychiatry. Regarding the current PRITE content outline, 69.3% of the respondents indicated that neurology and neurosciences should continue to be given a relative emphasis of 18% on the test. Many of the respondents who listed disadvantages of adopting the ABPN Part I content outline for the PRITE indicated that the outline gave too much emphasis to neurology and neuropsychiatry. Many respondents indicated that the current curriculum for residents must be reflected in the PRITE.

The percentages of respondents indicating agreement with the relative emphasis given to child psychiatry and consultation-liaison psychiatry in the current PRITE content outline were 64.7% and 75.8%, respectively. Many respondents who listed disadvantages for adopting the ABPN Part I content outline for the PRITE indicated that these content areas should remain as distinct areas, with scores reported.

The most common advantage indicated for adopting the ABPN Part I content outline for the PRITE was the element of practice or preparation for the ABPN examination. This was slightly confounded by other responses indicating that the PRITE is currently used as practice/preparation for the ABPN examination. Several respondents noted that the predictive validity of the PRITE for the ABPN examination would be one advantage in adopting the ABPN Part I content outline for the PRITE. The American College of Psychiatrists will pursue research to establish the relation between performance on the PRITE (with its current content outline) and performance on the ABPN Part I examination. It may be shown that evidence of predictive validity is already at a level sufficient for counseling residents.

The majority of the texts used for writing and referencing PRITE items were supported in the survey. The use of journals for writing and referencing PRITE items was also supported in the survey results.

A majority of the respondents indicated that no specific recommendations are given to residents preparing for the PRITE. Only small percentages of respondents actively prepare residents by scheduling study sessions, administering practice examinations, or relieving residents of on-call responsibilities. A majority of the training directors indicated that uniform practices in preparing residents for the PRITE should not be required. It appears that residency training directors are using the approaches that work best for their programs and would prefer not to have practices mandated.

Overall, the survey results provided strong support for the content areas covered in the PRITE and their relative emphases. The current practice of releasing PRITE items and answers was also well supported by the survey results. It appears that The American College of Psychiatrists' purpose for the PRITE, to provide educationally useful feedback for individuals and groups in the form of comparisons with peers in specific areas of knowledge, is supported by a large majority of the psychiatry residency training directors who subscribe to the PRITE.

*Objective: The American Psychiatric Association's DSM-IV Work Group on Late Luteal Phase Dysphoric Disorder (LLPDD) reanalyzed existing data from prospective, daily symptom ratings to evaluate the* DSM-III-R *criteria for LLPDD. The objectives were to 1) evaluate the individual symptoms presently required for the diagnosis and other symptoms, 2) determine the proportion of treatment-seeking women who meet the LLPDD criteria, and 3) explore the association between LLPDD and other mental disorders. Method: Data from over 1,000 women seeking evaluation for premenstrual complaints at five U.S. sites were examined. The data from 670 of these women were sufficiently complete to warrant evaluation by four different methods of assessing symptom change. Results: Depending on the assessment method used, 14% to 45% of the women met the criteria for LLPDD. The current* DSM-III-R *symptoms were classified as positive for 7% to 54% of the women. Each of these symptoms was significantly more common among women with LLPDD regardless of the assessment method used. Five symptoms not presently included were also significantly more common. Women who had had mental disorders in the past, but not present, showed a significantly greater, but very small, relative risk of LLPDD. Conclusions: The variability in the frequency of LLPDD diagnosis according to method of assessing symptom change underscores the need for a uniform assessment method. The five additional symptoms with frequencies comparable to those of the* DSM-III-R *symptoms should be studied further for possible inclusion in the criteria.*
(Am J Psychiatry 1992; 149:525–530)

---

Late luteal phase dysphoric disorder (LLPDD), as defined in *DSM-III-R*, is a subset of premenstrual syndrome (PMS). Women with LLPDD suffer primarily from severe mood symptoms that repeatedly occur in the luteal phase of the menstrual cycle. After reviewing the literature on PMS and LLPDD (1–10), the American Psychiatric Association's DSM-IV Work Group on Late Luteal Phase Dysphoric Disorder concluded that empirical justification of procedures for identifying a homogeneous group of women with the disorder was needed, as was some understanding of the relationship between LLPDD and other mental disorders. Therefore, the work group, in conjunction with the Task Force on DSM-IV, authorized a reanalysis of existing primary data from women seeking evaluation for premenstrual complaints.

LLPDD differs from other diagnoses in *DSM-III-R* because it requires the documentation of symptom change by prospective, daily records. Unfortunately, *DSM-III-R* does not specify how to compute the change, nor do researchers agree about how best to do so (11). The work group decided, therefore, to compare four existing methods that represented a range of simple to complex approaches.

The objectives of the database analysis were 1) to evaluate the individual symptoms presently required for the diagnosis and other symptoms, 2) to determine the proportion of women who met the LLPDD criteria, and 3) to explore the association between LLPDD and other mental disorders. We addressed them by first determining the percentage of women whose late luteal phase symptoms satisfied the four different change criteria. We then examined the association between the diagnosis and in-

**TABLE 1. *DSM-III-R* LLPDD Symptoms and Corresponding Symptoms From Rating Scales Used in Five Studies**

| *DSM-III-R* LLPDD Symptoms | Original Rating Scale Symptoms |
|---|---|
| Marked affective lability | Mood swings, feel labile<br>Rapid changes in mood |
| Persistent and marked anger or irritablity | Irritability, anger, temper, or impatience |
| Marked anxiety, tension | Anxious, jittery, nervous<br>Nervous tension<br>Feel under stress |
| Markedly depressed mood | Depressed, sad, low, blue, tearful, or lonely |
| Decreased interest in usual activities | Loss of interest or pleasure in usual activities<br>Avoid social activities |
| Easy fatigability or marked lack of energy | Low or decreased energy, fatigue, feel unable to move, tired or weak |
| Subjective sense of difficulty in concentrating | Distractible, difficulty concentrating<br>Confusion<br>More forgetful |
| Marked change in appetite or food cravings | Decreased appetite<br>Increased appetite<br>Craving foods |
| Hypersomnia or insomnia | Decreased or increased sleep, insomnia<br>More sleep, naps, stay in bed |
| Physical symptoms | Headaches<br>Breast tenderness, swelling, or pain<br>Abdominal bloating, swelling, pain, or heaviness<br>Back, joint, or muscle pain or aches<br>Feel bloated, have edema |

dividual symptoms, including the 10 LLPDD symptoms and 21 others. We also computed the relative risk of LLPDD as a function of psychiatric history.

The work group's approach to these questions was unique in its use of existing primary data from several cooperating investigators. This cooperation allowed us to directly compare symptom formats, methods of evaluating symptom change, and the association of psychiatric disorder history with a diagnosis of LLPDD.

## METHOD

### *Subjects*

The subjects for the present investigation were drawn from five PMS clinics associated with university and/or large urban hospitals in the eastern United States. Site selection was based on the availability and accessibility of data and the subjects' willingness to participate. Women at all sites were both recruited by advertisement and seen as patients seeking evaluation and treatment of premenstrual difficulties.

The original pool of 1,089 women rated their symptoms daily, providing data on 2,106 menstrual cycles. To minimize the inclusion of anovulatory cycles, only cycles between 22 and 35 days in length (mean=26.9, SD=4.0) were included (12). Women with symptom ratings for fewer than two complete menstrual cycles each or whose mental histories were not available were also excluded. The remaining 670 women can be summarized as follows: mean age=34 years (SD=5.6), percent of white subjects=95%, percent employed at least part-time=69%, percent with at least some college education=78%. These women reported an average of 1.3 children (SD=1.2), 1.9 pregnancies (SD=1.6), and a duration of premenstrual symptoms of 7.6 years (SD=6.7). Compared to the general U.S. population of women, this group was equally likely to be employed, was better educated, and had fewer children.

### *Measures*

At four sites data on lifetime mental history were collected by using structured interviews. At three sites the Schedule for Affective Disorders and Schizophrenia—Lifetime Version (13) was used and psychiatric diagnoses were made with the Research Diagnostic Criteria (14). At one site the Diagnostic Interview Schedule (15) was used and psychiatric diagnoses were made with the *DSM-III* criteria. At the remaining site a clinical interview was used and diagnoses were made with *DSM-III* criteria.

Each site used its own symptom rating form. The women were asked to rate from 17 to 33 symptoms daily. Items with content that was identical or very similar to the symptoms of LLPDD were selected to evaluate the presence or absence of these symptoms. The LLPDD symptoms and their relationship to the original items are shown in table 1.

Ratings were typically made on a 6-point rating scale on which each scale point was labeled to reflect the intensity of the symptom compared to the woman's symptom-free state. Symptoms were assessed by using four different procedures. Three procedures compared symptom ratings during follicular phase days 5–10 (where day 1 is the first day of menses) and the last 6 days of the luteal phase. These days were selected to avoid symptoms associated with menses or ovulation, to be of equal length, and to address criterion A of LLPDD, which requires the presence of symptoms "during the last week of the luteal phase" and remission of symptoms "within a few days after the onset of the follicular phase." The absolute severity method (16) required follicular phase ratings of no more than minimal (a rating of 2) for at least 4 of the 6 follicular phase days and a severe or extreme rating (a rating of 5 or 6) for at least 1 late luteal phase day. The percent change method (16) required mean late luteal phase severity to exceed by at least 75% mean follicular phase severity. The effect size method (17) required mean late luteal phase severity to exceed mean follicular phase symptom severity by at least the standard deviation of scores for that symptom in that cycle. The trend analysis method (18) defined a symptom as present if the exponentially forecasted severity score was significantly increased ($p<0.05$) on at least 1 day during the last 2 weeks of the cycle and was significantly decreased any time after cycle day 7 but not after the beginning of the increase.

An LLPDD diagnosis for each method required a

[a]See text for explanations of the four methods.

positive classification of at least five of the 10 symptoms—at least one of which was anxiety, depression, irritability, or mood lability—in two or more cycles. For compound symptoms (e.g., hypersomnia or insomnia), the symptom was considered present if any of the possibilities was present. This approach to assessing multiple cycles for the same woman reflects criterion E of LLPDD, which requires that symptoms be "confirmed by prospective daily self-ratings during at least two symptomatic cycles."

## RESULTS

The number of women who received diagnoses of LLPDD varied with the method used to assess symptom change. The absolute severity method produced the fewest number of women with diagnoses of LLPDD (N=95, 14%) and the lowest percentages of positive symptoms regardless of LLPDD diagnosis (7% to 18% of all women). The trend analysis method produced the largest number of women with diagnoses of LLPDD (N=304, 45%) and the highest percentages of positive symptoms regardless of LLPDD diagnosis (23% to 54% of all women). The effect size and percent change methods produced intermediate numbers of LLPDD diagnoses (N=253, 38%, and N=229, 34%, respectively) and percentages of women with positive symptoms (15% to 43% of all women and 14% to 40% of all women, respectively).

The frequency of occurrence of the 10 symptoms of LLPDD is shown in table 2. Individual symptoms were classified as positive for as few as 7% of the women and as many as 54%, depending on the symptom and assessment method used. Significantly more women diagnosed with LLPDD than women without LLPDD had positive LLPDD symptoms ($\chi^2$=56.2–270.3, df=1, p< 0.0001). For example, a subjective sense of difficulty in concentrating was found in at least 70% of the women with LLPDD, regardless of assessment method, and in as few as 9% of the women without diagnoses of LLPDD. Other symptoms—for example, easy fatigability or marked lack of energy—although found relatively infrequently in women without LLPDD, were also found relatively infrequently in women with LLPDD. Averaged across the four methods, sleep disturbance and concentration difficulties were the most common symptoms among the women with LLPDD and fatigability was the least common. Averaged across all four assessment methods, the proportion of subjects who had at least one positive symptom each was four times as high among the women with LLPDD (60%) as among the women without LLPDD (14%).

A total of 21 additional symptoms were rated by women from one or more of the sites. On average, the number of women who indicated premenstrual exacerbations of these symptoms was one-quarter to one-third the number who indicated symptoms of LLPDD. However, five of these 21 symptoms were assessed positively with all four methods approximately as frequently as the 10 LLPDD symptoms and with significant differences in frequency of occurrence between women with LLPDD and women without LLPDD ($\chi^2$=16.0–133.5, df=1, p<0.001). Data for these five symptoms are shown in table 3.

Nearly three-quarters of the 670 women, who were not prescreened for mental disorders, either never met criteria for any mental disorder (N=223, 33%) or met criteria for mental disorders only in the past (N=264, 39%). Among the women who met criteria for mental disorders only in the past, an average of 1.5 mental disorders (SD=0.7) was recorded. The criteria for a present

[b] Percent based on number of subjects with LLPDD diagnosis who rated the particular symptom.

history of mental disorder were met by 27% of the women (N=183). Slightly more than one-half of these women (59%) also met the criteria for a past history of mental disorder. Among all women with present histories, averages of 1.4 present disorders (SD=0.7) and 0.9 past disorders (SD=1.0) were recorded.

Significantly more of the women with only past histories of mental disorders were diagnosed with major depressive disorder than were women with present histories of mental disorders (61% versus 29%; $\chi^2$=44.2, df=1, p<0.001). Significantly more of the women with present mental disorders, compared to the women with only past histories, were diagnosed with depressive disorders other than major depressive disorder (51% versus 32%; $\chi^2$=14.9, df=1, p<0.001), with phobia (36% versus 5%; $\chi^2$=72.4, df=1, p<0.001), and with other disorders, including substance abuse, psychotic disorders, and personality disorders (44% versus 27%; $\chi^2$=12.9, df=1, p<0.001).

Relative risk estimates were used to compare the frequencies of LLPDD diagnoses in the groups with mental disorders in the past only and in the present with the frequency in the group with no mental disorders. For the group with histories of mental disorders in the past only, the relative risk of a diagnosis of LLPDD averaged 1.14. This indicates that in this group of women who sought help for premenstrual complaints, women with past histories of mental disorders had a 14% greater chance of being diagnosed with LLPDD than women with no history of mental disorders. As shown in table 4, all methods except the absolute severity method showed a significantly greater risk of LLPDD in women with past psychiatric histories only.

In contrast, a present history of a mental disorder did not increase the relative risk of receiving an LLPDD diagnosis regardless of assessment method (see table 4). Averaged over the four methods, the relative risk of being diagnosed with LLPDD for the group with present mental disorders was 0.92.

To determine if the greater risk of LLPDD in the group with mental disorders in the past only was due to their greater likelihood of having major depressive disorder, we examined the risk of LLPDD as a function of past-only or current major depressive disorder relative to no disorder. Risk was not significantly increased for women with past major depressive disorder only except when LLPDD was diagnosed by trend analysis (relative risk=1.32, 95% confidence interval=1.07–1.62, p<0.01). The relative risks for the absolute severity, effect size, and percent change methods were 0.74, 1.20, and 1.28, respectively (lowest p=0.13).

## DISCUSSION

These data demonstrate that the percentage of women evaluated for premenstrual complaints who receive the diagnosis of LLPDD varies from 14% to 45%, depending on the method chosen for evaluating changes in symptom severity. Among these women, the LLPDD symptoms, and relatively few others, were documented in significantly more women with LLPDD than women without LLPDD. Because only five of the 10 *DSM-III-R* symptoms were required for a diagnosis, it was predictable that no single symptom would be especially frequent among the women with LLPDD diagnoses. Among the additional 21 symptoms evaluated, five symptoms with frequencies comparable to those of the *DSM-III-R* symptoms were found. The content of four of these items is close to that of specific LLPDD symptoms, and their presence or absence was significantly related to these symptoms. The item "intense reaction to daily events" was associated with the LLPDD symptoms "marked affective lability" (kappa=0.70), and the items "decreased self-esteem" and "feeling gloomy, pessimistic, despondent" were closely related to the LLPDD symptom "markedly depressed mood, feelings of hopelessness, or self-deprecating thoughts" (kappa=0.62 for both). "Less desire to move, talk" was associated with the LLPDD symptom "easy fatigability or marked lack of energy" (kappa=0.68). Finally, "problems coping, out of control, feel overwhelmed" may relate to LLPDD criterion C, which involves the severity of a premenstrual disturbance: "seriously interferes

[d] $\chi^2=4.18$, df=1, $p<0.05$ (Mantel-Haenszel chi-square).
[e] $\chi^2=4.52$, df=1, $p<0.05$ (Mantel-Haenszel chi-square).

with work or with usual social activities or relationships with others." These five symptoms should be studied further for possible inclusion among the diagnostic criteria.

The weak association between major depressive disorder and LLPDD raises questions about previous reports of a higher than average likelihood of affective disorder among women with premenstrual complaints (19). Although the relative risks based on effect size and percent change diagnoses were not statistically significant, their magnitude was similar to the statistically significant estimate for trend analysis, suggesting a possible type II error. Even so, the higher risk of LLPDD among women with major depressive disorder in the past was slight when the women were diagnosed with the trend analysis, effect size, and percent change methods, and the risk was actually lower than for women with no psychiatric history when the women were diagnosed by the absolute severity method, which employed the strictest diagnostic criteria. These data demonstrate that the diagnosis of LLPDD is not merely synonymous with a diagnosis of another mental disorder or more likely among women with affective disorders when explicit criteria for late luteal phase severity and early follicular phase remission are used. Moreover, among these subjects, at least one in six of the women with no past or present mental disorders met the most stringent symptom definition of LLPDD.

We were not able to address the relationship between LLPDD and other mental disorders in sufficient detail to fulfill the LLPDD requirement that the symptoms of LLPDD not be "merely an exacerbation of the symptoms of another disorder." This would require data on the relative times of onset of these disorders and their symptom profiles, which were unavailable to us. However, at least one attempt has been made to separate symptoms of mental disorders that are exacerbated by the late luteal phase from other symptoms (20). Additional attempts to do so should be encouraged in order to determine the actual prevalence of LLPDD among women with past or present histories of mental disorders.

Using any of the assessment methods, we failed to confirm a pattern of symptom exacerbation related to menstrual cycle phase in one-third of the women. Since these data were provided by women who sought help for premenstrual complaints, we believe that a rigorous application of the full criteria for the disorder would make it difficult to confuse this diagnosis with minor symptomatic complaints associated with the menstrual cycle. These figures most likely represent an overestimate of LLPDD's frequency of occurrence in the general population and should not be generalized to reflect the prevalence of LLPDD among all women.

## CONCLUSIONS

Between 14% and 45% of the treatment-seeking women in this study met the *DSM-III-R* criteria for LLPDD. This variability in the frequency of occurrence of the diagnosis of LLPDD has been observed by others (11, 21) and underscores the need for researchers to use a uniform method for evaluating symptom change. These frequency estimates should not be used as prevalence estimates for LLPDD because they are based on a secondary analysis of previously existing data sets that were similar but not identical and involve primarily treatment-seeking subjects. Furthermore, the five sites from which these data were drawn may not adequately represent the various types of settings in which women with premenstrual complaints seek treatment. We recommend the systematic collection of data from representative sites with the same semistructured interview to determine the provisional diagnosis of LLPDD, the diagnosis of other mental disorders, and the age at onset for each. Such a study should also include the prospective evaluation of the LLPDD symptoms plus the additional five symptoms not directly represented among the existing criteria, in particular, the symptom "problems coping, out of control, feel overwhelmed." Given the better performance of the item "less desire to move, talk" than of "easy fatigability or marked lack of energy," consideration should be given to rewording this criterion for LLPDD.

We recommend the absolute severity method for determining symptom change since it ensures an asymptomatic follicular phase and a severely symptomatic late luteal phase. This method is the most conservative of the methods examined here and the easiest to apply clinically. No mathematical treatment of the prospective ratings is required, and an evaluation of the LLPDD criteria can be carried out by simple inspection of a plot of the daily ratings. For research purposes, however, an approach that combines absolute severity criteria with consideration of the variability in symptom severity throughout the entire menstrual cycle, such as the effect size method, would be preferable. This would allow investigators to assess changes in LLPDD severity (e.g., due to treatment or across cycles) and to compare their results with the results of investigators from different sites.

# Course of Premenstrual Syndrome Symptom Severity After Treatment

Ellen W. Freeman, Ph.D., Karl Rickels, M.D., and Steven J. Sondheimer, M.D.

*Objective: Patients from a randomized, double-blind, placebo-controlled study of progesterone suppository treatment for premenstrual syndrome (PMS) were followed up to determine poststudy PMS symptom levels and medication use. Method: An average of 1 year after the end of the treatment study, 129 subjects were contacted for telephone interviews. All subjects met criteria for PMS before the progesterone suppository treatment, and their symptoms were confirmed by daily symptom reports throughout the study. The outcome measure at follow-up was the patient's global assessment of symptom severity, which was also rated by the subjects during the treatment study. The ratings at enrollment, end of study, and follow-up were compared. Results: Only 27% of the subjects (N=35) were taking medications for PMS at follow-up. Symptom severity at follow-up was less than at enrollment but greater than at the end of the study. Conclusions: Some of the improvement gained during treatment was maintained, but overall the subjects remained moderately symptomatic. Validation of the PMS condition, education, and support and caring may account for the symptom decreases during treatment, and the end of treatment and withdrawal of these conditions may account for the moderate return of symptoms.*

(Am J Psychiatry 1992; 149:531–533)

Treatment of premenstrual syndrome (PMS) (provisionally termed "late luteal phase dysphoric disorder" in *DSM-III-R*) often results in symptom reduction, even when active medication is no more effective than placebo (1–3). However, to our knowledge there have been no follow-up reports of PMS patients to describe the course of symptoms after medical intervention. Improvement experienced during treatment could be due to numerous psychological factors affecting patient expectations and could have long-term as well as transitory effects (4).

We conducted a follow-up study of extensively evaluated PMS subjects who participated in an 8-month treatment protocol. In the double-blind, placebo-controlled crossover treatment study (5), there was significant symptom reduction from baseline but no statistically significant difference between the medication and placebo. Follow-up was conducted to determine symptom levels during the most recent menstrual cycle and to learn whether the subjects had continued to take their medications for PMS.

## METHOD

### *Subjects*

The 168 subjects in the original study were extensively evaluated and met criteria for PMS before their progesterone suppository treatment (5). The study staff contacted 129 (77%) of them for telephone interviews an average of 1 year after the end of the study. The other 39 subjects could not be located. There were no differences between the contacted and noncontacted subjects in comparisons of study variables that included medical history, background characteristics, and premenstrual symptom score (from daily reports) at the end of the study.

The subjects met the following criteria before random assignment to treatment in the initial study: 1) moderate to severe symptoms in the premenstrual week with relief after the onset of menses, 2) an increase of at least 50% in the total premenstrual symptom score (days 22–28) over postmenstrual score (days 6–12), based on the subjects' daily symptom reports (description to fol-

**TABLE 1. PMS Symptom Severity of 129 Women at Beginning of Treatment Study, End of Study, and Follow-Up**[a]

| | PMS Symptom Severity in Most Recent Menstrual Cycle (0=none, 4=extreme) | | | |
|---|---|---|---|---|
| | Follow-Up Less Than 12 Months (mean=6 months) (N=84) | | Follow-Up 12 Months or More (mean=18 months) (N=45) | |
| Time | Mean | SD | Mean | SD |
| Enrollment in study | 2.86 | 0.98 | 2.95 | 0.94 |
| End of study | 1.81 | 1.35 | 1.71 | 1.34 |
| Follow-up | 2.24 | 1.12 | 2.33 | 1.23 |

[a] ANOVA multivariate tests showed significant main effect of time (F=40.5, df=2, 124, p<0.0001) but nonsignificant main effect of group (F=0.03, df=1, 125) and interaction of time and group (F=0.14, df=2, 124). All between-time comparisons showed significant differences (p<0.05, pairwise t tests).

low), 3) low symptom score during the follicular phase, 4) no current major psychiatric diagnosis as determined by structured diagnostic interview using a modified version of the Schedule for Affective Disorders and Schizophrenia—Lifetime Version (6) and *DSM-III* criteria, 5) occurrence of PMS in most cycles during the past year according to subject report, and 6) confirmation of symptom status by daily symptom reports after a four-cycle evaluation period including two cycles of pill-placebo washout. These criteria met the National Institute of Mental Health guidelines for PMS (7). Most subjects also met the criteria for late luteal phase dysphoric disorder in *DSM-III-R,* which was published while this study was in progress.

### *Symptom Assessments*

Symptoms were assessed through the daily symptom reports maintained by the subjects throughout the eight-cycle study. The report form listed 17 symptoms that are associated with PMS and have been included in diaries used in previous PMS studies (8–10): nervous tension, mood swings, irritability, anxiety, loss of control, fatigue, depression, crying, insomnia, swelling, breast tenderness, headache, food cravings, confusion, poor coordination, aches, and cramps. The subjects rated each symptom daily from 0 (not at all) to 4 (severe). The scores were summed for a daily total score.

The outcome measure at follow-up was the patient's global assessment of symptom severity. The subjects were asked to indicate the overall severity of their symptoms (0=none, 4=extreme) during the most recent premenstrual time. During the treatment study, the subjects completed the same global assessment at enrollment and at the end of the study, and those results were consistent with the daily symptom scores, which were used as the primary outcome variable in the treatment study. The Pearson coefficient of correlation between the global severity scores and the daily symptom ratings at the end of the study was r=0.56 (p<0.0001). In the follow-up investigation, the severity scores at the three time points (enrollment, end of study, and follow-up) were analyzed by using repeated measures analysis of variance (ANOVA) with least squares means and paired t tests in post hoc pairwise comparisons.

## RESULTS

At follow-up, only 27% of the 129 subjects (N=35) were taking medications for PMS; the majority of this group (N=22) were using progesterone, which was prescribed for subjects who wished to continue to take it after the study. The other medications included nonsteroidal analgesics (N=5), vitamins (N=5), and anxiolytics (N=3). The mean symptom severity score of the subjects taking medications was compared with the mean for the subjects taking no medications, and the difference was nonsignificant (main effect of group: F=0.25, df=1, 125, p=0.62).

Table 1 presents the symptom severity scores at enrollment, the end of the treatment study, and follow-up for the subjects who were contacted within 1 year of the end of the study (mean=6 months) and those contacted 1 year or more after the end of the study (mean=18 months). In multivariate analysis, the only statistically significant result was the main effect of time; contrast between time points showed that severity was less at both follow-up (F=31.5, df=1, 125, p<0.0001) and the end of the study (F=66.9, df=1, 125, p<0.0001) than at enrollment. Although the symptoms had returned to a moderate level, at follow-up they were lower than at enrollment in the treatment study (all post hoc pairwise comparisons showed statistically significant differences between time points). As can be seen in table 1, the severity scores of the two groups were very similar at all times, indicating that symptom severity did not differ between the early and later follow-up periods.

We also examined whether the subjects who improved most during treatment (i.e., had a decrease in total premenstrual daily symptom score of at least 50%) were still more improved at follow-up. When the mean follow-up severity score of the improvers (mean=2.34, SD=1.17) was compared with the mean for the remaining subjects (mean=2.23, SD=1.11), the difference was not statistically significant (F=0.38, df=1, 124, p=0.54), indicating that the greater improvement of a subset of patients during treatment was not maintained. A separate analysis of the small group that continued progesterone treatment (N=22), comparing those who had improved 50% or more during the treatment phase with the remainder in this subgroup, also showed no difference in symptom severity at follow-up.

## DISCUSSION

These data describe the course of PMS severity after 8-month treatment of women who were carefully evaluated for this disorder. The PMS symptoms tended to return after treatment, although not to their original severity levels. Although some improvement gained during treatment was maintained, overall the subjects remained moderately symptomatic.

We suggest that the original decrease in symptom levels, which occurred in both the group that received placebo and the group that received progesterone treatment, resulted as much from the treatment process and from the women's expectations of treatment as from the medication, which did not result in a statistically better outcome than did placebo. The daily symptom recording and monthly review of symptoms with clinicians, maintained by the subjects throughout the treatment study, helped the women develop a more informed understanding of their symptoms. Expert clinicians and a long-term PMS treatment program gave credibility to and validated a poorly understood condition, reducing the subjects' anxiety about their psychiatric symptoms. The patients felt that they were not alone, that someone understood their condition and cared about them—perceptions that may be essential for health. The moderate return of symptoms that followed cessation of treatment may have in part resulted from the loss of support and the absence of consistent treatment, as signified by the discontinuation of medication for PMS by most of the women contacted at follow-up.

Effective immediately, Letters to the Editor critical of an article published in the *Journal* must be received within 6 weeks of the article's publication. Letters received after the deadline will not be considered and will be returned unreviewed.

# Dissociation in Women With Chronic Pelvic Pain

Edward A. Walker, M.D., Wayne J. Katon, M.D., Kathryn Neraas, M.D.,
Ron P. Jemelka, Ph.D., and Donna Massoth, Ph.D.

*Objective: The authors' goal was to determine if women with chronic pelvic pain are significantly more likely to use dissociation as a coping mechanism than women without pain. Method: The subjects were recruited from women who attended a university women's clinic during a 1-month period. Twenty-two women who reported that they had at any time in their lives experienced pelvic pain nearly every day for a period of at least 6 months were included in the study, along with 21 randomly selected women without a history of chronic pelvic pain. The 43 women were given structured sexual assault interviews and completed psychological self-report measures. Results: The women with chronic pain were significantly more likely to use dissociation as a coping mechanism, to show current psychological distress, to see themselves as medically disabled, to experience vocational and social decrements in function, and to amplify physical symptoms. They were also significantly more likely to have experienced severe childhood sexual abuse. In the total study group, women with a childhood history of sexual abuse had significantly higher scores on measures of psychological distress, somatization, and dissociation and viewed their physical health and functioning as more impaired. Conclusions: The authors discuss a model for the development of somatization, dissociation, and pain symptoms in victims of early sexual abuse.*

(Am J Psychiatry 1992; 149:534–537)

Chronic pelvic pain is a frequently encountered problem in primary care. Although the exact prevalence is unknown, our recent survey of 650 women attending two ambulatory care clinics found that 38% reported pelvic pain persisting for more than 6 months at some time in their lives and 12% stated it was the chief complaint for the clinic visit (1). Studies comparing women with and without chronic pelvic pain have shown that women with pain are significantly more likely to have histories of recurrent major depression, somatization, sexual and physical abuse, and chronic psychological distress (2–4), factors that have been shown to predispose to greater use of medical care services (3, 5). Childhood sexual and physical abuse have also been shown to lead to subsequent somatization, anxiety, and depression (6, 7), and the intensity of these sequelae appears to be correlated with the duration and severity of the abuse (3).

Patients who have experienced childhood physical and sexual abuse have also been found to use dissociation as a coping mechanism more often than patients without a history of this abuse (8, 9). As defined by *DSM-III-R*, dissociation is a disturbance or alteration in the normally integrative functions of identity, memory, or consciousness.

Since chronic pelvic pain and dissociation have both been independently associated with childhood physical and sexual abuse, we hypothesized that women with chronic pelvic pain would have higher scores on measures of dissociation and would be more likely to use dissociative defenses.

## METHOD

The subjects were recruited from women attending a university women's clinic during a 1-month period. All of the women who came to the clinic during this time were given a written invitation to participate in the study by the two medically trained interviewers (K.N. and D.M). The letter stated that we were interested in speaking briefly with women who had at any time in their lives experienced pelvic pain nearly every day for a period of at least 6 months.

Twenty-two women met the inclusion criteria for medically unexplained chronic pelvic pain persisting for more than 6 months and provided informed consent. These

**TABLE 1. Psychological Self-Report Test Scores of Women With and Without Chronic Pelvic Pain**

| Test | Women With Chronic Pain (N=22) |  | Women Without Chronic Pain (N=21) |  | Analysis |  |  |
|---|---|---|---|---|---|---|---|
|  | Mean | SD | Mean | SD | t | df | p |
| General Health Questionnaire | 11.4 | 7.4 | 3.9 | 4.7 | 3.89 | 39 | <0.001 |
| Barsky Amplification Scale | 22.0 | 6.7 | 15.6 | 7.3 | 2.93 | 39 | <0.005 |
| Dissociative Experiences Scale | 19.0 | 14.9 | 4.8 | 3.8 | 4.22 | 41 | <0.001 |
| Medical Outcomes Survey[a] |  |  |  |  |  |  |  |
| Health perception | 43.8 | 23.1 | 75.6 | 13.7 | 5.27 | 36 | <0.001 |
| Physical function | 66.5 | 27.8 | 89.2 | 16.3 | 3.14 | 36 | <0.005 |
| Role function | 57.4 | 40.3 | 89.8 | 20.0 | 3.23 | 36 | <0.01 |
| Social function | 64.7 | 30.4 | 87.6 | 18.4 | 2.87 | 36 | <0.01 |
| Mental health | 52.0 | 26.3 | 70.3 | 15.5 | 2.67 | 36 | <0.05 |

[a] Lower scores are associated with less physical, social, and role function and a worse perception of physical and mental health.

women were given a structured sexual assault interview by the two medically trained interviewers (K.N. and D.M). The interview took approximately 20 minutes and was conducted while the women waited for their appointments. The sexual assault interview was a 14-question instrument previously used in large community epidemiologic studies (10). On the basis of their responses, women were characterized as having severe childhood abuse (incest, rape, oral contact, or repeated fondling before age 14), less severe childhood abuse (exhibitionism, aborted attempts before age 14), or no abuse.

The women also completed a battery of self-report questionnaires. These included the 28-item General Health Questionnaire (11), a screening instrument that measures psychosocial distress; the short version of the Medical Outcomes Survey (12), a 17-item measure of physical and medical health perceptions and resulting physical and functional disability; the Barsky Amplification Scale (13), a 10-item rating scale for somatization; and the Dissociative Experiences Scale (14), a 28-item scale measuring the degree to which dissociation is used as a coping strategy.

Twenty-one women who came to the clinic during the same 1-month period and who did not report a history of chronic pelvic pain were randomly selected as a comparison group. They were interviewed in the same manner and completed the same psychological tests as the 22 women with chronic pelvic pain. They also provided informed consent.

Chi-square tests with Yates's correction were used to compare the two groups of women on categorical measures such as marital status, sexual abuse history, and social class, and two-tailed t tests were used to determine if the groups differed on continuous variables such as age and psychological test scores.

## RESULTS

The mean age of the 22 subjects with chronic pelvic pain was 27.6 years (SD=7.7), and their mean Hollingshead social class rating was 4.0 (SD=1.0). The mean age of the 21 patients without pain was 31.2 years (SD=7.8), and their mean Hollingshead social class rating was 3.4 (SD=1.3). The two groups did not differ significantly in age (t=1.52, df=41, n.s.) or social class rating (t=1.75, df=41, n.s.). Significantly more of the patients in the comparison group (N=17) than in the chronic pain group (N=9) were married ($\chi^2$=5.63, df=1, p<0.01).

The psychological test scores of the two groups of patients are summarized in table 1. The women with chronic pelvic pain had significantly higher dissociation scores, expressed significantly more current distress on the General Health Questionnaire, and were more likely to amplify somatic distress and perceive themselves as medically, vocationally, and socially disabled than the women who did not report pain. They were also significantly more likely to have experienced any form of childhood sexual abuse or severe childhood sexual abuse. Eighteen of the women with pain, compared with nine of the women without pain experienced any childhood abuse ($\chi^2$=5.41, df=1, p<0.02); 12 of the women with pain, compared with one of the women without pain, experienced severe childhood sexual abuse ($\chi^2$=10.37, df=1, p<0.002). The significance of the difference between women with and without pain in the number who had experienced severe childhood sexual abuse was confirmed by Fisher's exact test (p<0.0005).

Elevated dissociation scores were positively correlated with psychological distress as measured by the General Health Questionnaire (r=0.69, df=35, p<0.001) and by Medical Outcomes Survey scales relating to perception of health (r=0.70, df=35, p<0.001), impaired social functioning (r=0.56, df=35, p<0.001), and poor mental health (r=0.77, df=35, p<0.001). There were no significant correlations between high Dissociative Experiences Scale scores and physical functioning, social/occupational role functioning, or somatic amplification.

The range of Dissociative Experiences Scale scores was 1–63 in the pain group and 1–14 in the comparison group. The median score of the comparison group (4.0) was comparable to the normal median reported for adults (4.4) (14). Women with pain, however, had a median score of 17. Twenty of the women with pain, compared with only six of the comparison group, had Dissociative Experiences Scale scores above the adult norm median of 4.4. Three of the pain patients had Dissociative Experiences Scale scores above the reported

**TABLE 2. Psychological Self-Report Test Scores of Women Who Did or Did Not Experience Severe Childhood Sexual Abuse**

[a] Lower scores are associated with less physical, social, and role function and a worse perception of physical and mental health.

median for psychiatric inpatients with posttraumatic stress disorder (PTSD) (31.3), and one had a score above the median for patients with multiple personality disorder (57.1).

We divided the entire study group of 43 women into those with (N=13) and those without (N=30) childhood histories of severe sexual abuse and compared the psychological test scores of these two groups (table 2). Women with a childhood history of severe sexual abuse had significantly higher scores on measures of psychological distress, somatization, and dissociation and viewed their physical health and functioning as more impaired.

## DISCUSSION

As demonstrated in previous studies (2–4), the women in this study who reported chronic pelvic pain had significantly more psychological distress and were more likely to amplify physical sensations than did the women who did not report such pain. The women who experienced pelvic pain perceived their health and social and vocational functioning as more impaired and were significantly more likely to have experienced severe childhood sexual abuse. As hypothesized, women with chronic pelvic pain were also significantly more likely to report more dissociative experiences than the comparison group.

Dissociative defenses may develop to help a person adapt to overwhelming painful experiences such as abuse or trauma. Dissociative mechanisms may alter perceptions (derealization, depersonalization) and allow the person to forget (psychogenic amnesia) or even completely disown the experience as occurring in another person (multiple personality) (8). However, the dissociated and repressed painful memories are not completely hidden or dormant and tend to return as nightmares, flashbacks, and floods of feelings and sensations related to the original experiences (8, 9). These sensations and feelings often can occur as vivid full memories and emotions or perhaps, more commonly, as bits and pieces of the original experience. Intense autonomic arousal may occur when a stimulus elicits a memory of abuse without an accompanying full visual or cognitive schema, or both can be experienced simultaneously (9). Social and emotional withdrawal in victims of PTSD have been hypothesized as coping mechanisms that enable the patient to avoid stimuli that evoke aversive visual and autonomic memories of trauma.

The high dissociation scores in this group of women with self-reported medically unexplained chronic pelvic pain may be the somatic representation of the severe physical and/or emotional traumatization that occurs secondary to childhood sexual and, possibly, physical abuse. Thus, the patient with chronic pelvic pain may experience the pain as a partial "memory" of the abuse without being consciously aware of the full extent of the memory (i.e., the physical, autonomic, and emotional traumatic memory of the abuse) (9). The symptom of pelvic pain is also often associated with dyspareunia and sexual avoidance (2). This may be an adaptive response that allows the patient to avoid stimulating more complete memories of painful childhood sexual victimization.

Although a dissociative coping style might be an adaptive response to early trauma, it can interfere with the proper diagnosis and treatment of women with disorders such as chronic pelvic pain. Women who have experienced early physical or sexual abuse sometimes repress it, deny it, or withhold this information from an interviewer due to fear of social consequences, thus limiting the accuracy of a diagnostic interview. Our findings suggest that the measurement of dissociation may provide a useful, indirect assessment of the possibility of previous sexual abuse in women with chronic pelvic pain.

Dissociation may also influence the patient's response to treatment. Chu and Dill (8) recently found that psychiatric inpatients with histories of childhood physical and sexual abuse had a higher level of dissociative symptoms and had experienced significantly more hospitalizations and more somatic treatments (medications and ECT) than those without such histories. These patients were usually not diagnosed as having dissociative symptoms; the treatment data suggest that this lack of accurate diagnosis may be associated with repeated hospitalizations and resistance to treatment. Although the Dissociative Experiences Scale scores in our study group were not as high as those reported in a psychiatric inpatient setting, they were surprisingly high for a group of ambulatory medical patients.

Our recent pilot study of antidepressant treatment in women with chronic pelvic pain (15) suggested that patients with histories of significant childhood sexual abuse were more likely to drop out of the study due to excessive medication side effects and to show poor response to pharmacological therapy alone than were patients without abuse histories. Women with chronic pelvic pain who have also experienced childhood sexual abuse may require multimodal treatment strategies, including behavioral and insight-oriented psychotherapies, in addition to pharmacotherapy (15).

The findings reported in this paper should be considered preliminary because of the small number of subjects, possible bias in subject selection, and the limitations noted in obtaining a valid sexual abuse history. We also used a random comparison sample rather than a matched comparison group and did not record the patients' medical diagnoses. Nevertheless, the results of this study suggest that it is important to continue to study women with chronic pelvic pain to ascertain rates of PTSD, severe dissociative disorders, and multiple personality disorder because high scores on the Dissociative Experiences Scale are not diagnostic but are associated with these disorders. A larger study group would also allow multivariate analysis to determine the factors most highly correlated with dissociative symptoms (i.e., psychological distress, severe childhood physical and/or sexual abuse, and somatization).

*Objective:* *Sleep deprivation is a rapid, nonpharmacologic antidepressant intervention that is effective for a subset of depressed patients. The objective of this study was to identify which brain structures' activity differentiates responders from nonresponders and to study how metabolism in these brain regions changes with mood.* *Method:* *Regional cerebral glucose metabolism was assessed by positron emission tomography (PET) with [$^{18}$F]deoxyglucose (FDG) before and after total sleep deprivation in 15 unmedicated awake patients with unipolar major depression and 15 normal control subjects, who did the continuous performance test during FDG uptake.* *Results:* *After sleep deprivation, four patients showed a 40% or more improvement on the Hamilton Rating Scale for Depression. Before sleep deprivation the depressed responders had a significantly higher cingulate cortex metabolic rate than the depressed nonresponders, and this normalized after sleep deprivation. The normal control subjects and nonresponding depressed patients showed no change in cingulate metabolic rate after sleep deprivation.* *Conclusions:* *Overactivation of the limbic system as assessed by PET scans may characterize a subset of depressed patients. Normalization of activity with sleep deprivation is associated with a decrease in depression.*

(Am J Psychiatry 1992; 149:538–543)

---

Sleep deprivation has been shown to have a rapid, nonpharmacologic antidepressant effect in studies involving over 1,500 patients (1–3). In normal subjects sleep deprivation is associated with diminished vigilance and decreased metabolism in the thalamus and midbrain, according to studies using positron emission tomography (PET) (4). Since normal and depressed subjects seem to have different responses to sleep deprivation (1), a different regional metabolic response to sleep deprivation might well occur in such patients, perhaps involving the cingulate and other limbic structures. The limbic system has been hypothesized to be involved in mood (5). In this report we present the results of what we believe to be the first study of sleep deprivation in depression using PET with [$^{18}$F]deoxyglucose (FDG) to assess limbic system metabolic correlates of mood and the antidepressant effects of sleep deprivation.

## METHOD

### *Subjects*

The subjects in this study were 15 normal control subjects (nine women, six men; mean age=31.9 years, SD=9.1) and 15 depressed outpatients (12 women, three men; mean age=30.5 years, SD=10.2). They were studied with FDG PET scans after a night of normal sleep and again after all-night sleep deprivation. All depressed subjects met the *DSM-III-R* criteria for unipolar major depression and had scores on the Hamilton Rating Scale for Depression of 17 or greater at the time of screening. Neither the patients nor the normal subjects had taken psychoactive medications for at least 2 weeks before the study. Ten of the patients had never taken antidepressants. The other five had previously received amitriptyline, desipramine, or alprazolam. The

The authors thank Drs. Paul Jerabek and Manuel Lagunas-Solar for production of FDG, Madeline Rose, R.N., and Cary Fox for nursing and technical support, and Martin Hetu for statistical support.

Supported in part by NIMH grant MH-42955 to Drs. Wu, Buchsbaum, Gillin, and Bunney, by the National Alliance for Research on Schizophrenia and Affective Disorder (Young Investigator Award to Dr. Wu), and the Brain Imaging Center Committee, the authors' community support group.

mean time without medication for these five patients was 4.7 months (SD=4.0). They reported that they had achieved clinical response to these medications and had relapsed when the medications were discontinued.

All subjects were free of physical disorders. The control subjects and their first-degree relatives were determined to be without mental disorders. Eight of the 15 normal control subjects in this study were reported on in our previous study of normal subjects (4). The depressed and normal control subjects were recruited through newspaper advertisements. Informed consent was obtained after the procedure was fully explained.

### *Experimental Protocol and Clinical Assessment*

The subjects were deprived of sleep and kept under continuous supervision from approximately 7:00 a.m. until after the scanning procedure the following afternoon at 1:00–5:00 p.m. Mood was measured with the 21-item Hamilton questionnaire, from which questions 4–6 were deleted because they deal with how the subject sleeps and are not applicable when the subject is deliberately deprived of sleep. The questionnaire was administered between 9:00 a.m. and noon on the baseline PET scan day (after a night of normal sleep) and on the second PET scan day (after sleep deprivation). On the basis of our previous findings (6), patients were defined as responders to sleep deprivation if their Hamilton depression scores decreased by at least 40% after total sleep deprivation. The FDG PET procedure has been described previously (7). During the uptake of FDG the subjects did the continuous performance test, a visual vigilance task (8).

### *Brain Imaging Protocol*

Approximately 45 minutes after the injection of FDG, nine slice images were obtained. The repositioning of the patients during the two studies was accurate to within 2 mm because for each patient we reused a custom-molded thermoplastic mask that was aligned with the anatomical landmarks of the lateral canthus and external auditory meatus. The scan was transformed to a glucose metabolic rate as described previously (7).

Cortical metabolic rates were measured by using our cortical peel technique (4). Subcortical structures were assessed by using stereotaxic coordinates derived from a standard neuroanatomical atlas (9), as we have previously described (7). We analyzed the absolute metabolic rate, which was expressed in micromoles of glucose per 100 g of tissue per minute.

The brain was divided into eight main systems: lateral cortex (average of frontal, temporal, parietal, and occipital lobes), medial cortex (precuneus, paracentral, medial frontal, rectal gyri, calcarine, and medial temporal), limbic system (average of amygdala, hippocampus, and cingulate), basal ganglia (average of caudate, putamen, and globus pallidus), thalamus, white matter (average of frontal white matter, corpus callosum, and optic radiation), midbrain, and cerebellum.

Statistical analysis comprised a four-way repeated measures multivariate analysis of variance (MANOVA) with BMDP 4V software (10), followed by post hoc t tests. The dimensions of the MANOVA were diagnostic group, brain system, hemisphere, and sleep condition. All significant interactions between group and sleep condition are reported. When significant interactions between brain regions and conditions were observed, we used simple effects analysis and t tests as post hoc contrasts.

## RESULTS

### *Clinical Response*

Of the 15 depressed patients, four were identified as responders (decrease in Hamilton depression score ≥40%). The responders and nonresponders did not differ significantly in mean age (responders: mean=29.8 years, SD=10.3; nonresponders: mean=30.8 years, SD=10.6), sex distribution (responders: four women; nonresponders: eight women and three men), or mean baseline Hamilton depression score (responders: mean=19.8, SD=5.9; nonresponders: mean=21.3, SD=7.3). The responders showed a significantly greater decrease in depression score; their mean Hamilton score after sleep deprivation was 6.0 (SD=2.1), compared to 19.9 (SD=9.4) for the nonresponders.

### *Changes in Regional Metabolic Rates*

At baseline the responders differed significantly from the nonresponders in their metabolic rate pattern (see table 1). Simple effects analysis and follow-up t tests revealed that the baseline glucose metabolic rate in the limbic system was significantly higher in the depressed responders than in either the depressed nonresponders or the normal control subjects (see table 1). Similar analyses indicated that the depressed responders had a significantly higher metabolic rate in the medial cortex than did the normal control subjects. No differences in whole brain metabolic rate were found, i.e., the main effect of subject group was not significant.

There was a significant difference in the patterns of change in absolute brain system metabolic rates after sleep deprivation among the responders, nonresponders, and normal control subjects (see table 1). The responders experienced a significant decrease in their initially high metabolic rate in the limbic system after sleep deprivation, whereas neither the normal control subjects nor the nonresponders showed a significant change as indicated by ANOVA. Again, no main effect across all structures was confirmed, indicating regional specificity for the effect.

The rates in the cingulate, amygdala, and hippocampus were measured to obtain the limbic system average (see figures 1 and 2). At baseline the depressed responders had significantly higher cingulate and amygdala glucose metabolic rates than either the nonresponders or

[j] Significantly lower than at baseline (t=4.01, df=14, p<0.05).

the normal control subjects. In contrast, the glucose metabolic rates in the hippocampus did not significantly differ between the responders and either the nonresponders or the normal control subjects. The glucose metabolic rate in the cingulate decreased significantly after sleep deprivation for the responders, whereas the nonresponders and normal control subjects showed little change. The amygdala did not show a statistically significant decrease in the responders. These findings were confirmed by a three-way ANOVA interaction (Diagnostic Group by Brain System by Sleep Condition: F=2.74, df=3.69, 48.02, p<0.05, Greenhouse-Geisser corrected) and exploratory post hoc t tests.

After sleep deprivation all of the responders showed a decrease in the cingulate of at least 2.0 μmol glucose/100 g tissue per minute. Of the 11 nonresponders, four showed similar decreases, two showed increases, and five showed no change.

Vigilance was assessed quantitatively by using the d′ measure (4). Greater vigilance is associated with a higher d′ value. Before sleep deprivation the mean d′ vigilance score on the continuous performance test was higher for the depressed responders than for either the depressed nonresponders or the normal control subjects (see table 1). All three groups had lower d′ values after sleep deprivation, and the change was significant for all three groups according to paired t tests, but the differences did not vary between groups.

Significant negative correlations between change in vigilance score and baseline metabolic values in the limbic system, thalamus, and cerebellum were found for the depressed responders (see table 1). A significant positive correlation was found between the baseline thalamus metabolic value and change in d′ score for the depressed nonresponders.

Hypofrontality values were calculated by taking the

[a] All images are displayed with the same metabolic rate scale, shown as a bar at the bottom. Note the high cingulate activity (A) in the responders before sleep deprivation and the normalization of cingulate activity (B) after sleep deprivation.

metabolic rates for the four frontal lobe segments in each hemisphere (superior, middle, inferior frontal gyri, and precentral gyrus) and dividing these by the occipital lobe metabolic rate. No significant group differences were found between the depressed responders and either the depressed nonresponders or normal control subjects according to ANOVAs or t tests.

## DISCUSSION

The baseline metabolic rates for the cingulate cortex and amygdala were significantly higher in the depressed patients who responded to sleep deprivation than in the patients who did not respond or the normal control subjects. The metabolic rate for the cingulate fell significantly toward normal in the depressed responders after sleep deprivation, while that for the amygdala decreased nonsignificantly. These findings should be viewed as preliminary because of the relatively small number of responders and should be replicated in a larger cohort of depressed patients.

On the basis of our findings, we tentatively hypothesize that overactivation in the limbic system as measured by FDG PET scans is present in a subset of depressed patients before sleep deprivation. We suggest that in this subset sleep deprivation reduces depression by reducing the overactivity in these regions. These interpretations are consistent with earlier suggestions (11, 12) that some depressed patients are "overaroused" and that sleep deprivation acts by reversing this abnormality.

A subset of depressed patients have subnormal slow wave sleep (13, 14), and it may be this subset who respond best to sleep deprivation (15). Slow wave sleep has been hypothesized (16, 17) to slow down metabolic activity as a way of dissipating the heat load incurred during awake time. An impaired ability to activate slow wave sleep in a subset of depressed patients could result in an inability to slow down metabolism. Depressed patients have been shown to have abnormally high core body temperatures during the sleep period (18–20), and this finding is especially true in the subtype of patients who respond to sleep deprivation (21). Wehr (22) has hypothesized that prolonged awake time might reduce body metabolism. Prolonged awake time (i.e., sleep deprivation) might act like slow wave sleep to reduce body metabolism, whereas REM sleep may maintain high body temperature.

In addition to subnormal slow wave sleep and higher than normal nocturnal temperature, high levels of thyroid hormones differentiate the subset of depressed patients who respond to sleep deprivation (23). Higher than normal levels of thyroid hormones may be a neuroendocrine correlate of overarousal in this subset of depression.

We also observed higher baseline vigilance scores (as measured by the d′ on the continuous performance test) in the depressed responders than in either the nonresponders or the normal control subjects. This observation is consistent with the theory of overarousal in depression, since vigilance is associated with arousal (11, 12). In a study of sleep deprivation in 16 depressed patients by Bouhuys et al. (24), self-reported arousal was correlated with mood response. The cingulate cortex has been implicated in maintenance of vigilance (25), which is also associated with arousal (26).

In a previous study (7), the cingulate gyrus was the only cortical structure with a significantly higher glucose metabolic rate during REM sleep than during the normal waking state. REM sleep is associated with an increase in cholinergic activity and a decrease in aminergic activity (27). Short REM latency in depressed patients may also be an indicator of hyperarousal. Further studies are needed to determine the causal chain of events.

The cingulate cortex is innervated by cholinergic input from cells in the basal forebrain (28, 29). Depressed patients have been hypothesized to have an overactive cholinergic system (30), in part because of a supersensitive responsiveness to the cholinergic REM induction test (31, 32). An overactive cingulate cortex might also be associated with an underactive aminergic system, which has also been hypothesized for depression (30). Depressed patients treated with sertraline, a serotonergic reuptake inhibitor, were found to have significantly decreased cingulate cortex metabolism, as assessed by PET scans (J.C. Wu, unpublished data). Enhancement of serotonergic function by lithium has been shown to prevent relapse with recovered sleep after total sleep deprivation (33) or after partial sleep deprivation (34). Decreasing serotonergic function through tryptophan depletion has been found to precipitate a depressogenic relapse in patients who have responded to antidepressants (35).

The large decrease seen in the cingulate cortex of the depressed responders after sleep deprivation was seen in only a few of the nonresponders and normal control subjects. In our previous study of normal subjects (4), in which eight of the 15 normal control subjects in this study were also studied, the limbic system did not show a significant decrease in glucose metabolic rate after sleep deprivation. Our present analysis with the larger cohort of normal control subjects also shows no significant decrease in the cingulate cortex rate for normal subjects. The limbic system was the only one of eight brain systems (including the dorsolateral cortex, medial cortex, basal ganglia, thalamus, midbrain, white matter, cerebellum) that showed a significant difference between depressed responders and both the normal subjects and depressed nonresponders.

The method used to study the regions of interest relies on stereotaxic coordinates based on a neuroanatomical atlas (9). Using the Talairach atlas (36), we estimated the volume of the hippocampus to be 3000 mm$^2$. The approximate dimensions of the hippocampus are 12 mm thick by 25 mm long by 10 mm wide. The dimensions of the hippocampus can easily accommodate our stereotaxic boxes, which are 10 mm thick by 6 mm long by 6 mm wide. The approximate dimensions of the amygdala are 8 mm thick by 12 mm long by 10 mm wide, for a total volume of approximately 960 mm$^2$. Although it is smaller, this structure can also accommodate our 10 mm by 6 mm by 6 mm stereotaxic box. Talairach et al. (36) and Vanier et al. (37) have demonstrated that a proportional system for localizing structures in the brain is much more reliable than using distances from bony landmarks in millimeters. This is because a proportional-based system normalizes the brains of different individuals and permits individual cases to be reduced to a common scale. Random variation caused by individual differences in brain proportions, vertical position of the plane studied, and variation in head position and reposition would all tend to create random error and diminish group differences.

The higher right precentral gyrus metabolic rate in the depressed responders than in the depressed nonresponders is consistent with the hyperfrontality in depressed unipolar patients previously reported by our group (38), but it is not consistent with the hypofrontality reported by Baxter et al. (39). This may be due to the differences in the cognitive task studied during the glucose-uptake period.

This study has some important clinical implications. It may be possible to better characterize subtypes of depression with different responses to treatment by using an objective biological measure (e.g., PET scans) as a basis for classification. This study provides evidence for a distinct subtype of depression with overactive limbic system metabolism that responds to sleep deprivation.

## ADDENDUM

Since this manuscript was submitted, similar findings were presented by D. Ebert, H. Feistel, and A. Barocka at the 5th World Congress of the World Federation of Societies of Biological Psychiatry, Florence, Italy, June 9–14, 1991. Using technetium $^{99m}$Tc HMPAO SPECT, they showed that responders to sleep deprivation, but not nonresponders, were more hyperperfused in the limbic system than normal control subjects.

# Undetected HIV Infection Among Acutely Ill Psychiatric Inpatients

Michael Sacks, M.D., Helen Dermatis, Ph.D., Salome Looser-Ott, M.A.,
William Burton, M.A., and Samuel Perry, M.D.

*Serological testing of waste bloods revealed that 25 (7%) of 350 acutely ill psychiatric inpatients had HIV infection. Eight of the 10 HIV-positive patients whose serological status was not recorded on admission were discharged with their status still unrecorded and presumably undetected. Thirty-nine (51%) of the 77 inpatients with HIV-related risk behaviors identified on admission were discharged with no record of their having been serologically tested before or during hospitalization.*

(Am J Psychiatry 1992; 149:544–545)

With the established efficacy of early medical interventions for patients with HIV infection (1), serological testing has been encouraged for those at risk (2); however, current estimates are that most at-risk individuals have not yet been tested (3). HIV testing may be especially important for at-risk individuals admitted to a psychiatric hospital because their mental changes may be caused or worsened by the direct effects of HIV on the brain (4). Further, we have found high rates of HIV risk behaviors (18%–22%) among acutely ill psychiatric inpatients (5, 6).

Despite the medical and diagnostic indications for voluntary HIV testing, psychiatric inpatients may be too disturbed or distrustful either to reveal risk factors or to provide informed consent for HIV testing. Understandable concerns about disclosure in the medical record and to third-party payers may be an additional reason for refusal, and HIV testing may be inadvisable during an acute psychiatric illness. Because of these inherent problems, many HIV-positive psychiatric inpatients may go undetected during hospitalization.

To examine this possibility, we determined the actual number of HIV-positive inpatients in our facility and then reviewed medical records to examine how many HIV-positive inpatients were discharged with their serological status unrecorded and presumably undetected.

## METHOD

After institutional review board approval, a seroprevalence study was conducted on all psychiatric inpatients between 18 and 55 years old who were admitted to an acute inpatient facility in Manhattan from November 1989 through May 1990. The waste residue of each patient's admission blood chemistry work was serologically tested for HIV. We reviewed each patient's admission history to estimate known HIV-related risk behaviors such as males having sex with males and parenteral drug use as well as factors of lower risk, such as having five or more heterosexual partners in 1 year and/or being the heterosexual partner of a person known or suspected to be HIV positive. Also recorded were the patient's sex, age, race, social class, ethnicity, and whether his or her HIV status was positive, negative, or unknown. This chart information was connected to the waste blood and assigned a random number. All other data were destroyed, including the patient's name and chart number. This "unlinking" helped protect patients' anonymity. The charts,

including laboratory results and discharge summaries, of all patients admitted during the study period, were reviewed by a research assistant 6 months later to determine whether the patient was known to be HIV positive or HIV negative at discharge. The reviewer was blind to data from both the admission chart review and the seroprevalence survey.

## RESULTS

Of the 383 patients admitted during the study period, sufficient waste bloods were available for 350 (91%). Twenty-five (7%) of these patients were HIV positive. Ten of the 25 patients were not recorded as being HIV positive on admission. Two of these 10 patients were serologically tested during hospitalization. Thus, the great majority of HIV-positive inpatients whose serological status was unrecorded on admission left the hospital with their seropositivity still unrecorded.

An attempt was made to identify variables associated with detection. As shown in table 1, on admission only three of the 25 patients who were HIV positive had no recorded risk factors according to their charts, and recorded seropositivity was positively associated with males having sex with males. No relationship was found between recorded seropositivity at admission and gender, race, age, ethnicity, or social class; however, because of the small number of HIV-positive patients, the risk of an erroneous negative finding (type II error) is high.

We examined how many inpatients with HIV-related risk factors were serologically tested before or during hospitalization. On admission, risk factors were recorded for 77 (22%) of the 350 inpatients (32 males having sex with males, 32 parenteral drug use, and 13 other). Reports of previous testing indicated that 15 of these 77 patients were HIV positive and that three were HIV negative. Of the remaining 59 patients with recorded risk factors, the HIV antibody status of 20 was determined during hospitalization (two were HIV positive, and 18 were HIV negative). Thus, of 77 inpatients with recorded risk factors, 39 (51%) left the hospital with their serological status still unrecorded (five who were HIV positive and 34 who were HIV negative).

## DISCUSSION

Three major findings emerged from this study. First, psychiatric hospitalization was not associated with detection of HIV positivity. Of the 10 HIV-positive inpatients whose serological status was not known on admission, eight were not serologically tested during hospitalization and were discharged with their HIV infection still unrecorded and presumably undetected.

Second and related to the first finding, serological testing was not vigorously pursued during hospitalization. Among the 59 previously untested inpatients with HIV-related risk factors identified on admission, the HIV antibody status of only 20 (34%) was determined during their hospital stay.

**TABLE 1. HIV-Related Risk Factors Among HIV-Positive Inpatients Whose Serological Status Was or Was Not Recorded**

| Risk Factor | Patients With Recorded HIV Infection (N=15) | Patients With Unrecorded HIV Infection (N=10) |
|---|---|---|
| Males having sex with males[a] | 10 | 2 |
| Parenteral drug use | 3 | 2 |
| Males having sex with males and parenteral drug use | 1 | 0 |
| Other | 1 | 3 |
| None documented | 0 | 3 |

[a] $\chi^2=4.86$, df=1, $p<0.05$.

Third and more encouraging, severe mental illness did not generally preclude determining risk factors and HIV infection. Among the 25 HIV-positive patients, a history of risk factors was recorded on admission for 22, and 15 knew that they were HIV positive.

The study was limited to a single hospital in an area of the Northeast where the prevalence of HIV seropositivity is high and may not reflect the experience in other hospitals, particularly those in a low seroprevalence area. It could be argued that both physicians and subjects in a high seroprevalence area are more sensitive to the need for HIV testing than their counterparts in hospitals in lower seroprevalence areas. It could equally be argued that this awareness, together with concerns for confidentiality, greater experience, and availability of other test sites, might result in a decision not to test for HIV in the hospital setting.

Given the medical and diagnostic indications for determining HIV serological status in at-risk psychiatric inpatients, these findings suggest that further studies be conducted to identify factors impeding HIV testing of this population.

# Agitation and Postdexamethasone Cortisol Levels in Alzheimer's Disease

Brian A. Lawlor, M.D., Gabriel Tsuboyama, M.D., Theresa Ryan, B.S.,
Richard C. Mohs, Ph.D., Bonnie M. Davis, M.D., Michael Davidson, M.D.,
Steven Gabriel, Ph.D., and Kenneth L. Davis, M.D.

*The clinical correlates of hypothalamic-pituitary-adrenal (HPA) functioning were examined in 29 patients with probable Alzheimer's disease. The 8:00 a.m. postdexamethasone cortisol levels of these patients were highly correlated with higher agitation scores but not with the degree of depressed mood or memory impairment. The possible neural basis for the association between hypercortisolism and behavioral disturbance in Alzheimer's disease warrants further exploration and replication.*

(Am J Psychiatry 1992; 149:546–548)

Up to 50% of patients with Alzheimer's disease demonstrate nonsuppression of cortisol following dexamethasone administration (1–5), and mild elevations of basal cortisol have also been described (4, 6). However, the clinical significance and underlying pathogenetic mechanism of hypercortisolism in Alzheimer's disease are poorly understood. Greater hypothalamic-pituitary-adrenal (HPA) axis activity may reflect changes in cortical or subcortical function intrinsic to the Alzheimer's disease process, may be a nonspecific result of neuronal degeneration, or could be the end result of behavioral complications associated with the disease process.

This study explored the relationship between indexes of HPA axis function (basal cortisol and postdexamethasone cortisol levels) and specific aspects of behavior and cognition in 29 carefully characterized patients with Alzheimer's disease.

## METHOD

### *Subjects*

Twenty-nine patients with a mean age of 67.24 years (SD=7.53) (20 men and nine women) who met the National Institute of Neurological and Communicative Disorders and Stroke–Alzheimer's Disease and Related Disorders (NINCDS-ADRDA) criteria for probable Alzheimer's disease (7) participated in this study. All subjects were inpatients, were physically healthy, and were free of medications that could affect HPA axis functioning for at least 3 weeks before testing. Informed consent was obtained from all patients and/or their next of kin.

### *Rating Scales*

Cognitive and noncognitive function in the patients with Alzheimer's disease was evaluated by using the 21-item version of the Alzheimer's Disease Assessment Scale (8, 9). Agitation was defined as the sum of the items "uncooperative," "pacing," "increased motor activity," and "tremors" on this scale. Depression was defined as the sum of the items "tearful" and "depressed mood." Psychosis was defined as the sum of the items "hallucinations" and "delusions." These items are all scored from 0 (not present) to 5 (very severe). The memory impairment score was the sum of errors on items "word recall" (scored 0–10) and "word recognition" (scored 0–12); a higher score indicates more severe impairment. The severity of dementia in the 29 patients was assessed by using the Blessed Dementia Scale (10), a 33-point scale on which higher scores indicate greater impairment, and the Memory and Information Test (10), a 20-point scale on which lower scores indicate greater impairment. The mean score of the 29 patients on the Blessed Dementia Scale was 20.07 (SD=7.91); their mean score on the Memory and Information Test was 5.83 (SD=5.00).

### *Procedure*

Blood for determining basal cortisol levels was drawn from all patients at 12:00 noon, 4:00 p.m., 8:00 p.m., and 11:00 p.m., and the mean of these four samples was

**TABLE 1. Pairwise and Multiple Correlations of Alzheimer's Disease Assessment Scale Variables and Indexes of HPA Axis Function in 25 Patients With Alzheimer's Disease**

| | Pairwise Correlation (r) | | | | | |
|---|---|---|---|---|---|---|
| | | Mean Postdexamethasone Cortisol | | | | |
| Measure From Alzheimer's Disease Assessment Scale | Mean Basal Cortisol | 8:00 a.m. | 12:00 noon | 4:00 p.m. | 11:00 p.m. | Multiple Correlation (R) |
| Agitation | –0.00 | 0.65[a] | 0.42[b] | 0.28 | 0.54[a] | 0.69[c] |
| Memory impairment | 0.30 | 0.04 | 0.23 | 0.34 | 0.13 | 0.47 |
| Depression | 0.01 | –0.05 | 0.21 | 0.06 | –0.06 | 0.41 |

[a] $p<0.01$.
[b] $p<0.05$.
[c] $p=0.02$.

calculated as the basal cortisol level. The dexamethasone suppression test (DST) was performed in the standard manner. Cortisol levels were determined at 8:00 a.m., 12:00 noon, 4:00 p.m., and 11:00 p.m. following the administration of 1 mg of oral dexamethasone at 11:00 p.m. the night before. Samples were centrifuged within 15 minutes and were stored at –20 °C until assayed. Plasma cortisol was assayed by using a radioimmunoassay with kits obtained from ICN/Micromedic Pharmaceuticals of Carson, Calif. The intra-assay and interassay coefficients of variation were 6% and 10%, respectively.

### *Data Analysis*

The data were analyzed by using multiple regression analyses. Agitation, depression, and memory impairment scores on the Alzheimer's Disease Assessment Scale were the dependent variables, and mean basal cortisol and four postdexamethasone cortisol levels were the independent variables. Because baseline cortisol levels were not available for four of the patients, the overall analysis included 25 patients. Multiple regression analyses were also used to determine whether there was a significant association of any of the dependent variables with age, gender, relative weight, duration of illness, and age at onset. For this part of the analysis, data were available for 27 patients.

## RESULTS

Table 1 presents pairwise correlations of the five independent variables with the three dependent variables as well as the multiple correlation coefficients. For the dependent variable agitation, the overall multiple correlation was significant (F=3.45, df=5, 19, p=0.02). Of the five predictors, the largest beta (1.13) (t=2.5, p=0.02) was for the 8:00 a.m. postdexamethasone cortisol level. For the other dependent variables (memory impairment and depression), neither of the multiple correlations was significant (p>0.10 in both cases).

None of the multiple correlations of the dependent variables with the covariates—age at onset, illness duration, gender, relative weight, and age—was significant (p>0.10 for all analyses).

## DISCUSSION

The major finding in this study is that postdexamethasone cortisol levels are associated with greater agitation in patients with Alzheimer's disease. The relationship between hypercortisolism and agitation is similar to the reported findings in depressed patients, where nonsuppression on the DST is also associated with agitation (11, 12). A previous study from our center (4) found a correlation between the 8:00 a.m. postdexamethasone cortisol level and the number of major but not minor symptoms of depression. In that study, major symptoms were those usually associated with endogenous depression, including agitation, psychomotor retardation, and loss of interest, symptoms that are reflected in behaviors similar to those identified by the agitation score on the Alzheimer's Disease Assessment Scale. Thus, it appears that postdexamethasone hypercortisolism may be associated with agitated behavior rather than with depressed mood per se.

If HPA axis abnormalities in Alzheimer's disease are consistently associated with a particular behavioral complication such as agitation, these indexes may be a useful marker to monitor response to pharmacological or other therapeutic interventions in this population. However, all reports of associations or lack thereof between symptoms and HPA axis measures must be interpreted in the light of the range of behavior in the patients studied. Until now, almost all studies exploring HPA axis function in Alzheimer's disease have used only patients without substantial behavioral disturbance. A relationship between postdexamethasone cortisol level and agitation in our relatively nonbehaviorally disturbed group of patients with Alzheimer's disease suggests that future studies need to explore HPA axis abnormalities in patients with Alzheimer's disease with a broader range of behavioral disturbances.

# Frontal, Temporal, and Striatal Proton Relaxation Times in Schizophrenic Patients and Normal Comparison Subjects

**Peter Williamson, M.D., David Pelz, M.D., Harold Merskey, D.M., Sandra Morrison, Ph.D., Stephen Karlik, Ph.D., Dick Drost, Ph.D., Thomas Carr, M.D., and Patrick Conlon, M.D.**

*Spin-lattice ($T_1$) and spin-spin ($T_2$) magnetic resonance relaxation times were examined in frontal, temporal, and striatal regions of 24 patients with schizophrenia and 10 normal comparison subjects. The schizophrenic patients had more prolonged $T_2$ values than did the comparison subjects, particularly in the left temporal cortex and white matter, suggesting tissue pathology.*

(Am J Psychiatry 1992; 149:549–551)

Spin-lattice ($T_1$) and spin-spin ($T_2$) magnetic resonance relaxation times have been regarded as superior to CT scan Hounsfield numbers in characterizing tissue abnormalities (1). Detectable abnormalities, determined by relaxation time measurements, can also be present even with normal results on gross examination of the magnetic resonance imaging (MRI) scan (2). However, studies in schizophrenic patients have generally measured only $T_1$ values and have shown inconsistent results (3). Part of these differences may be related to the precision of the $T_1$ measure. We have previously found prolonged $T_2$ relaxation times in the left dorsolateral cortex in association with negative symptoms in schizophrenic patients (4). $T_2$ values in this study showed much less variability and may have been more sensitive to pathological change.

The purpose of the present investigation was to examine both $T_1$ and $T_2$ relaxation times in schizophrenic patients and in normal subjects. Because evidence from a number of sources has implicated involvement of the frontal lobes, basal ganglia, and temporal lobes in schizophrenia (5), we hypothesized that $T_2$ relaxation times would be prolonged in these regions.

## METHOD

### *Subjects*

Twenty-four schizophrenic patients (22 men and two women) between the ages of 25 and 53 (mean=36.8, SD=7.1) volunteered to participate in the study. All were outpatients receiving depot neuroleptic medications; their mean chlorpromazine-equivalent dose was 631.3 mg/day (SD=502.7). The diagnosis of schizophrenia was confirmed by a psychiatrist (P.W.) using the Structured Clinical Interview for DSM-III-R (6). An average of 14.0 years (SD=5.7) had elapsed since the onset of symptoms in this group. All but one patient reported that they wrote and threw a ball with their right hand. None of the patients was found to have a history of head injury, drug or alcohol abuse, or serious medical illness. One patient reported a history of three seizures before the age of 8. He was not treated with anticonvulsants. None of the patients was taking medication other than the neuroleptic plus, in some patients, antiparkinsonian medication.

Ten normal subjects (nine men and one woman) between the ages of 21 and 47 (mean=32.0, SD=8.5) also volunteered to participate in the study. Each was interviewed by a psychiatrist (P.W.) using the Structured Clinical Interview for normal subjects (6). All but one subject reported that they wrote and threw a ball with their right hand. None had a history of psychiatric illness, head injury, drug or alcohol abuse, or serious medical illness. None of these subjects was taking medication of any type. Informed consent was obtained from all subjects in both groups.

### *MRI*

MRI scans were performed with a GE 1.5-T Signa system. A TR 400 TE20 "scout" sagittal image was used to set up the 13-slice, 5-mm thick, 5-mm gap coronal spin echo acquisitions: the first a TR600 TE20 and the second a TR2000 TE20, 40, 60, and 80. The field of view was 20 cm; the matrix was 256 by 128; there were two excitations for each of the 128 phase-encoded steps. One technician performed all of the scans. This technician placed 3-mm by 3-mm regions of interest to obtain the average $T_1$ and $T_2$ for the dorsolateral prefrontal cortex, middle frontal lobe white matter, temporal cortex, medial temporal lobe white matter, and lenticular

[a] Significant difference between schizophrenic patients and normal subjects in left $T_1$ (U=181, p=0.02) and $T_2$ (U=214, p=0.0004); the difference for $T_2$ remained significant after adjustment for multiple comparisons.

[b] Significant difference between schizophrenic patients and normal subjects in left $T_1$ (U=175, p=0.04) and $T_2$ (U=200, p=0.003); the difference for $T_2$ remained significant after adjustment for multiple comparisons.

[c] Significant difference between schizophrenic patients and normal subjects in left $T_1$ (U=167, p=0.08) and $T_2$ (U=217.5, p=0.0003); the difference for $T_2$ remained significant after adjustment for multiple comparisons.

[d] Significant difference between schizophrenic patients and normal subjects in left $T_2$ (U=181.5, p=0.02). Significant difference between schizophrenic patients and normal subjects in right $T_2$ (U=176.5, p=0.03).

[e] Significant difference between schizophrenic patients and normal subjects in left $T_1$ (U=183, p=0.02) and $T_2$ (U=204.5, p=0.001); the difference for $T_2$ remained significant after adjustment for multiple comparisons.

nuclei on both sides, as in our previous study (4). A region of interest in the hippocampus posterior and medial to the amygdala was also selected on both sides for this study. To check the technician's consistency in positioning the regions of interest, the $T_1$ and $T_2$ analyses were repeated on the same images and resulted in mean differences of 4.0% in $T_1$ and 1.2% in $T_2$. To test the long-term $T_2$ precision of the system, a uniform phantom head inside a coil loader was imaged with the same $T_2$ protocol that was used for the test subjects each month. The $T_2$ measures with a region of interest enclosing most of the phantom head varied from 170 to 154 (SD=6); there was no long-term drift in values.

Ventricular size was rated by visual examination of the images by a radiologist (D.P.) who was unaware of relevant data in the study, apart from group assignment. Ventricular size was rated on a 3-point scale on which 0 indicated normal size and 2 indicated the largest ventricles of the group. Similar techniques have been shown to provide reliable estimates of ventricular size in a previous study (7).

### *Analysis*

A conservative approach was taken to analysis in view of the number of comparisons involved. Differences between groups were assessed with the Mann-Whitney U test because a normal distribution was not assumed. Probability values are for two-tailed tests. Assuming that alpha=0.05, a significant difference with 12 related comparisons would require a probability of less than 0.004 (Bonferroni procedure).

## RESULTS

Gross examination of the MRI scans was generally unremarkable and has been described in detail in our previous report on MRI scans in schizophrenic patients (4). Eleven of the 24 schizophrenic patients had a ventricular size rating of 1 or 2. No significant abnormalities were found in the normal subjects, apart from a finding in one subject of greater signal intensity in $T_2$-weighted images in the right temporal lobe, thought to be not clinically significant. The ventricular size ratings in the comparison group were all normal with the exception of one patient who had a rating of 1.

Table 1 shows the differences in $T_1$ and $T_2$ between normal subjects and patients. Higher values of $T_2$ are evident in the schizophrenic patients, particularly in the left frontal white matter, left temporal cortex and white matter, and left lenticular nucleus. There are fewer differences on the right side or in frontal cortical regions. A single $T_2$ measurement in the right frontal cortex in a normal comparison subject was not included in the mean in this table because the original image data were accidentally erased. The left frontal white matter, left temporal cortex, left temporal white matter, and left lenticular differences remained significantly different from those of the schizophrenic patients at p=0.004, allowing for multiple comparisons. There was no difference in $T_2$ values between schizophrenic patients with and without ventricular enlargement at any location demonstrating a difference from normal subjects.

Higher $T_1$ values were found in schizophrenic patients than in normal subjects in the left frontal white matter, left temporal cortex, left temporal white matter, and left lenticular nucleus (table 1). However, the standard deviations for these values were generally much higher than those found with $T_2$ values. None of these values was significant after allowing for multiple comparisons, although they may well represent a weak but meaningful trend in the same direction as the more definite $T_2$ findings.

## DISCUSSION

This study demonstrates longer $T_2$ relaxation times, particularly in left temporal regions, in schizophrenic patients than in normal subjects. We are aware of only preliminary data (8) on six patients reporting a similar difference in $T_2$ values in the left temporal white matter. It is intriguing that these areas correspond to those found to be smaller in volume by an earlier study (9). The finding of prolonged relaxation times suggests that tissue differences as well as volumetric differences occur in this region in schizophrenic patients. The $T_2$ differences found in the left frontal white matter and lenticular nucleus of schizophrenic patients compared with normal subjects are in keeping with those from many other imaging techniques (5). Although there were no differences between patients and normal subjects in the frontal cortex, the elevated $T_2$ values seen with negative symptoms in patients in our earlier study (4) were much higher than the means of the normal subjects in this study.

$T_1$ and $T_2$ relaxation times depend on protons in macromolecules, mobile fatty acids, and bound and free water, along with the exchange rates among these compartments (10, 11). Various pathological processes influence these measures directly and therefore alter $T_1$ and $T_2$, but changes in $T_1$ and $T_2$ are not specific to any particular pathological condition (10). Recent in vitro findings (12, 13) suggest that changes in $T_1$ and $T_2$ are not caused by changes in the water compartments but by changes in the cell structure. One possibility is that changes in cell membranes alter $T_1$ and $T_2$ values (13, 14). This would be in keeping with membrane changes reported in schizophrenia with magnetic resonance spectroscopy (15, 16).

A number of limitations must be acknowledged in this study. Lack of field homogeneity, from slice to slice and within a slice, was a problem that was minimized by placing regions of interest at the same location in the same slice. Therefore, $T_2$ values tended to be similar in comparable regions with relatively low standard deviations between subjects. Repeated analysis in one subject demonstrated a high degree of reliability. Partial volume effects were minimized with small regions of interest and consistent image slice location from the "scout" image. There were also no differences in $T_2$ between patients with and without ventricular enlargement. Medication effects cannot be completely ruled out but seem unlikely because differences were not seen in many frontal and right-sided locations.

CLINICAL AND RESEARCH REPORTS

# Past Substance Abuse and Clinical Course of Schizophrenia

Sidney Zisook, M.D., Robert Heaton, Ph.D., John Moranville, M.D.,
Julie Kuck, M.A., Terry Jernigan, Ph.D., and David Braff, M.D.

*To evaluate the effects of previous alcohol and drug use on the course and symptoms of schizophrenia, the authors compared 34 patients with schizophrenia who had histories of substance abuse with 17 patients with schizophrenia who were lifelong abstainers. Surprisingly, they did not find that individuals with past histories of abuse were more impaired or had more symptoms.*

(Am J Psychiatry 1992; 149:552–553)

Although the frequent co-occurrence of schizophrenia and substance abuse is well established (1), the net effect of substance abuse on the long-term course of schizophrenia has not been determined (2). Most studies have concentrated on the acute effects of substance use and have found that patients with schizophrenia who met criteria for current substance abuse had more symptoms, were more impaired, and were more treatment resistant than patients who did not abuse substances (3–5). However, some investigators have noted potential benefits of specific substances, such as amphetamines improving negative symptoms (6) and cocaine enhancing attention (5).

To investigate a group of patients with "pure" schizophrenia, we designed a study with restrictive entrance criteria that excluded patients if they had *ever* abused alcohol or psychoactive street drugs. Unfortunately, patient enrollment was severely limited because so many of the schizophrenic patients available to us had either past or present histories of substance abuse. It became clear that the results of the study might be compromised by the small number of patients in the study as well as the lack of generalizability to all patients with schizophrenia, many of whom use and abuse various drugs (1). Therefore, we initiated the current study to compare the clinical characteristics of subgroups of schizophrenic outpatients with and without past histories of substance abuse.

## METHOD

Informed consent was obtained from 65 subjects who met *DSM-III-R* criteria for schizophrenia, were medically stable, and did not meet criteria for any other axis I diagnosis (including alcohol or other substance abuse within 6 months of study entry). A detailed history of the frequency and quantity of all psychoactive and illegal substances was obtained from subjects and corroborated by chart review, medical records, and interviews with relatives whenever possible.

Since *DSM-III-R* criteria for substance abuse are based largely on psychosocial impairment, they are difficult to apply to schizophrenic patients. Consequently, we developed our own operational criteria for substance use. To be classified as an "abstainer," a patient had to meet the following criteria: 1) never consumed more than five alcoholic drinks on any one occasion, 2) never consumed alcohol on more than 3 consecutive days, and 3) never experimented with marijuana or other substances of abuse. Of the 65 patients who entered the study, 17 (26%) were classified as "abstainers." The 34 (52%) who were classified as "past substance abusers" met at least one of the following criteria 6 or more months before the intake assessment: 1) drank more than five alcoholic beverages per day at least 5 days a week over any 6-month period of time, 2) smoked more than one marijuana cigarette per day at least 5 days a week over any 6-month period of time, 3) reported more than 30 occasions of illegal drug use other than marijuana over their life span. The remaining 14 (22%) patients had histories of substance use but did not meet criteria for abstinence or past abuse.

## RESULTS

The most commonly used substance was marijuana, followed by alcohol; use of amphetamines and hallu-

cinogens was considerably less common. The majority of patients had used more than one substance. Only seven (41%) of the 17 abstainers were men, compared with 26 (77%) of the 34 past substance abusers ($\chi^2$= 6.18, df=1, $p<0.01$). The abstainers and past abusers were similar in mean age (28.8 years [SD=7.9] versus 30.3 years [SD=7.7], respectively) and amount of education (13.8 years [SD=1.7] versus 12.9 years [SD=1.7]). However, the abstainers were significantly younger at the time of their first psychiatric contact (17.8 years [SD=4.8] versus 21.3 years [SD=5.5], t=2.33, df=36, $p<0.05$). The two groups did not differ in mean number or length of hospitalizations or medication doses; nor did they differ on the percentages of individuals who were married, living alone, receiving disability, or working. Although there were no significant differences between the groups on total Brief Psychiatric Rating Scale (BPRS) (7) scores or on the three-item BPRS depression cluster, there was a trend for the abstainers to have higher scores on the BPRS thought disorder cluster (8.7 [SD=4.3] versus 6.4 [SD=3.6], t=1.87, df=28, p= 0.07). Total global scores on the Scale for the Assessment of Positive Symptoms (8) were also higher in the abstinent group (8.2 [SD=2.8] versus 5.6 [SD=4.7], t= 2.43, df=47, $p<0.05$), but total global scores on the Scale for the Assessment of Negative Symptoms (8) were not significantly different. Finally, the abstainers had a significantly higher percentage of subjects who were subtyped as "disorganized" than did the past abusers (41% [N=7] versus 18% [N=6], $\chi^2$=6.03, df=2, $p<0.05$). Although the lack of more differences between the two groups may be related to the small number of subjects (type II error), the associated probabilities for most analyses did not even approach significance.

## DISCUSSION

Contrary to our initial hypothesis, schizophrenic patients with past histories of substance abuse did not have more symptoms and were not more impaired than schizophrenic patients who had never abused drugs. Indeed, the groups were similar on most demographic, historical, clinical, and outcome variables. If anything, the schizophrenic patients with past histories of substance abuse appeared "healthier" in that they had less severe thought disorders and positive symptoms, were less likely to be described as disorganized, and were older at the time of their first psychiatric contact. It may be that these individuals, who were able to stop their substance abuse, possess other attributes that could ultimately contribute to a better prognostic outcome.

This study should *not* be interpreted as suggesting any benefits to patients with schizophrenia from substance abuse. We have no way of knowing how the abused substances may have affected the lives or the course of illness of the abusing patients with schizophrenia. Indeed, these patients may be functioning at lower levels than if they had remained drug-free throughout their lives. Further, we feel certain that had we studied subjects who were *currently* abusing drugs, the results would have been quite different. However, these results suggest that a history of substance abuse does not necessarily interact with schizophrenia to yield a particularly malignant or intractable form of the illness (9). After 6 months of abstinence, schizophrenic outpatients who kept their substance abuse under control were doing at least as well as patients with schizophrenia who had never abused alcohol or drugs. These results may be consistent with a recent community survey suggesting that some drug use is more "normal" than total abstinence (10) and with an inpatient study showing more improvement in past and present abusers than in nonabusers during hospitalization (9). Many of the abstainers in this study, especially those with the virulent subtype of disorganized schizophrenia, may have been too socially withdrawn or disorganized to have been exposed to drugs or the social situations that encourage experimentation during adolescence. Further prospective studies using larger numbers of patients are needed to enhance our understanding of how substance abuse affects the course of schizophrenia.

# Comorbidity in Mania at First Hospitalization

Stephen M. Strakowski, M.D., Mauricio Tohen, M.D., Dr.P.H.,
Andrew L. Stoll, M.D., Gianni L. Faedda, M.D., and Daniel C. Goodwin

*Comorbidity was studied in 41 manic and mixed-state bipolar patients at first hospitalization. The lifetime prevalence of comorbidity was high; 21 subjects (51.2%) had at least one other psychiatric diagnosis (N=16, 39.0%) or medical disorder (N=9, 22.0%). Nine subjects had multiple comorbid diagnoses. Women were 2.7 times more likely to have a comorbid diagnosis. The presence of comorbidity was not associated with differences in outcome measures.*

(Am J Psychiatry 1992; 149:554–556)

In 1978, Krauthammer and Klerman (1) reported 21 cases of mania associated with medical or pharmacologic conditions and proposed the existence of secondary mania. Later, Cummings (2) reviewed mania associated with various medical conditions. Black et al. (3) defined complicated mania as "manic syndromes occurring in the context of antecedent or coexistent psychiatric disorders or a concurrent serious medical disorder." They retrospectively studied 57 patients with complicated mania and 114 subjects with uncomplicated mania, who were matched by age, sex, and year of admission and were drawn from a larger cohort of 438 patients with mania. They observed significant differences in demographic variables between groups and poorer initial treatment response in the group with complicated mania (3). Stimulated by these reports, we sought to clarify further the relationship between mania and comorbidity and now report on the risks of comorbidity in bipolar manic patients at first psychiatric hospitalization.

## METHOD

Patients 18 years or older who were consecutively admitted for a first psychiatric hospitalization with manic symptoms were approached for participation in this study. Subjects who met *DSM-III-R* criteria for bipolar disorder, manic or mixed, and provided informed consent were included. Patients were not excluded because of the presence of possible organic precipitants (*DSM-III-R* mania criterion F). Diagnostic assessments were made with the Structured Clinical Interview for *DSM-III-R* (4); after completion each interview was reviewed by a second investigator (S.M.S.). Medical diagnoses were established through patient examinations and review of the medical record. Comorbidity (complicated mania) was defined after Black et al. (3) as the presence of nonaffective *DSM-III-R* axis I psychiatric diagnoses or serious or potentially life-threatening medical illnesses, such as cancer and myocardial infarction, but not well-controlled conditions, such as chronic hypertension.

Weekly assessments were made with the Clinical Global Impression scale (CGI) (5) and an expanded 27-item Brief Psychiatric Rating Scale (BPRS) (6) that included the following nine additional items: speech, euphoria, increased motor activity, sexual interest, sleep, insight, suicidal thoughts, appetite, and dysphoria. In addition, each *DSM-III-R* criterion for mania and major depression was scored on a 1- to 7-point scale of severity, as for the CGI. Treatment was determined clinically and was not controlled by the investigators. Outcome variables were length of hospitalization, change in BPRS score, final CGI score, and antipsychotic drug use at discharge. Recovery from mania was defined as a CGI score of 2 or less (2=very mildly ill), a rating of 3 or less on the *DSM-III-R* mania A criterion, no B criterion rated higher than 3, and no more than two B criteria rated equal to 3. Recovery from depression was defined as a CGI score of 2 or less, no *DSM-III-R* depression criterion rated higher than 3, and no more than three depression criteria rated equal to 3.

Nonparametric statistical analysis was performed. Categorical variables were compared by using the one-tailed Fisher exact test; continuous variables were evaluated by using the Wilcoxon rank sum test.

## RESULTS

Forty-one bipolar subjects met criteria for inclusion; 33 (80.5%) were manic and eight (19.5%) were in a

[a] Nine subjects had more than one diagnosis.

[b] Significant difference between sexes (p=0.008, Fisher's exact test).

[c] Significant difference between sexes for any substance abuse (p=0.02, Fisher's exact test).

[d] One patient had pneumonia with an acute asthmatic exacerbation.

[e] One patient received prednisone for an exacerbation of Reiter's syndrome; the other for an allergic rash to imipramine 3 weeks previously.

mixed manic-depressive state. The mixed-state patients averaged 10.9 years older than the manic patients (mean ages=40.4 years, SD=11.7, versus 29.5, SD=12.7; Z=2.42, p=0.02) but otherwise showed no differences in demographic, comorbidity, or outcome variables. Twenty-five subjects (61.0%) were women; they averaged 8.0 years younger than the men, a difference that did not reach statistical significance (mean=28.5 years, SD=9.1, versus mean=36.5, SD=16.8; Z=1.11, p=0.27). Comorbidity, or complicated mania, was present in 21 (51.2%) of the subjects, including 16 (39.0%) with another antecedent or concurrent axis I psychiatric disorder and nine (22.0%) with concurrent medical illness. More than one comorbid diagnosis was present in nine subjects (22.0% of the total). Women had a 2.7-fold higher rate of comorbidity (17 of 25 women [68.0%] versus four of 16 men [25.0%]; p=0.008, Fisher's exact test). No significant differences between patients with complicated and uncomplicated mania were observed in age (mean=32.2 years, SD=10.0, versus mean=30.4, SD=16.0; Z=–1.45, p=0.15), length of hospitalization (mean=34.3 days, SD=15.4, versus mean=37.0, SD=16.7; Z=0.57, p=0.57), change in BPRS score (mean=30.3, SD=16.2, versus mean=31.2, SD=19.8; Z=0.16, p=0.88), final CGI score (mean=2.1, SD=1.1, versus mean=2.1, SD=1.1; Z=–0.15, p=0.88), number of subjects taking antipsychotic medication at discharge (13 of 21 versus 14 of 20; p=0.42, Fisher's exact test), or recovery rate (12 of 21 patients versus 14 of 20 patients; p=0.30, Fisher's exact test).

Specific comorbid diagnoses are listed in table 1. Women were 6.4 times more likely to have a history of comorbid substance abuse or dependence (10 of 25 women [40.0%] versus one of 16 men [6.3%]; p=0.02, Fisher's exact test). Subjects with a history of drug abuse or dependence were 3.2 times more likely to have another comorbid psychiatric diagnosis (six of seven with drug abuse or dependence [85.7%] versus nine of 34 without [26.5%]; p=0.006, Fisher's exact test). A similar association was noted for alcohol abuse or dependence (six of 10 with alcohol abuse or dependence [60.0%] versus six of 31 without [19.4%]; p=0.02, Fisher's exact test) (table 1). Of the nine subjects with medical comorbidity, three had chronic, stable illnesses (cerebral palsy, treated hypothyroidism, and temporal lobe epilepsy), and six had acute illnesses or acute exacerbations of chronic medical conditions (table 1). The six subjects with concurrent acute medical conditions averaged 10.3 years older than the other 35 subjects (mean=40.4 years, SD=11.2, versus mean=30.1, SD=12.9; Z=2.12, p=0.03), were 4.4 times less likely to have antipsychotic medication prescribed at discharge (one of six subjects [16.7%] versus 26 of 35 subjects [74.3%]; p=0.01, Fisher's exact test), and had a hospitalization that was 34% shorter (mean=24.8 days, SD=7.3, versus mean=37.5, SD=16.3; Z=–1.90, p=0.06).

## DISCUSSION

To our knowledge, this is the first study to examine comorbidity in mania at the time of first hospitalization. Complicated mania was nearly four times more prevalent in our cohort of 41 consecutively admitted bipolar patients than in the group reported by Black et al. (3). Further, unlike that study, we did not observe significant differences in early clinical outcome between groups with complicated and uncomplicated mania.

These discrepancies likely reflect methodologic differences. Whereas the study by Black et al. (3) used retrospective chart reviews, thereby relying on the clinical recording of diagnoses (both axis I and axis II) and outcome variables, the present study was prospectively designed with structured diagnostic patient interviews (for axis I), review of current treatment records, and recovery operationally defined from clinical ratings. These significant methodologic differences limit the comparability of the two studies.

The most common comorbid diagnoses in the present study were alcohol and drug abuse or dependence. It has been suggested that bipolar patients may abuse substances to self-medicate their affective symptoms or that substance abuse may precipitate or perpetuate affective episodes (7). Conversely, primary substance abusers frequently demonstrate affective psychopathology, and substance abuse is known to produce significant affective symptoms (8). In fact, in all but one subject the onset of substance abuse preceded hospitalization by more than 1 year. However, possible prodromal affective symptoms predating or concurrent with the onset of substance abuse could not be reliably determined in the present cohort, limiting conclusions that can be drawn. The reasons for the nearly threefold higher rate of comorbidity among women, much of which was due to substance abuse, are unclear. Whether this may reflect differences between men and women in reporting past histories of substance abuse requires further study.

Concurrent acute medical conditions in our cohort were associated with older age, less likelihood of antipsychotic medication being prescribed at discharge, and a trend toward a shorter hospitalization. Whether this small subgroup represents mania resulting from medical conditions, so-called secondary mania, rather than expressions of primary bipolar disorder requires further study.

Several diagnoses appeared to be more common in the present cohort than in the general population, compared to the lifetime prevalence reported by the recent Epidemiologic Catchment Area study (9). These diagnoses included alcohol abuse or dependence (24.4% versus 13.5%), drug abuse or dependence (17.1% versus 6.1%), obsessive-compulsive disorder (7.3% versus 2.5%), and panic disorder (4.9% versus 1.6%).

The most significant limitation of this study is the small sample size and limited statistical power; only six subjects had acute medical illnesses. Further, we studied only hospitalized, acute, manic, or mixed-state bipolar patients, limiting the applicability of these results to bipolar disorder in general. Despite its limitations, this study examined an important clinical issue in a unique cohort of bipolar patients at first hospitalization. Our results suggest that the prevalence of comorbidity in bipolar disorder may be higher than previously thought, even early in the course of the illness. Although the long-term effects of comorbidity are uncertain, early identification of additional medical and psychiatric diagnoses is important for the development of appropriate clinical treatment.

# Associations Between Dimensions of Religious Commitment and Mental Health Reported in the *American Journal of Psychiatry* and *Archives of General Psychiatry:* 1978–1989

David B. Larson, M.D., M.S.P.H., Kimberly A. Sherrill, M.D., M.P.H.,
John S. Lyons, Ph.D., Frederic C. Craigie, Jr., Ph.D., Samuel B. Thielman, M.D., Ph.D.,
Mary A. Greenwold, and Susan S. Larson, M.A.T.

*The authors assessed all measures of religious commitment (N=139) reported in research studies published in the* American Journal of Psychiatry *and* Archives of General Psychiatry *in 1978 through 1989 (N<35). For nearly two-thirds of the measures, the studies either made no hypotheses or reported no results concerning the relationship of religious commitment to mental health status. For the great majority of the measures assessed, the studies reported a positive relationship between religious commitment and mental health.*

Am J Psychiatry 1992; 149:557–559)

There is evidence that religious practices and beliefs are understudied phenomena in clinical fields such as psychiatry (1) and family medicine (2). When religion has been studied, it has usually been assessed by using a static measure—denominational affiliation. Psychiatric studies seldom contain variables reflecting religious commitment, such as measures of religious experience, belief, attitudes, or practice (1).

Studies concerning dimensions of religious commitment have emphasized its multidimensional nature (1–4), including meaning, ceremony and sacramental activities, social support, and relationship with the deity (5). Each of these religious dimensions might have positive or negative relationships to various aspects of clinical status. For instance, there have been some reports of negative or harmful associations between religious commitment and mental health (6), but other reports have detailed positive or beneficial effects (4, 7–10).

A systematic review by Bergin (3) took an important step in clarifying the association between religiousness and mental health. Not only did Bergin find little relationship between religiousness and psychopathology, he also found that religious commitment had a positive association with mental health in nearly half (47%) of the study effects tabulated. In contrast, associations with mental health were neutral in 30% and negative in less than one-fourth (23%) of the tabulated associations.

A recent review by Gartner et al. (8) revealed several interesting trends in research on the relationship between religious commitment and psychopathology or mental health. Most of the studies assessing nonclinical populations (e.g., college students) that used measures of psychopathology not based on psychiatric nosology found religion to have either a neutral or harmful role more often than a positive role. In contrast, studies assessing clinical populations that used measures based on psychiatric nosology found religious commitment to have a beneficial role more often than a harmful role. In addition, studies that included measures of religious practice found religiousness to be associated with mental health benefits more often than did studies including measures of religious attitudes.

Our current study was undertaken to follow up the findings of the review of the field of psychology (3) and the review of the combined mental health field (8) and to provide for psychiatry a state-of-the-art review of associations between religious commitment and mental health. The review entailed the systematic assessment (1, 2) of all religious commitment variables found in research studies published in the two leading psychiatry journals over a 12-year period. Using the method of Craigie et al. (10), we determined whether positive, negative, or neutral associations between mental health and religion were found, hypothesized, or reported. We also tabulated the associations and classified them according to the typology of religious dimensions used by Craigie et al. (10).

**TABLE 1. Associations Between Dimensions of Religious Commitment and Mental Health Reported in the *American Journal of Psychiatry* and *Archives of General Psychiatry:* 1978–1989**

| | Number of Measures Assessing Dimension of Religious Commitment | | | | | | |
|---|---|---|---|---|---|---|---|
| | Hypothesis of Study | | | Results of Study | | | |
| Dimension of Religious Commitment | Positive Association | Negative Association | None | Positive Association | Negative Association | Neutral Association | Association Not Tested |
| Ceremony | 2 | 0 | 11 | 4 | 0 | 0 | 9 |
| Meaning | 3 | 5 | 34 | 7 | 4 | 0 | 31 |
| Social support | 11 | 1 | 13 | 7 | 0 | 1 | 17 |
| Prayer | 3 | 0 | 13 | 4 | 1 | 0 | 11 |
| Relationship with God | 1 | 0 | 14 | 9 | 0 | 0 | 6 |
| Indeterminate | 1 | 3 | 24 | 5 | 3 | 5 | 15 |
| Total | 21 | 9 | 109 | 36 | 8 | 6 | 89 |

## METHOD

The first step was to locate all quantified religious measures found in research studies published in the *American Journal of Psychiatry* and *Archives of General Psychiatry* in 1978 through 1989. Each religious measure was then categorized into one of the following religious dimensions: 1) ceremony (participation in religious ceremonies, sacraments, or rituals), 2) meaning (personal purpose, values, beliefs, and ethics), 3) social support (use or influence of social support), 4) prayer (prayer or personal religious devotional practices), and 5) relationship with God (issues concerning a personal relationship with God). Because of the ambiguous nature of the remaining measures, a sixth category termed "indeterminate" (e.g., use of the term "religion" or "religiosity" with no further specification) was developed. Measures of denomination were excluded because of their differences with measures of religious commitment (1, 2, 9, 10). Finally, each religious measure was evaluated to discern whether the research study hypothesized a positive or a negative association between religious commitment and mental health and whether a positive, negative, or neutral result was reported.

Interrater reliability was sufficient across all ratings. Using a kappa coefficient, we found that the reliability of all ratings of the association between religious commitment and mental health was 0.89. The reliability for all hypothesized associations between religious commitment and mental health was 0.82, but it was slightly higher—0.93—for all reported associations between religious commitment and mental health. The reliability kappa for ceremony was 0.82; for meaning, 0.82; for social support, 0.82; for prayer, 0.90; for relationship with God, 0.78; and for the indeterminate dimension, 0.76.

## RESULTS

In 1978–1989, all quantified studies in the *American Journal of Psychiatry* and *Archives of General Psychiatry* (N<35) contained 139 quantified religious commitment measures. Table 1 presents the number of measures for which positive or negative associations between mental health and six dimensions of religious commitment were hypothesized, the number of measures for which the hypothesis regarding these associations were not specified, the number of measures for which positive, negative, or neutral associations were reported, and the number of measures for which the association was not tested. Only 30 (22%) of the 139 measures were in studies that hypothesized results concerning religion, and only 12 of these were in studies that later tested the given hypothesis. All seven of the 21 associations that were expected to be positive and were tested turned out to be positive. Five of the nine associations that were expected to be negative were tested, and four of these turned out to be negative.

Although only 12 of the 30 studies with an a priori hypothesis reported an association between religious commitment and mental health, an additional 38 reported such an association even though no hypothesis was given. Thus, for only 50 (36%) of the 139 measures the study reported an association between religious commitment and mental health. Of these 50, 36 (72%) of the associations were positive, eight (16%) were negative, and six (12%) were neutral. As for the dimensional findings, four of the six dimensions (ceremony, social support, prayer, and relationship with God) had uniformly positive, or beneficial, associations (24 of 26, or 92%). The remaining two religious dimensions—meaning and the indeterminate dimension—accounted for seven of the eight negative findings and five of the six neutral findings.

## DISCUSSION

Consistent with several reviews, the present study found that when a religious variable is studied, it often has a positive association with measures of health (4, 10) or mental health (3, 8). Quite similar to the findings of the family medicine review (10), the dimensions of ceremony, social support, prayer, and relationship with God, although seldom assessed, were all found to have positive associations with mental health. More studies clarifying the clinical role of these dimensions, similar to recent studies by Pressman et al. (7) and Williams et al. (9), are needed.

The dimension of meaning appears to have a greater potential for negative associations. This finding is consistent with the reported research in family medicine (10), where only one of 15 studies including this dimension found a positive association with clinical status. Future studies including the dimension of religious meaning need to pay greater attention to precisely defining and accurately measuring religious meaning as well as to evaluating both the negative and the positive effects of this dimension. Given previous research concerning the clinical benefits of religious practices (4, 7–10), a next step would be to look at the associations between clinical variables and high levels of religious meaning combined with low levels of religious practice. For example, subjects attesting to a high meaningfulness of religion but not attending religious services could experience this incongruity as personal conflict, which would result in a negative mental health effect.

That the indeterminate or ambiguous measurement of religion is associated with most of the neutral findings should not be surprising. Inadequate measurement is generally associated with unreliability and the probability of deflated correlations (11).

What is perhaps most surprising is that in the majority of cases in which a religious variable was specified, there were no reported efforts either to formulate hypotheses or to test the association between religious measures and mental health. For only 30 (22%) of the 139 measures was a hypothesis specified. Of these 30, only 12 (40%) reported the results. For only 50 (36%) of the 139 religious measures did the study report findings concerning associations between religious measures and mental health.

Although one can only speculate why the majority of studies neglected to present associations, one possible explanation is that associations were tested, found to be neutral, and, because of their "no effect" status, not reported. Another explanation is that the associations were simply not tested. Unfortunately, in the case of nearly two-thirds of the measures, the studies failed to report any associations whatsoever—whether neutral, positive, or negative—thus leaving important research information for an underdeveloped field of study unaddressed.

In summary, the findings of the present review suggest that religious commitment is a clinically relevant, multidimensional phenomenon with the potential for frequent beneficial and occasional harmful mental health effects. Future research efforts concerning how religious commitment influences mental health status require improvements in research methods. Improvements should include 1) the specification of a priori hypotheses, 2) the accurate measurement of the relevant dimension of religious commitment, and 3) the presentation of the study results concerning the association of religious commitment and mental health status. These improvements are necessary if the next steps are to be taken in this previously neglected but promising area of psychiatric research.

# International Reliability of a Diagnostic Intake Procedure for Panic Disorder

Janet B.W. Williams, D.S.W., Robert L. Spitzer, M.D., and Miriam Gibbon, M.S.W.

---

*Test-retest diagnostic reliability interviews using the Upjohn version of the Structured Clinical Interview for DSM-III (SCID) were conducted with 72 patients at 13 international sites of the Cross-National Collaborative Panic Study. Agreement on the diagnosis of panic disorder was very good. For the subtypes (uncomplicated, with limited phobic avoidance, and agoraphobia), agreement was fair to good.*

(Am J Psychiatry 1992; 149:560–562)

---

Initial results from the Cross-National Collaborative Panic Study, a two-phase, multicenter, controlled clinical trial sponsored by the Upjohn Company, have already been reported (1–3). Phase Two of the trial was unique in its geographic scope and compared alprazolam, imipramine, and placebo in patients with panic disorder or agoraphobia with panic attacks in 13 centers in North America, South America, and western Europe. Before the beginning of Phase Two in the summer of 1984, a multicenter reliability study of the diagnostic intake procedure, using the Upjohn version of the Structured Clinical Interview for DSM-III (SCID) (4), was conducted. This report presents the reliability of the diagnosis of panic disorder and its subtypes, as determined in that study.

## METHOD

Each country that was participating in the treatment study agreed to participate in the reliability study as well. The Upjohn version of the SCID was created specifically for this study. It contains an overview and a diagnostic section for panic disorder and its subtypes as well as sections for disorders to be ruled out. Training on the Upjohn version of the SCID took place over approximately 2 days during a general meeting of the Phase Two investigators in November 1983. Videotapes were used to demonstrate correct interviewing techniques, and direct interviews of the participants were observed by trainers from the Biometrics Research Department of New York State Psychiatric Institute.

The "test-retest-interview" method (rather than the "joint-interview" method) of assessing interrater reliability was chosen for this study because it most closely approximates the model of interchangeable interviewers. According to this method, a reliable diagnosis is one that can be made in the same subjects by different interviewers. Although it would have been ideal to select the pairs of interviewers in random order, the participants' busy clinical schedules made this impossible. Therefore, interviewers were selected on the basis of who was available when a particular patient needed to be evaluated. The test-retest evaluations were, ideally, to be the first contact with that patient for each of the two clinicians in the interviewing pair. If there was additional information about the patient from a referral note or the initial screening, it was made available to both clinicians in written form, so that both evaluations were based on the same data to the extent possible. The retest evaluation was completed by the second clinician as soon as possible after the first evaluation to minimize the possibility of the patient's condition changing between the two interviews.

All patients were prescreened over the telephone by a research assistant to ensure that they were suffering from some symptoms of panic disorder, even though they may not actually have had the diagnosis. Patients were randomly selected for test-retest evaluations from everyone who passed through the initial screen. The inclusion criteria for the Phase Two treatment study specified having a diagnosis of panic disorder, agoraphobia with panic attacks, or panic disorder and limited phobic avoidance that was not severe enough to meet the criteria for agoraphobia. All patients were between the ages of 18 and 64 and were in good physical health; they were excluded if they had current symptoms of psychosis, suicidality, or dementia or a history of bipolar, cyclothymic, or obsessive-compulsive disorder, seizures, melancholia, or drug or alcohol depend-

ence. Patients currently in psychotherapy or behavior therapy were also excluded.

When an interview was completed, each clinician independently completed an Upjohn version of the SCID diagnostic score sheet. Data analysis was conducted by the Biometrics Research Department. Tests from all sites were analyzed together to estimate the reliability of the international participants as one study team.

## RESULTS

Thirteen sites in 11 countries participated in this study: Belgium, Brazil, Canada, Colombia, France, Mexico, Spain, the United Kingdom, the United States, Germany, and Austria. Countries contributed from one to 19 test-retest interview pairs; the mean was 7; on average, five clinicians per country participated in this study. Altogether, 72 patients were evaluated; 52 (72%) were retested within 1 week of the first interview (range=0–40 days).

Table 1 presents the kappa coefficients of agreements for the diagnostic category of panic disorder and its three subtypes. Agreement on the diagnosis of panic disorder was very good. For the subtypes, within the group of patients who were diagnosed as having panic disorder, agreement was fair to good.

**TABLE 1. Agreement and Disagreement on Diagnoses of Panic Disorder and Its Subtypes by Interviewers in 13 International Sites**

| Diagnosis | Agreements | | Disagreements | Kappa |
|---|---|---|---|---|
| | Positive | Negative | | |
| Panic disorder | 62 | 8 | 2 | 0.87 |
| Subtypes | | | | |
| Uncomplicated | 9 | 47 | 5 | 0.73 |
| With limited phobic avoidance | 24 | 25 | 12 | 0.61 |
| Agoraphobia with panic attacks | 15 | 37 | 9 | 0.66 |

## DISCUSSION

This was the first international diagnostic reliability study within a clinical trial (here, the Cross-National Collaborative Panic Study). Interviews of a series of patients each evaluated by two clinicians on separate occasions (test-retest reliability) demonstrated very good agreement for panic disorder and fair to good agreement for its subtypes.

In an NIMH-funded multisite reliability study of a later version of the full SCID (modified for *DSM-III-R*), kappas of 0.58 and 0.59 were obtained for 390 psychiatric patients and 202 nonpatients, respectively, for the diagnosis of panic disorder (5). These are somewhat lower than in the current study, probably because there was no prescreening of subjects and no specific focus on panic disorder; all diagnoses in the full SCID were assessed.

Using the Schedule for Affective Disorders and Schizophrenia—Lifetime Version Modified for the Study of Anxiety Disorders (SADS-LA), a clinical interview guide designed to focus specifically on anxiety disorders, Mannuzza et al. (6) obtained a kappa of 0.79 on evaluations of 104 patients in an anxiety disorder clinic. Their kappas for the subtypes were 0.76 for uncomplicated, 0.62 for limited phobic avoidance, and 0.81 for agoraphobia. These kappas, and those in the present study, are relatively high, undoubtedly because both studies focused on anxiety disorders and because patients were prescreened.

Maier et al. (7) interviewed 40 consecutive inpatients with depressive and/or anxiety syndromes using the Upjohn version of the SCID in a test-retest design. The kappa for panic disorder (N=12) was 0.83, and the kappa for "panic disorder, with avoidance behavior" (N=11) was 0.53. Since both of these kappas were statistically significantly higher than corresponding kappas obtained from the test-retest administration of a diagnostic checklist (0.66 and 0.48, respectively), the authors concluded that "the application of structured clinical interviews in clinical trials for the evaluation of . . . anxiety disorders (*DSM-III*) is clearly recommended by these data."

We conclude that very good diagnostic reliability for panic disorder can be obtained with a structured interview guide in patients who have been prescreened and determined to have anxiety disorders. In nonpatients and general samples of patients, however, agreement is only fair. Future research should be directed toward improving agreement in unselected samples.

## ACKNOWLEDGMENTS

The Cross-National Collaborative Panic Study, Second Phase, consists of a Steering Committee (James H. Coleman, Kalamazoo, Mich., Chairman, and Gerald L. Klerman, New York City, Co-Chairman) and project directors (Jose Luis Ayuso, Madrid; Per Bech, Hillerod, Denmark; Otto Benkert, Mainz, Germany; Sydney Brandon, Leicester, England; Giovanni B. ## Information on APA Periodicals at the 1992 Annual Meeting

*American Journal of Psychiatry* staff will be located in the APA Resource Center and the editorial office in Room 19, Level 1, Convention Center. Hours of operation: Saturday, May 2, noon–5:00 p.m.; Sunday, May 3, 10:00 a.m.–5:00 p.m.; Monday, May 4, through Thursday, May 7, 8:00 a.m.–5:00 p.m. Staff at both locations will be available to schedule office appointments with the Editor, answer authors' questions, and receive papers submitted for publication. The *Journal* publishes only original material that has not been published elsewhere in any form and that is not being considered for publication elsewhere. Five copies are required.

*Hospital and Community Psychiatry* staff will be located in the APA Resource Center. Hours of operation are the same as the Resource Center: Saturday, May 2, noon–6:00 p.m.; Sunday, May 3, 8:00 a.m.–6:00 p.m.; Monday, May 4, through Wednesday, May 6, 7:30 a.m.–6:00 p.m. Staff will be available to answer questions about *H&CP* and about writing for publication in psychiatric journals. Authors may submit papers (unpublished material) for publication. Five copies are required.

*Psychiatric News* operates its news gathering and reporting activities from Room 19, Level 1, Convention Center. Hours of operation: Sunday, May 3, 10:00 a.m.–5:00 p.m.; Monday, May 4, through Thursday, May 7, 8:00 a.m.–5:00 p.m. Persons who wish to contact editors or reporters may make arrangements for appointments here, or may leave written announcements, suggestions for articles, or letters to the editor for the newspaper's consideration.

## AFFECTIVE DISORDER

**Psychotherapy for Depression,** *by T. Byram Karasu. Northvale, N.J, Jason Aronson, 1990, 190 pp., $25.00.*

Psychiatry is indebted to Dr. Karasu for his efforts at "rapprochement, both within and across psychologic and pharmacologic domains" (p. vii) and for assembling and summarizing important trends in psychiatric treatment (1). Examples of this include two excellent articles on psychotherapy of depression in the February and March 1990 issues of the *Journal* (2, 3). This book is a handsomely packaged, essentially verbatim reissue of those articles.

The merits of the articles remain. Dr. Karasu succinctly describes three psychotherapeutic approaches to depression: cognitive and interpersonal therapies, whose importance is demonstrated in outcome research, and psychodynamic psychotherapy, widely used by psychiatrists in the United States. In broad strokes he succinctly highlights advantages and limitations of each approach. He raises the crucial, unanswered question of differential therapeutics for depression, a heterogeneous condition without a uniformly ideal treatment. Depression is defined as a spectrum condition spanning dimensions of symptomatology, severity, periodicity, and normality versus pathology—characteristics with presumed implications for treatment. Dr. Karasu concludes with discussions of combining antidepressant pharmacotherapy with each psychotherapy and choosing among and integrating the three psychotherapeutic techniques.

As a Broadway hit may show signs of strain when enlarged on the Hollywood screen, translating these journal articles to book form has introduced tensions. Article paragraph headings have been blown up into chapter titles, each assigned a separate page, and the paragraphs themselves have been developed into brief chapters whose length rarely exceeds three pages. Whereas the articles were long, pithy, admirably crafted epitomes of periodical summation, the identical prose in hard cover can read as breathless and telegraphic. When a paragraph becomes a book chapter, the broad strokes that were strengths of the articles can seem hurried, stretched, overly simplified. For example, generic references to dynamic psychotherapy sometimes leave unclear which model Dr. Karasu has in mind: Luborsky's? Strupp's? Bemporad's? The average clinician's? On page 101, he implies that cognitive therapy and interpersonal therapy are used exclusively for research. Such ellipsis—leading to blank divider pages—may frustrate readers.

The book format offered an opportunity to elaborate on the important issues Dr. Karasu deals with. Largely uncritical descriptions of the psychotherapies might have been developed into fuller critiques. He might have reinforced theory with data from treatment studies and the NIMH Treatment of Depression Collaborative Research Program (4, 5), which give some indication of the relative efficacy and mode specificity or lack of mode specificity of interpersonal therapy and cognitive therapy. For its intended audience of "practitioners" (p. viii), clinical vignettes demonstrating differences in psychotherapeutic approaches might have been helpful.

This text remains a masterly brief overview of three important antidepressant psychotherapies. It will not replace manuals of the treatments it describes but may well whet the reader's appetite for them. It meets its aim "to expand the repertoire of practitioners unfamiliar with some of these approaches and . . . provide a systematic delineation for better communication among them" (p. viii).

**Animal Models of Depression,** *edited by George F. Koob, Cindy L. Ehlers, and David J. Kupfer. Boston, Birkhäuser (New York, Springer-Verlag, distributor), 1989, 284 pp., $55.00.*

The use of animals in biomedical research continues to be the subject of much controversy and debate. We in the medical community frequently find ourselves faced with opposition from animal rights activists (or "animal rights terrorists," as Secretary Sullivan of the U.S. Department of Health and Human Services, called them in a speech made in Washington, D.C., on June 7, 1990) and the need to justify support for the use of animals in research. There is perhaps no field of medicine more vulnerable to such possible attack than mental illness research. Ultimately, because mental illnesses may be uniquely human disorders, the critical question becomes, Is there anything truly important and meaningful to be learned from animal models?

*Animal Models of Depression* is an important contribution to the field, particularly because of the light it sheds on the promises of animal models in mental disorder research and what it encompasses. The book is a compilation of papers originally presented at a conference in September 1986 on the

Psychobiology of Depression, sponsored by the MacArthur Foundation Research Network. The book follows the outline of the conference and is divided into three sections. The first three chapters present a conceptual overview of animal models in psychiatry. Chapters four to thirteen each present a single study approach using a different animal model. The authors of each of these chapters summarize recent research efforts in the area of study presented and discuss directions for future study. Chapters four to nine present developmental and behavioral models, and chapters ten to thirteen focus on pharmacological models.

Despite the array of contributors, the book is readable, cohesive, and nicely balanced and provides a broad introduction to a number of very different research methodologies. Some of the chapters in the second and third sections may present more detail than the average reader wants to know about specific experimental designs and results. However, because each chapter is self-contained it is easy to pick and choose among topics of interest. In this regard *Animal Models of Depression* is a nice book to have along on a vacation to educate one's self more comprehensively about the rationale, methodology, and progress of different research approaches in the study of depression.

For the clinician who is skeptical about the value of animal models, the first three chapters are especially noteworthy. These chapters discuss from a more theoretical prospective the promises and limitations of animal models and thus provide a foundation from which to approach the rest of the book. In the first chapter McKinney defines animal models as "experimental paradigms developed in one species for the purpose of studying specific aspects of the human illness." He adds, "They are not replicas of human depression in its entirety." The clear consensus that emerges from this book is that there is no one comprehensive animal model for depression and no one best model. Rather, it is argued that different experimental paradigms should be used to investigate different, selected aspects of psychopathology. In the second chapter, Kornetsky nicely distinguishes three types of animal models. He cautions that "a common error is assumption that similar overt behavior [in animals] implies similar [human] mood or experience."

These chapters clearly delineate the potential contributions of animal models to preclinical research. Such models allow greater control and isolation of experimental variables. In addition, the study of parallel processes in animals may spark new research formulations leading to new testable hypotheses and possibly safer, more effective treatments of depression. Although this book focuses on the role of animal models in depression, the theories could be applied just as persuasively to the use of animal models in research on schizophrenia, anxiety disorders, substance abuse, and other mental disorders. In short, *Animal Models of Depression* is a valuable book for clinicians as well as researchers wishing to broaden their scope of understanding of the important contributions of animal models to mental illness research.

**Depressive Disorders: Facts, Theories, and Treatment Methods,** *edited by Benjamin B. Wolman and George Stricker. New York, John Wiley & Sons, 1990, 424 pp., $49.95.*

This volume is part of the Wiley series on personality processes. The preface of the book explains that the series is directed toward behavioral scientists who have an interest in the theory, measurement, and treatment of human personality.

This particular volume is divided into three major sections: Theories of Depression, Symptomatology, and Diagnostic and Treatment Methods. The chapters in the first section run the gamut of biological, psychodynamic, existential, cognitive-behavioral, psychosocial, and genetic theories. The chapters on symptomatology cover depressive states and somatic symptoms, mood disorders and self-defeating behaviors, symptoms, prevention and treatment of attempted suicide, and levels of depression. The third section consists of chapters dealing with interviewing methods, projective assessment, rating scales, somatic therapies, psychoanalytic therapy, behavior treatments, cognitive therapy, interactional psychotherapy, interpersonal psychotherapy, and marital therapy. Most of the individual chapter authors are well-known in their areas of expertise. The referencing of each chapter is thorough and current through the year of publication (1990). There is an author index, which I found quite useful, as well as a subject index, which although brief covers the material adequately.

In attempting to review this volume, I tried to read it straight through and found this to be a somewhat difficult task. Indeed, it was probably not meant to be used in this manner but, rather, used as a reference base for behavioral scientists interested in depression and, more pointedly, in specific aspects of depression that might be covered in each section. For example, the chapter on interviewing methods gives the background and history of structured interviews and then elaborates in a practical way on a number of interviews used for depression, describing each interview, indicating which affective disorders are diagnosed by the interview, what training is required for administering the interview, how much time the interview takes, etc. Issues relating to reliability and validity for each interview are also discussed.

Some books about mood disorders are written for patients, and some are written for clinicians. This book is likely written for neither group but more for researchers, particularly young researchers who wish to grasp something of the history and theory of mood disorders. As such, the book serves a useful purpose, although its general use may be limited.

One of the striking difficulties with this book is the lack of a uniform or integrated definition of mood disorders. The concept of mood disorder as a personality attribute is given as much weight as is the concept of mood disorder as a medical syndrome. The applicability of personality theories related to mild depressive states needs to be carefully weighed by the reader against descriptions of psychotic depression and bipolar affective disorder. However, given this caveat, the descriptions are quite thorough within each topic and the reader can easily grasp the major concerns of each chapter.

Some of the chapters I found particularly of interest. For example, the chapter on biological theories of depression by Golden and Janowsky is comprehensive in scope, well referenced, and provides an overview of each of the amine theories of depression. Although brief, the chapter presents a level of neurochemistry that would be adequate for someone beginning in the field. The chapter on inventory and rating scales is the most comprehensive on the different ways of measuring depression that I have encountered and would be of interest to many clinicians, at least for the description of each test (MMPI, Hamilton Rating Scale for Depression, Zung Self-Rating Scale, etc.), in terms of what each scale measures, how it is applied, and what is not measured.

This book is a useful reference for investigators interested in depression. I doubt that it would be of interest to patients who suffer from depression or most clinicians who are involved in treating mood disorders. For the researcher, however, it stands as a notable reference text for the decade of the 1990s.

DAVID L. DUNNER, M.D.
*Seattle, Wash.*

**Affective and Schizoaffective Disorders: Similarities and Differences,** *edited by A. Marneros and M.T. Tsuang. New York, Springer-Verlag, 1990, 285 pp., $89.70.*

This is an edited volume based on a conference that was a follow-up to an earlier conference, which also resulted in a volume by the same editors (1). In addition to one introductory and two concluding chapters by the editors, this book has 22 chapters, only four of which are from U.S. research teams. Two of the first authors of the other papers come from Great Britain, one from Austria, one from Italy, one from Sweden, one from Switzerland, and 12 from Germany.

This volume has several strengths. Most importantly, it provides an opportunity for monoglot anglophonic psychiatrists to familiarize themselves with diagnostically oriented psychiatric research from European and especially German centers. Furthermore, several chapters of this collected work are particularly noteworthy. Paykel provides a pithy and very well-informed summary of life events research as it applies to affective and schizoaffective disorders. Over three chapters, Marneros and colleagues give an extensive summary of premorbid features, course, and long-term outcome of patients with schizophrenic, schizoaffective, and affective disorders from the Cologne study on the long-term course of functional psychoses. Maier and colleagues provide a brief overview of what appears to be a carefully designed large-sample family study of functional psychosis performed in Mainz, Germany. Tsuang summarizes a thoughtful attempt to empirically validate a proposed subdivision of schizoaffective disorder on the basis of long-term outcome from the Iowa 500 and non-500 series. In one of the more innovative chapters, Coryell attempts to interrelate outcome, neuroendocrine measures, and familial psychopathology in patients with affective, schizoaffective, and schizophrenic disorders. Other chapters, particularly those on treatment, are weaker, being more anecdotal than scholarly in tone and content.

This book has two major weaknesses. First, it suffers from several flaws unfortunately common in edited volumes. There is considerable repetition. For example, the book contains numerous discussions of Kasanin's initial report on schizoaffective disorder (2) and how it relates to current concepts. There is little synthesis of the varying results and perspectives. Although Marneros' final summary chapter is helpful, the disparate chapters need more integration than is provided. Second, it is disappointing that, with a few notable exceptions, most of the authors conducted their studies and reached their conclusions on the basis of a single definition of "schizoaffective disorder." If anything has been shown in research on this problematic category over the last two decades, it is that, depending on the definition of the disorder and/or the method of patient recruitment, it is possible to obtain a syndrome that is either very much like typical affective disorders *or* very much like typical schizophrenia. None of the papers in this volume, for example, examined the *DSM-III-R* criteria for schizoaffective disorder to see whether they succeed at defining a syndrome that is relatively distinct from affective illness.

For those looking to update themselves on European and especially German descriptive psychiatric research on the major functional psychoses, this will prove a useful volume. Those seeking a definitive, integrated review of the relationship of schizoaffective disorder to more typical affective illness will be disappointed.

KENNETH S. KENDLER, M.D.
*Richmond, Va.*

**Aging and Clinical Practice: Depression and Coexisting Disease,** *edited by Robert G. Robinson, M.D., and Peter V. Rabins, M.D. New York, Igaku-Shoin, 1989, 233 pp., $29.95 (paper).*

At the outset, I should state that I have a particular interest in the relationships between syndromes of depression and neurological and systemic illness and in the proper care of patients suffering from such co-occurrence of illness. Further, I view these co-occurrences as having a biological foundation that requires biological intervention as a primary treatment strategy.

Although this book generally takes this theoretical tone, it has some clear and serious weaknesses. The editors define their goal as presenting a book that will be 1) a detailed reference source for the "latest research findings" of the relationship between depression and various coexisting neurological and systemic disorders and 2) "a guide for clinical care" of these co-occurring, and in many instances comorbid, combinations. These goals, while salutary, are not fully realized in this volume.

My fundamental criticism of this book is that it was planned to simultaneously aid the primary care physician and the psychiatrist. Unless psychiatric training is less than I think it is and primary care training is more, I cannot conceptualize a book that can be of benefit as a research reference source and a clinical guide to both specialties. For example, how could the prescription and administration of ECT be meaningfully presented simultaneously to both readerships? The book deals with this issue by giving less information about ECT than is usually presented to medical students rotating through their psychiatry clerkship. No clinical guide here. On the other hand, how could a sophisticated review of the latest research be presented to the primary care physician who does not have the background knowledge or a command of the technical language of modern psychiatry to make useful sense of that research?

In my view, in trying to be all things to specialists and generalists, this book becomes unhelpful to both. Despite the importance of the topic and the clear expertise of the many authors involved, this book would suggest that psychiatric clinical skills can be practiced at the state-of-the-art level by nonspecialists. If there is validity to our specialty, we should acknowledge that in the understanding and care of psychiatric patients we have a greater knowledge base and clinical skills than do other specialists, including the primary care physician. A better service to primary care physicians would be either a true how-to-do-it book written at the level of a postgraduate year 1 or 2 psychiatric resident or a registry of competent, medically oriented psychiatric consultants.

Whatever is the reality of the broader issue, this book still does not achieve its goals. The latest literature review is presented, but not in a critical way. Any specialist interested in the topics would be buying a list of references and comments, not an academically or clinically useful discussion of the research. Clear summaries of the latest material are indeed presented, but at a level suitable for the generalist. More importantly, this book fails as a clinical guide. For example, nowhere in this book on depression is there a discussion of the risk factors for suicide, how to assess these factors, and what to do about them. The chapter on depression and heart disease does not mention the use of ECT. Most chapters that describe treatments recommend psychotropics as the treatment of choice for co-occurring depressions, whereas the chapter on chronic pain avers that ECT is the treatment of choice for melancholia. What is the primary care physician to make of that apparent conflict?

I have other problems with the book. The chapter on depression and the aged offers a relatively lengthy discussion of the psychosocial theories of comorbid depression but does not discuss suicide in this age group and, further, implies that psychological and biological treatments for comorbid depression are of equal benefit. My experience and reading of the literature suggest to me that although interpersonal and social interventions are important, biological treatment is essential in cases of major depression. The discussion of treatments of depression associated with endocrine disorders is also lacking, boiling down to the suggestion that if you treat the endocrine disorder the co-occurring depression will likely resolve. Not much meat on that bone.

It all comes down to the fundamental issue of the validity of psychiatric specialization. As a final example, the use of all sorts of psychotropic drugs is repeatedly recommended as if primary care physicians were as competent as are psychiatrists to use these agents. If they are not, then why write a book encouraging them to use these agents? If they are, why do we need psychiatrists?

MICHAEL ALAN TAYLOR, M.D.
*Chicago, Ill.*

## SCHIZOPHRENIA

**International Perspectives in Schizophrenia: Biological, Social and Epidemiological Findings,** *edited by Malcolm Weller. London, John Libbey, 1990, 321 pp., $78.00.*

Malcolm Weller, editor of this volume and author of three of its chapters, opens this book with the statement, "There have been some exciting developments in the conceptualization and treatment of schizophrenia which are inaccessible without sifting a large and growing number of journals" (p. vii). Dr. Weller and his colleagues are to be congratulated. Not only does the volume they produced neatly summarize the relevant material on schizophrenia in one place, but it does so in a balanced and well-thought-out manner.

*International Perspectives in Schizophrenia* is the result of two conferences held in London in the late 1980s under the auspices of the National Schizophrenia Fellowship. Although the title includes the term "international perspectives," most of the chapters were written by British investigators. For any reader, however, the volume provides an unusually complete overview of the field.

The editor says in his preface that he wants to include information about the biology, epidemiology, and psychosocial aspects of schizophrenia. He succeeds admirably. There are separate sections on biology, genetics, epidemiology, pharmacology, and social aspects of schizophrenia. For a book as broad-based as this, the degree of sophistication of many of the chapters is a welcome surprise. A number of the sections, in fact, can be considered the definitive review of the area at the current time.

The section on biology reviews organic aspects of schizophrenia. Several of the chapters are excellent, but the review by Liddle entitled "Prefrontal and Subcortical Dysfunction in Schizophrenia" is particularly relevant to an understanding of the current theories of schizophrenic psychopathology and the potential mechanisms of action of both the typical and the atypical neuroleptic drugs.

Perhaps the strongest section in the book is the entire discussion on genetics. It provides an in-depth review of current theories and techniques. Kety reviews the well-known Danish adoption strategies, Blackwood and colleagues discuss the concept of trait markers, Ghurling and colleagues describe the use of molecular genetics techniques, and Crow presents the basis for a possible viral etiology of schizophrenia.

The section on epidemiology provides a review of techniques used in the study of schizophrenia and emphasizes in particular the need for accurate diagnostic assessment. I was particularly struck by the fascinating discussion about resource utilization in Great Britain for the treatment of schizophrenic patients. The discussion about the implications of hospital closings on social policy, a topic of great interest in the United States, is presented with a uniquely British twist.

The section devoted to pharmacology is also extremely well-done. There is a chapter by Barnes describing drug-induced akathisia and tardive dyskinesia. Jones and Costall and colleagues describe the potential value of serotonin-blocking drugs (particularly drugs affecting the $5\text{-HT}_3$ receptor) as putative treatments for schizophrenia. Van Kammen and colleagues from the United States review their thoughts on the potential role of noradrenaline as one factor involved in the response to and relapse from antipsychotic medication. Finally, Jenner and colleagues describe the drug sulpiride and its unusual $D_2$ receptor effects.

The final section, on social aspects, reviews the work of Leff on expressed emotion. It also contains a particularly interesting chapter by Falloon on family management techniques as one aspect of the overall treatment of patients with schizophrenia.

This description will undoubtedly give the reader an inkling of the diversity of the material presented in this volume. What is surprising, however, is the depth in which the authors describe their particular topics. That depth provides for the richness of the book but also may make it somewhat "rough going" for novice readers. The only addition that I would have wished to see would be more of a discussion about the role of clozapine as an atypical neuroleptic, both as a potentially more effective treatment for schizophrenia and as a probe into the neurochemical pharmacology of the antipsychotic drugs. But this is a fine point, and the volume stands on its own as it is. Any student or practitioner wishing to get a comprehensive overview of the status of research and practice relating to schizophrenia would do well to read Dr. Weller's compilation. Indeed, he and his colleagues have succeeded in putting much of the relevant information about schizophrenia in one place.

ALAN I. GREEN, M.D.
*Boston, Mass.*

**Office Treatment of Schizophrenia,** *edited by Mary V. Seeman, M.D., F.R.C.P.(C), and Stanley E. Greben, M.D., F.R.C.P.(C). Washington, D.C., American Psychiatric Press, 1990, 208 pp., $28.50.*

This is a concise and readable text written with the outpatient practitioner in mind. It succeeds in providing a useful overview of outpatient treatment for "the large majority of schizophrenic patients, with whom the duration of the difficulties presented by the illness can be measured not in months, but in years" (p. 3). There are 11 logically organized chapters, each a freestanding module that addresses a different aspect of treatment. Six chapters are written by the editors, and five are the product of as many other clinicians.

The first chapter explores the reluctance of many clinicians to treat these patients and makes a compelling case for undertaking long-term treatment with them. This is followed by a concise outline for conducting the initial clinical assessment. The third chapter ("Engaging Patient and Family in Treatment") seems intended for a less experienced audience, but it is well-written and reflects the work of a skilled and thoughtful clinician devoted to caring for the chronically ill.

"Individual Psychotherapy" (chapter four) provides an optimistic view of the role of individual psychotherapy in this disorder, focusing primarily on the experience of the ongoing relationship for both patient and therapist. It is very enjoyable reading despite superfluous definitions of such familiar concepts as "transference," "countertransference," "real relationship," and "working alliance." A shortcoming of this chapter is the absence of any consideration that some schizophrenic patients may not benefit from therapy and how this situation might be recognized and managed. Chapters five ("Family Therapy") and six ("Group Therapy") are clearly written and helpful to those unfamiliar with these modalities; they contain straightforward, practical information presented with a solo, office-based practitioner in mind.

In contrast, the two psychopharmacology chapters are somewhat disappointing. Chapter seven ("Antipsychotic Pharmacotherapy") contains useful observations about management issues associated with neuroleptic administration (e.g., resistance and noncompliance), but experienced practitioners will probably find it too general to be useful. Chapter eight ("Adjunct Therapies") is problematic. The stated goal of this chapter is "to outline new approaches to the diagnosis and management of some of the more common difficulties of the schizophrenic patient" (p. 143). Perhaps this explains the author's decision to highlight some unproven treatments (e.g., calcium supplementation for "neuroleptic-induced extrapyramidal reactions" and iron supplementation for akathisia) rather than focusing more on typical interventions. Individual studies are given as much weight as well-established findings rather than being presented in perspective. Sweeping statements are made without benefit of citation. Examples of these include, "Anxiety and depression are the most common symptoms of schizophrenia" (p. 143), "Currently, lithium represents the single most important and potentially useful adjunct to our conventional treatment of schizophrenia of all of the other . . . [alternative treatments] that have been proposed" (p. 152). The importance of distinguishing between depression and akinesia on the one hand and anxiety and akathisia on the other is emphasized repeatedly, but no attempt is made to provide guidelines for making these distinctions in practice. A minor point: the use of alprazolam for akathisia is discussed without ever mentioning another benzodiazepine by name.

Chapter nine ("Networking") emphasizes the importance of the psychiatrist's role as patient advocate and community liaison. Chapter ten ("Dealing With Crisis") is unfortunately too brief to adequately address the pertinent clinical crises it describes. The final chapter recapitulates the book's central emphasis on the patient-therapist relationship.

Overall, this is an enjoyable and useful book. Clinical vignettes are used generously throughout to illustrate an abundance of practical suggestions and cogent observations. It is most successful when discussing issues in the interpersonal domain and when advocating a humanistic and individualized treatment approach to this patient group. The psychopharmacology chapters appear to fall short of meeting the average practitioner's needs, however, and there is no discussion of patients with dual diagnoses or medicolegal issues. Nevertheless, anyone who treats chronic schizophrenic patients in an outpatient setting or who is contemplating doing so will find this book helpful.

*Brockton, Mass.*

## CHILD PSYCHIATRY

**The Course of Life, revised ed., vol. III: Middle and Late Childhood,** *edited by Stanley I. Greenspan, M.D., and George H. Pollock, M.D., Ph.D. Madison, Conn., International Universities Press, 1991, 562 pp., $65.00.*

In 1980, under the aegis of NIMH, Drs. Greenspan and Pollock brought out a well-received three-volume compilation of psychoanalytic papers on normal and pathological development from birth through senescence. The present volume is the third of a greatly expanded revision of that collection, incorporating much new material and updating early contributions. It deals with the phase designated by Freud as the "latency" period—the years from about 5 to prepuberty, classified here more "atheoretically" as "middle and late childhood."

What is most notable in this multiauthored assemblage is the wide range of approaches taken by the authors, all of whom fall within the spectrum of "mainstream" psychoanalysis. Several remain wedded to "classical" libido theory, offering rather formulaic recapitulations or elaborations of the traditional literature on "latency" and thus adding little to what Anna Freud and Berta Bornstein, among others, wrote long ago. More interesting and, I believe, more clinically useful are the efforts of contributors like Marshall Schechter and Lee Combrinck-Graham and Fred Pine, who attempt to integrate psychoanalytic and cognitive approaches to development and psychopathology; Paulina Kernberg, who casts childhood psychosis in the mold of object-relations theory; and Robert Stoller, whose revisionist views of gender identity and sexual identity formation, although fairly familiar by now, are both imaginative and much in tune with current data from direct observation studies.

Other noteworthy pieces include that of Kyle Pruitt, who reports research demonstrating that fathers do very well as primary caretakers of young children, and Serge Lebovici, who offers a characteristically French approach to the assessment of psychopathology in children. Lebovici's perspective emphasizes mother-child interactions, much in the spirit of Winnicott, but he is particularly concerned with the impact of the mother's prenatal fantasies and expectations on the child's development.

As in most multiauthored collections, there is a good deal of overlap among the various essays. Reviews of the Freudian and other early literature are repeated from paper to paper in an almost ritualized form. Still, there is much of value in this anthology, not least an effort by Greenspan, Hatleberg, and Cullander to formulate a systematic approach to the assessment of early psychopathology on developmental lines—a method that may prove somewhat cumbersome for the busy clinician but would seem to be of great value for the investigator.

*The Course of Life, revised ed., vol. III* is not a book to be read from cover to cover, but it is a valuable reference source for students and practitioners who wish either to review basic psychoanalytic developmental concepts on the "latency" period or to be brought up-to-date on contemporary viewpoints within the psychoanalytic frame of reference.

AARON H. ESMAN, M.D.
*New York, N.Y.*

## Application of Basic Neuroscience to Child Psychiatry, *edited by Stephen I. Deutsch, Abraham Weizman, and Ronit Weizman. New York, Raven Press, 1990, 400 pp., $49.50.*

The last two decades have seen an unprecedented evolution in child psychiatry. The development of criteria-based diagnostic categories and the use of structured interviews, rating scales, and psychopharmacological interventions have all added to its developing a firmer, broader scientific basis. Nevertheless, an understanding of the neurobiological basis of childhood psychiatric disturbances remains a stepchild of these advances and a distant relative of those seen in adult psychiatry. It is within this context that I approached this book, in the hope that it would answer a number of questions concerning how neuroscience might approach childhood psychiatric disturbances and what future neurobiological investigations may hold for child and adolescent psychiatry.

The book is divided into three sections: Basic Neuroscience Considerations, Application to Specific Clinical Disorders, and Evaluation, Drug Development, and Ethical Considerations. Section one has several chapters of excellent quality that cover basic neuroscience areas and then provide either theoretical or applied links to child psychiatry. Other chapters fail to provide descriptions of future implications or demonstrations of current applications of neuroscience techniques to child psychiatry. A number of important areas that would appear to have potential applications to child psychiatry research are not covered or covered only very briefly. These include imaging techniques, endocrine challenges, brain immune interactions, and receptor strategies. Despite the authors' efforts to present coherent and broad reviews of the field of neuroscience as it applies to child psychiatry, the book does not adequately achieve this goal. Unfortunately, this accurately reflects the lack of knowledge in this area.

The second section represents the strength of the book. Here are reviews of neuroscience studies as they relate to major childhood psychiatric disturbances, including autism, pervasive developmental disorders, childhood-onset schizophrenia, Tourette's syndrome, obsessive-compulsive disorders, suicide, and Down's syndrome. In general, each one of the chapters is well-prepared. Surprisingly, no mention is made of biological studies of childhood major depressive disorders, an area that has led in the application of neuroendocrine and sleep strategies. Further, the schizophrenia chapter could have been complemented by current adult work to allow a better perspective for future research.

Section three includes a chapter on ethical issues in research in child psychiatry that is one of the book's major contributions. Some of the most important difficulties in performing research in child psychiatry are explored in this chapter.

This text represents a step in the evolution of the application of neuroscience techniques to child psychiatry. Despite its limitations, it is the only text in its class for those interested in developing an overview of major childhood psychiatric disorders and neuroscience-based studies. The book's principal shortcoming is in its effort to strive beyond application without clear links to future studies. We strongly recommend this text to those interested in research in child psychiatry and to those clinicians who are still skeptical of the potential for the application of neuroscience to the understanding of the etiology of childhood psychiatric disturbances.

## Adolescent Psychotherapy, *edited by Marcia Slomowitz, M.D. Washington, D.C., American Psychiatric Press, 1991, 199 pp., $29.95.*

Any book covering the topic of adolescent psychotherapy is a difficult undertaking. One has only to remember that the patients are emerging from dependent childhood and are supposed to emerge as independent adults during the next approximately seven years. Innumerable physical and emotional changes take place during this period. The adolescent is struggling with many physical changes and emotional variations and is concerned about his or her own stability. Referral to a mental health worker is often met with resistance because it implies to teenagers that somebody thinks they are crazy; they are concerned that this may be true.

The authors have chosen to divide this book into three sections, Theory, Treatment, and Specific Disorders and Their Treatment. Each section has several chapters. The first chapter, which has a psychoanalytic orientation, does a creditable job in covering different psychoanalytic contributions to adolescence. The author points out a couple of things that are of tremendous importance. First, the teenage years can be divided into early, middle, and late, each having its own particular tasks. Second, the success or lack of it in terms of how well adolescence is accomplished depends in large measure on the success of the preadolescent development. A pubescent youngster who has had many problems before adolescence will bring these to the teenage years and have additional difficulty. The child who reaches adolescence successfully, however, will probably do well during adolescence.

Chapter three, "Biological Facets of Psychotherapy," is brief but touches on the most salient features of the biological development of the adolescent. The chapter entitled "Social Systems Contributions to Psychotherapy" quite correctly points out that effective psychotherapy with the teenager requires attention to both the intrapsychic and the systems variables that patients experience emotionally in social functioning. Like children, adolescents rarely refer themselves to a therapist but, rather, are sent by a responsible adult, usually a parent. This means that from the very beginning the role of each of the adults as well as the teenager must be worked out to the satisfaction of all. Adolescents are due the respect of confidentiality, and it is essential that this be given them. By the same token, the adolescent must know that the responsible adults must be brought in for consultation if something serious arises. In other words, each of the parties must understand his or her particular role in general and be willing to accept it before therapy begins.

Chapter six, entitled "Group Psychotherapy of Adolescents," points out that group psychotherapy is often essential and that many adolescents prefer it. It is necessary, however, that the group leader not become authoritarian or dictatorial. The last chapter, "Psychotherapy of Adolescents With Attention-Deficit Disorder," reminds us that one of the most common misconceptions about attention deficit disorder is that children outgrow it as they enter adolescence. This is by no means true, although it is possible that they outgrow attention deficit disorder with hyperactivity. The following three chapters discuss psychotherapy of adolescents with behavior disorders, adolescents with mood disorders, and adolescents with neurotic disorders. Each of these is concisely written and of practical value.

This book is written for all mental health workers and includes a large number of references for those who wish to pursue particular points. It is to be recommended for anyone who deals with the mental health of adolescents.

STUART M. FINCH, M.D.
*Green Valley, Ariz.*

**Adolescent Psychiatry: Developmental and Clinical Studies, vol. 17. Annals of the American Society for Adolescent Psychiatry,** *edited by Sherman C. Feinstein, Aaron H. Esman, John G. Looney, George H. Orvin, John L. Schimel, Allan Z. Schwartzberg, Arthur D. Sorosky, and Max Sugar. Chicago, University of Chicago Press, 1990, 544 pp., $40.00.*

This volume of *Adolescent Psychiatry* is a diverse collection of essays, literature reviews, and clinical research studies. It includes specific psychotherapy techniques useful in the treatment of adolescents, current theoretical concepts in development, clinical vignettes in different treatment settings, and a discussion of the impact of the current political and social climate on our work in adolescent psychiatry.

The text is divided into four sections. The first, Adolescence: General Considerations, starts with chapters by two authors who question the current "goals" of the health care system and the educational system. Frank T. Rafferty argues that in the United States the free-market economic forces of supply and demand force the health care system to operate on at least two tiers and that the "planned, controlled social engineering that would be required to truly meet all the needs of children and adolescents" is inconsistent with our culture. Richard A. Gardner provides a provocative diatribe on the failing educational system and its deleterious effects on the psychological development of children and adolescents. I found the last two chapters in this section particularly helpful for my own work with adolescents. Philip Katz discusses techniques for engaging an adolescent during the first few minutes of the first interview. His clinical vignettes clearly illustrate his points. Derek Miller concisely describes the meaning of treatment termination for adolescents in different developmental stages as well as for the hospitalized adolescent.

The second section, The Chestnut Lodge Adolescent Experience, is the weakest section in this volume. There are some highlights here, however. E. James Anthony provides a literary description of the long-term setting, describing the ideal development of an adolescent during his or her stay at Chestnut Lodge. I found Douglas A. Chavis' case study of a boy with a severe narcissistic personality disorder richly descriptive and thoughtful. His discussion of transference and countertransference should be read by any health care provider working with adolescents. The chapters on family therapy and group therapy were disappointing. Perhaps the disorganization and use of confusing jargon is proportional to the number of authors of this chapter. The chapters on the research experience at Chestnut Lodge are varied, including such subjects as personality and demographic differences in adjustment to the milieu, the attachment process in brain-damaged adolescents, and effects of the sex and experience of the therapist on psychotherapy, but most of the studies are superficially constructed. Wells Goodrich provides a well-organized overview of characteristics of adolescents who are hospitalized, the hospital treatment processes in three phases, and the four patterns of response to treatment during hospitalization. He does not pretend that the research he presents is rigorous but does provide us with questions to be studied with more reliability. Linda Beth Berman and Wells Goodrich thoroughly review the literature on runaways from home and hospital and describe a retrospective study on runaways from Chestnut Lodge. Their results must be carefully studied for clinical relevance.

The third section, Developmental Issues in Adolescent Psychiatry, is the most challenging to read but also the most rewarding. Joseph Palombo studies normal development during late adolescence within the framework of self psychology. He carefully reviews Kohut's definitions of "the cohesive self" and "the nuclear self." He then describes the work necessary to establish these developmental formations. Drew Westen and colleagues report their study of the developmental differences in object relations between borderline adolescents and adults. They question the current object relations construct on the basis of their findings that there are developmental differences in object relations between adults and adolescents. Despite the limits of the research, the question begs further study. Sheila Hafter Gray takes us beyond adolescence but within the context of a developmental continuum not marked by isolated phases. She describes the developmental tasks of young adulthood, notably the consolidation of a genital character structure. Bernard A. Stein and colleagues report data from a longitudinal study of the change and consistency in personality characteristics from middle to late adolescence. Max Sugar describes the different (and constant) anxieties during the phases of adolescence, not only for the adolescent but for the parent as well.

The fourth section, Psychopathology and Psychotherapy of Adolescent Emotional Disorders, comprises chapters devoted to specific disorders. Susan J. Bradley provides a rich overview of panic disorder with a detailed literature review and relevant clinical vignettes. Nancy H. Weil and Andrew M. Boxer describe their research on the treatment of adolescent mothers and their children with impaired attachments. They used conjoint psychoanalytic psychotherapy with the mothers and infants. The study is descriptive rather than quantitative. The cases presented illustrate the complexity of such treatment—the multiple dyadic relationships in the treatment room requiring close monitoring and the transference and countertransference issues in this treatment. Kevin R. Ronan and Philip C. Kendall, using cognitive-behavioral therapy, provide a detailed, almost "how-to" approach to the treatment of adolescents who lack self-control.

The overall quality of volume 17 of *Adolescent Psychiatry* is good. I recommend a selective reading, with more attention to the first and third sections. Reading this book made me more aware of the variety of study and perspectives within this work. This volume is broad in scope; it illustrates the complexity of this developing subspecialty.

## RESEARCH METHODS

**An Introduction to Psychiatric Research,** *by Richard E. Gordon, C.H. Hursch, and Katherine K. Gordon. New York, Cambridge University Press, 1988, 288 pp., $37.50.*

This book provides a very general introduction to doing research in the broad field of applied general psychiatry. Its nontechnical approach combined with an amicable writing style and moderate level of content makes the book readable by even the least experienced. Although not stated, the intended audience is either a student who has just started training or a more advanced practitioner with very little exposure to research. The broad scope addresses subjects ranging from how and where to get an idea to rewriting rejected manuscripts. The cost of this broad coverage, however, is that few subjects are covered in depth and many topics receive only cursory examination.

The authors organized the chapters following a classification scheme that groups research efforts into six progressive categories: 1) research to develop an initial working hypothesis (literature reviews or clinical impressions backed by single sample descriptions), 2) research on scale or instrument development, 3) "observed relation research" (simple correlational studies with no causal inferences), 4) "observed causal research" (weak experimental, quasi-experimental, or correlational studies with causal inferences), 5) "causal relation research" (case-control or experimental research), and 6) theory development work (synthesizing and formalizing previous research information).

The chapters address each type of research in turn. Additionally, there are chapters on some simple statistics, research ethics, and other general introductory issues.

From my perspective as an active researcher and biostatistician who has taught research methods, I welcomed the progressive arrangement. By organizing research efforts on the basis of level of development the authors avoided a common pitfall found in many introductory texts: using a simple correlational versus experimental dichotomy for the sake of simplicity. Grossly simplifying important ideas often causes more confusion than it tries to avoid. The confusion—due to lack of fit—frequently becomes clear as soon as the system is applied to real situations.

In contrast, Gordon, Hursch, and Gordon show how the chapters relate to real research by featuring at least one or two of their own published research projects as examples for each type of research presented. These provide the reader with actual examples of research issues (e.g., postpartum reactions). These also demonstrate the progressive nature of a long-term research project and add continuity to the book. On the other hand, there are few examples of the research of others, so the examples may not represent general psychiatry. For instance, few strictly biological or physiological examples are detailed.

Unlike the clear organization of the chapters, the text within a chapter often jumps unexpectedly from one topic to another. It is sometimes difficult to see the connection between paragraphs that appear one after the other within a chapter. For instance, in chapter two the flow of topics proceeds immediately from library computer searches (e.g., MEDLINE) to descriptive statistics and the normal distribution and then to writing up a paper. Sometimes ideas that are introduced are not discussed until several pages later, and, occasionally, definitions are presented following the discussion of an item.

At times, the order in which ideas are introduced could result in perceived inconsistencies. For instance, in the chapter on developing measuring instruments, the subheading "Getting Subjects for Research" suggests that good places to obtain subjects are in the reader's (i.e., a psychiatrist's) waiting room or a hospital. Random sampling is then appropriately defined on the next page, and on the following page is a warning not to use special groups selected on the basis of convenience. These unintentional problems with continuity make the material hard to follow, but, fortunately, most occur in the early chapters; subsequent chapters flow smoothly.

Some individual topics are presented too superficially for reasonable coverage. For instance, reliability and validity receive perhaps a couple of pages of text. In this quick treatment, criterion-related validity is mentioned only in the context of concurrent validity. As another example, the book deals with scales of measurements using the classifications of S.S. Stevens (1) (nominal, ordinal, interval, and ratio). Gordon and colleagues do not cite Stevens' work but do repeat his rather dogmatic, even odd, admonitions about performing arithmetic operations on certain numbers. Stevens' warning would preclude figuring scholastic grade-point averages because these require adding and dividing by N. In practice, most people have no difficulty with the concept of calculating grade-point averages using addition and division. Calculating means from most psychiatric rating scales would also be taboo according to Stevens' rules. There is little discussion of how measurement scales relate to psychiatric research.

According to the authors, measurement scales determine whether to use parametric (e.g., t tests) versus nonparametric (e.g., Mann-Whitney U tests) statistics. Nothing is said in this context about normal versus nonnormal distributions or any other assumptions about parametric statistics. The introduction to normal curves appears in an earlier chapter with only a vague reference to subsequent statistical analysis. In practice, violating the assumptions of parametric statistics leads one to consider the nonparametric alternatives and not whether the scale of measurement is interval or ratio. It would appear that most of this book's wisdom about this issue comes from the introduction to Siegel's book (2), which is heavily influenced by Stevens' notions about doing arithmetic on numbers. However, even nonparametric statistics require some arithmetic and would thus, according to that rule, be inappropriate for many measurements of interest to psychiatrists. This oversimplified and somewhat dogmatic notion may do more harm than good.

In general, the treatment of statistical material is very traditional but usually much like a cookbook. There are no references to any of the newer graphical techniques (e.g., box plots). There are numerous worked examples of simple analyses. The instructions for calculating chi-square are unnecessarily difficult. The simple and general formula is not presented until after a couple of different calculational methods. Also when a two-by-two chi-square is first introduced with low expected frequencies (fewer than 5), Yates's correction is offered as the solution and not Fisher's exact test. Fisher's exact test is referenced later. The discussion of statistics often mentions the sound advice of seeking help from statisticians and using a personal computer.

In many ways this book is a good practical guide for beginning researchers. It is simple and specifically concerned with general psychiatric research. I had some problems with the material because introductory books by nature of their intent need to be almost pristine. An introductory book has a good chance of being the only book a person might read on a subject. Also, the reader of an introductory book may not be in a position to judge its accuracy. If this book were used for a course, supplemental material would be absolutely necessary to provide examples from other research areas. More detailed discussion of other perspectives could also be provided by including some original source materials on quasi-experimental methods.

## Media Coverage Versus Fluoxetine as the Cause of Suicidal Ideation

SIR: Since the publication of an article by Martin H. Teicher, M.D., and associates (1) on six case reports of patients who experienced suicidal ideation with fluoxetine treatment, the media have paid close attention to the phenomenon. Stories concerning the fluoxetine defense for violent crime and suits brought concerning suicidal ideation have been reported. The following case reflects some of the difficulty in treating patients with fluoxetine during this time of intense media attention.

> Mr. A was a 49-year-old man who was HIV positive but asymptomatic. He was first seen psychiatrically with complaints of anxiety. On examination he showed evidence of anhedonia, feelings of guilt, depressed mood , and thoughts of death for the past 6 months. Recent losses included the death of his mother 6 months earlier. He was doing well medically but refused to take zidovudine because he heard that it had serious side effects. A regimen of fluoxetine, 20 mg every morning, was begun, and within a week the patient returned, stating that he had stopped the medication. He claimed that the medication made him feel "horrible on the inside" but he had no idea what the cause could be until he saw the news on a local channel which covered a story of a woman who had made suicide attempts and who attributed this to fluoxetine. He claimed that his symptoms began before the broadcast and that he knew they were the same. Convinced that the fluoxetine was the cause of this "horrible" feeling, he became fearful of the medication, stating that he did not want to kill himself (which by now he was convinced he would do if he continued the medication).

This case reflects some of the difficulties that the recent media coverage may cause. The patient had already shown a reluctance to take medication because of the side effects that he was told might occur. He was also unable to state what the feeling was, instead stating that it sounded like what he saw on television. It is unfortunate, given the need to document information on adverse effects of the psychotropic agents, that such confusion concerning the etiology was present.

## Carbamazepine-Induced Atrioventricular Block

SIR: Carbamazepine is currently widely used in neurology and is now more and more recommended for lithium-resistant and rapid cycling patients. Carbamazepine-induced cardiac electrical conduction disorders have previously been reported in patients already suffering from a cardiac condition, but little is known about electrical abnormalities appearing in an otherwise normal heart.

> Ms. A, 63 years old, had been treated for a unipolar affective disorder with periods of mood-noncongruent psychotic features for the past 10 years. All previous heart evaluations, including ECGs, had been normal. She was admitted to the hospital for a depressive psychotic episode and slight signs of confusion. Neuropsychological tests suggested features of organic brain disorder. CT scan showed calcifications in basal ganglia and slight cerebellar atrophy. ECG showed bilateral temporal theta waves with irritative features. Carbamazepine, 100 mg b.i.d., was introduced and brought a progressive improvement. She was followed up for 3 years as an outpatient and showed sustained clinical stability and even improvement on neuropsychological tests.
>
> After 3 years, Ms. A presented an effort dyspnea. ECG was normal but the treadmill stress test showed a second-degree atrioventricular block, and episodes of third-degree atrioventricular block with ventricular escape were documented on Holter monitoring. No symptoms of intoxication were found. Carbamazepine was stopped and dyspnea disappeared. Because her psychiatric condition rapidly worsened, carbamazepine was reintroduced with close supervision. After a few weeks, cardiac symptoms reappeared and the drug was definitely stopped. Holter monitoring was normal thereafter, as were ECG, thallium stress test, and echocardiography. ECG never showed conduction defects on follow-up.

According to Hewetson et al. (1), Steiner, in 1970, reported that carbamazepine prolongs atrioventricular conduction time in dogs. Meyrignac et al. (2) reported cases of carbamazepine-induced complete atrioventricular blocks. Boesen et al. (3) reported on other abnormalities such as an intermittent complete atrioventricular block, an atrioventricular block with a functional escape rhythm, and an intermittent asystolia. Others like Benassi et al. (4) and Ladefoged and Mogelvang (5) have reported carbamazepine-induced heart conduction disorders, but in patients with already-known heart disease.

Our patient seems to be a rare case of a pure carbamazepine-induced severe heart conduction disorder without previous heart disease. It is interesting also to note that symptoms appeared 3 years after the beginning of the drug treatment without apparent preceding symptoms. The most plausible physiopathogenic explanation for this phenomenon is the chemical structure of carbamazepine (like tricyclics), with quinidine-like effects on cardiac conduction pathways.

We therefore recommend that dyspnea, dizziness, or syncope appearing in a carbamazepine-treated patient should be taken seriously, even in the absence of other cardiac symptoms and an apparently normal heart. ECG is not necessarily adequate to detect conduction defects, and it therefore should be complemented by a stress test and Holter monitoring if ECG is not demonstrative. If carbamazepine is the only drug to which such a patient responds, a cardiac pacemaker should then be mandatory.

## Successful Treatment of Bowel Obsessions With Nortriptyline

SIR: Several authors have described individuals who suffer from agoraphobia without panic, or from social phobia, whose incapacity rests in an excessive preoccupation with the sudden loss of bowel control (1, *DSM-III-R*). Some have called these worries "bowel obsessions" and have suggested that the condition is a variant of obsessive-compulsive disorder (2–4). Case reports have documented successful treatment with clomipramine, doxepin, imipramine, and behavioral techniques (2–4). I am reporting the case of a patient whose symptoms responded to nortriptyline.

> Mr. A was a 65-year-old man who presented preoccupied with the worry that he would be flatulent in public. He had never been flatulent around other people. The problem had developed 30 years earlier and had progressed with negligible waxing and waning in its course. It was followed by extreme social withdrawal and the loss of a very successful business career. Prior treatment with psychodynamic psychotherapy, diazepam, chlordiazepoxide, propranolol, and dicyclomine had produced no improvement. Treatment with adinazolam had produced a modest benefit but had to be stopped because of impotence. Trials of fluoxetine, alprazolam, and clomipramine produced no benefit. After 3 weeks on a regimen of nortriptyline, 10 mg/day, he noticed a "remarkable improvement" never before felt in his life. He was much more comfortable in public, much less preoccupied with being flatulent, and able to triple his activities. At a dose of 50 mg at bedtime there was further improvement. The blood level at this dose was 167 ng/dl. These beneficial effects continued unabated after 6 months.

This patient's case and the literature discussed raise the question of how to classify bowel obsessions. The presence of recurrent, intrusive, senseless thoughts suggest that this is a variant of obsessive-compulsive disorder. In Mr. A's case, the lack of success with two serotonin uptake blockers argues against this hypothesis. The type of incapacity seen in the condition argues in favor of it being a social phobia. Response to several different treatments, particularly benzodiazepines, suggests that anxiety reduction is a factor in improvement. Although this is an uncommon problem, the disability to which it leads is profound, and the relief after treatment is greatly appreciated. It is hoped that future study will shed more light on the classification and treatment of this interesting disorder.

## Treatment of Generalized Anxiety Disorder and Trichotillomania With Buspirone

SIR: To my knowledge there has been no previous report to document the use of buspirone in the treatment of an anxiety disorder with coexistent trichotillomania.

> Ms. A, a 31-year-old woman, presented with several months of paroxysmal episodes of acute anxiety accompanied by attendant autonomic hyperactivity. This included the occurrence of hyperventilation, palpitations, dyspnea, and paresthesias. The patient also exhibited an uncontrollable urge to pull out her hair. This occurred over the same period of time and resulted in a section of alopecia.
>
> She reported intrusive thoughts of having an underlying disease state, despite reassurances from physicians on several occasions. This state did not appear to meet the criteria for obsessive-compulsive disorder.
>
> A previous 2-week trial of alprazolam appeared to be of no benefit. Ms. A was then started on a regimen of buspirone, 30 mg/day p.o. Within 4 weeks, the trichotillomania remitted completely. A significant improvement of anxiety symptoms was noted on the Sheehan Patient Rated Anxiety Scales.

Previous studies have documented successful treatment of both obsessive-compulsive disorder and trichotillomania with clomipramine, a strongly serotonergic tricyclic antidepressant (1, 2). Buspirone, a well-known anxiolytic agent, a 5-hydroxytryptamine agonist, is also thought to affect serotonin balance. This agent was shown to facilitate the effects of fluoxetine in the treatment of obsessive-compulsive disorder (3). These studies may offer an explanation of the efficacy of buspirone in this case.

## Lithium Treatment of a Bipolar Patient With Cystic Fibrosis

SIR: We are reporting the case of a patient with cystic fibrosis and bipolar disorder who was treated with lithium. This case is of interest because of a hypothesis suggesting that lithium may correct the defect in chloride transport seen in cystic fibrosis (1).

> Ms. A was a 30-year-old woman with cystic fibrosis who had had episodes of mania and depression of increasing frequency and severity since she was 19 years old. She was first hospitalized 2 years ago when she was acutely psychotic with mixed depressed and manic symptoms. She was successfully treated with lithium carbonate and chlorpromazine, and she was discharged on lithium maintenance. After 6 months she was readmitted with mania and psychosis. She responded well to lithium carbonate and perphenazine, but this hospitalization was complicated by pneumonia. She continued to do well on these medications 6 months after discharge.
>
> Serial electrolyte determinations from serum and sweat were made initially and after 2, 3, 5, 7, and 8 months. Ms. A's serum lithium levels were 0.97, 0.87, 0.93, 0.90, 1.24, and 1.02 meq/liter, respectively, at a consistent dose of lithium carbonate, 450 mg b.i.d. Measured simultaneously in sweat, lithium levels were <0.1, 1.8, 1.6, 2.08, 2.36, and 3.2 meq/liter, and chloride levels were 102, 93, 126, 88, 128, and 121 meq/liter.

Cystic fibrosis is an autosomal recessive disorder of defective chloride transport in the epithelia of organs of exocrine function caused by a mutation on chromosome 7 (2). The defect in chloride transport in cystic fibrosis may be influenced by lithium. Calcium functions as an intracellular second messenger in many cellular processes, and lithium can counterbalance the effects of calcium abnormalities, as suggested in lithium treatment of bipolar disorder (3). There is some controversial evidence that the intracellular pool of calcium is increased in cystic fibrosis cells, which led to the hypothesis that lithium might limit the amount of intracellular calcium and restore normal membrane permeability to chloride (1). Clinical trials of 10 weeks of lithium therapy for patients with cystic fibrosis caused a decrease in sweat chloride in two-thirds of the subjects but also a mild reversible decline in pulmonary function (4). There has been one other young woman with manic-depressive disorder and cystic fibrosis treated effectively with lithium (4).

Lithium therapy for our patient had no apparent impact on cystic fibrosis, but it was beneficial for mood disorder. Her response to lithium therapy and her lithium levels in serum and sweat were similar to those of other patients with bipolar illness without cystic fibrosis. An initial decrease in sweat chloride was reversed in later determinations, which calls into question the hypothesis that lithium can reverse the underlying defect in cystic fibrosis by its influence on intracellular calcium.

With regular determination of serum lithium levels and monitoring of renal and pulmonary function, lithium therapy appears to be an effective option for treating mood disorders in patients with cystic fibrosis.

## Massive Ingestion of Trihexyphenidyl

SIR: The abuse of trihexyphenidyl and other anticholinergics for euphoric or psychedelic effects has been previously documented (1–5). The following case report serves as a reminder that some individuals may take larger than prescribed doses to diminish depression and improve functioning (1, 3–5). The case is particularly notable because of the unusually large doses of trihexyphenidyl that were ingested.

> Ms. A, a 33-year-old mother, was brought to the emergency room by her family because of restlessness, depression, and periods of confusion. She had dry skin, dry mouth, and blurred vision and showed disorientation for time. Auditory hallucinations, which had been sporadic for 2 or 3 years, intensified, and visual hallucinations began 2 weeks prior to her presentation. She was transferred to a psychiatric inpatient unit.
>
> Two weeks prior to presenting to the emergency room, Ms. A had separated from her husband because of marital discord. For the past 8 years she had been treated with trihexyphenidyl, 5 mg t.i.d., for a longstanding neurological disorder characterized by spasticity and deformity. She admitted to chronic abuse of her medication which had exacerbated during the past 2 weeks. During this period, she took approximately nine tablets (45 mg) daily, sometimes ingesting this amount in a single dose. Six months previously, after a period of increasing abuse, she had, on several occasions, ingested as many as 21 tablets (105 mg) over a time span of a few hours. She stated that during that period, marital stress and the loss of a homemaker overwhelmed her. She felt that the large doses of medication had improved her mood and level of activity. She used devious means to obtain trihexyphenidyl and knew she was "hooked" on it. There was no recent use of any other drugs and no previous psychiatric hospitalization.
>
> During her hospitalization the only medication used was lorazepam, as needed. Visual hallucinations cleared rapidly, disorientation soon after, and depression and auditory hallucinations in a few days. No substantial withdrawal symptoms were noted. Her longstanding neurological condition was diagnosed by a consultant as cerebral palsy. The psy-

chiatric impression was adjustment disorder with depressed mood and anticholinergic psychosis (hallucinosis).

While doses of 45 mg/day of trihexyphenidyl would not be unusual in a patient who abuses or is dependent on this medication (1–5), we have not seen reports of individuals ingesting daily doses of 100 mg or more. Rubinstein's estimate that a patient in a particular month "had probably received at least 2000 mg" of trihexyphenidyl (2) stands out in the literature as the largest amount presumably abused by a patient, but there is no statement as to his actual daily dose.

The fact that Ms. A did not suffer severe toxic effects from her massive ingestion 6 months previously may have been attributable to the development of tolerance reported with antimuscarinic agents (5). Her current decompensation on lower doses of trihexyphenidyl may have been due to a more rapid acceleration of dosage permitting less time for tolerance, along with the psychological effects of the breakup of her marriage.

## Spouses' Assessments of Alzheimer Patients' Response to THA and Lecithin

Sir: Following a recent report by Summers et al. (1) of dramatic improvements in Alzheimer patients treated with tetrahydroaminoacridine (THA, or tacrine), there has been some controversy in the various media about the magnitude of this drug's clinical benefits. Despite the study's methodological problems (2, 3), reports by family members that THA caused significant improvement have been widely published.

We recently reported results of our clinical trial of oral THA and lecithin (4). We have also evaluated spouse perception of patient performance during that double-blind trial. In addition to standard investigator assessments, five of the 10 original inpatients were blindly evaluated for behavioral and cognitive improvement by their spouses. At the end of each of 3 weeks, the same nurse and the spouses, each of whom was previously trained to administer the Nurse's Observation Scale for Inpatients (NOSIE), independently rated the patients' behavior. Due to significant liver enzyme abnormalities in four patients, only six of the 10 inpatients were able to continue in a subsequent 15-week double-blind outpatient phase. In addition to investigator measures of behavior and cognition, all six spouses completed weekly the Geriatric Evaluation by Relatives Research Instrument (GERRI), an outpatient measure of cognition, mood, and social behavior.

Inpatient phase analysis of variance revealed that THA had no significant effect on spouse perception of patient performance on any of the five NOSIE scales. Correlation between spouse and nurse perceptions was low (r=0.18). During the outpatient phase, only one of six spouse ratings (GERRI cognitive scale) agreed with investigators' positive cognitive ratings, whereas two of six spouse ratings agreed with investigator assessments which found no cognitive change between drug and nondrug periods. Investigators' measures revealed some cognitive improvement in three outpatients. Only one spouse was able to distinguish correctly the THA period from placebo. This subject improved markedly on the GERRI mood and social scales but not the cognitive scale. Furthermore, there was no significant improvement in spouse-assessed functional capacity of patients, although spouses frequently expressed the belief that THA was able to improve the cognitive performance of the patients.

Our results suggest that improvement under THA, as measured by the investigators, was modest, restricted essentially to cognitive measures, and limited to a fraction of the patients (4). These findings appear largely undetected in the blinded spouse ratings. However, informal spouse impressions consistently praised the effects of the drug. Poststudy pressure to provide THA was high despite minimal findings. We believe that spouses' desire to see hope in new treatments for this disease renders objectivity regarding these treatments difficult.

Whereas a small number of Alzheimer patients might benefit modestly from THA, neither dramatic improvement nor low toxicity has been substantiated thus far. This suggests that THA must be thoroughly evaluated, including its ability to promote actual functional gain beyond test score improvement without undue toxicity for aged patients. If marketing and monitoring of THA become greater possibilities, questions of cost versus risk to the elderly should be discussed in an open debate involving the public and diverse representatives of the medical community as well as private interests. Premature closure on such a debate could adversely affect those who can least afford to pay or risk adverse effects for marginal gains.

## Prevalence of Depressive Symptoms Among White and African-American Caregivers of Demented Patients

Sir: Dementia is characterized by a slow, progressive process that includes both cognitive and functional deterioration as well as a variety of behavioral disturbances (1). The occurrence of dementia affects family members in many ways, including increased risk for mental health problems such as symptoms of depression (1). Studies have shown that about

50% of caregivers suffer from symptoms of depression (1). While a number of variables affecting depression among caregivers have been investigated, relatively little is known about the prevalence of depressive symptoms among caregivers from different ethnic groups living in the United States. The lack of data on African-American demented patients and their caregivers is of particular concern, since this population, especially its older members, has been increasing dramatically in recent years (2).

Presented here are the preliminary findings from baseline evaluation of a cross-cultural prospective study to assess the mental health of white and African-American caregivers of demented patients in South Carolina. Eighty-three patients and their caregivers (63 white non-Hispanics and 20 African-Americans) were randomly selected for interview from the more than 5,000 demented patients currently identified in the State of South Carolina Dementia Registry and area support groups. The mean age for patients was 76.9 years and for caregivers was 61.1 years. There were no statistically significant differences in patient or caregiver age among the two groups. There were no significant differences in socioeconomic status and educational background between the two groups of caregivers. There were also no significant differences between the two groups in the sex of patients or caregivers. The sex distribution among patients was roughly equally distributed among males and females, while the caregivers were primarily females. Fifty percent of the patients in each group were considered mildly or moderately impaired, with the remaining 50% considered severely impaired according to the Global Deterioration Scale.

Symptoms of depression among caregivers were studied using the Center for Epidemiologic Studies Depression Scale (CES-D Scale) (3). The results of this preliminary survey show significant differences in the prevalence of depressive symptoms among the two groups. African-American caregivers demonstrated significantly less depression than white caregivers when the data were analyzed using a cutoff value of 16 to differentiate among those who presented significant levels of depression. Using this cutoff our sample showed that 62% of the white caregivers had significant symptoms of depression, while only 30% of the African-American caregivers exhibited symptoms of depression ($p<0.05$). When a lower cutoff of 9 was utilized, significant values were also present, with 78% of the white caregivers, compared to only 41% of the African-American caregivers, presenting with comparable levels of depressive symptoms ($p<0.05$). Similar patterns were found when CES-D Scale mean scores were compared (for white, mean=19.3; for African-American, mean =12.4; $p<0.05$).

These findings are consistent with previous publications reporting increased levels of depression among caregivers of demented patients (1, 4). These findings support earlier data reported by Mintzer et al. (4), who found significant differences in caregiving patterns between Hispanic and matched white caregivers. The preliminary findings reported here tend to confirm the existence of ethnically bound differences in the prevalence of mental health symptoms, especially depression, among caregivers of different ethnic groups. These findings highlight the need for increased research efforts in this area and further exploration of the interaction between culture and mental health in elderly patients.

## Diagnostic Criteria for Multiple Personality Disorder

SIR: If multiple personality disorder occurs in as many as 5% of psychiatric inpatients (1), but most psychiatrists, guided by *DSM-III-R*, diagnose it rarely, then the current diagnostic criteria clearly have inadequate sensitivity. To improve not only sensitivity but also validity, I propose the following revision of the diagnostic criteria:

The existence within the person of two or more distinct personalities or personality states (each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self) that recurrently control the person's behavior and result in an inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness. The personalities often present as a puzzling changeability or incongruity of the person; their amnesia usually must be inquired for; and they must satisfy certain requirements, as follows.

A. Puzzling changeability or incongruity as indicated by one or more of the following:
   1. Kaleidoscopic presentation: The person has received a succession of different diagnoses or is diagnostically controversial because of a polysymptomatic, changeable presentation.
   2. First-rank symptoms in a person who is not basically psychotic. For example, a person hears voices conversing in his head, but does not have loose associations, flat affect, poor reality testing, poor interpersonal relatedness, mania, psychotic depression, or other medical conditions to account for the voices. (In multiple personality disorder, first-rank symptoms may be the presenting personality's experience of other personalities' acting from behind the scenes.)
   3. States: A person who is usually alert, mature, and oriented has recurrent episodes of altered states of consciousness, childlike behavior or disorientation that cannot be accounted for by intoxication, epilepsy, dementia, or other medical conditions.
   4. Changeable personal attributes: recurrent puzzling changes in knowledge, skills, tastes, values, attitudes, visual acuity, allergic responses, or other personal attributes.

B. Amnesia for extensive, complex, nonautomatic behavior (not due to intoxication, epilepsy, or other medical condition) as indicated by a positive answer to any of the following questions:
   1. Do people say that you do things that you honestly don't remember doing?
   2. Do you ever find that things have been done or changed, and nobody else could have done it, but you don't remember doing it?

3. Do you ever find yourself in places but can not recall how you got there?
4. Do you ever have difficulty remembering where you were and what you were doing during the preceding hour?
5. Are there years or areas of your life for which you have much less memory than you would expect to have?

C. Alternate personalities, which must have 1) their own independent sense of personhood, 2) their own memory bank, and 3) a history of recurrently controlling the person's behavior since childhood, or at least prior to any legal problem or psychiatric evaluation.

## Body Dysmorphic Disorder: A Controlled Study of Patients Requesting Cosmetic Rhinoplasty

SIR: In the recent article by Katharine A. Phillips, M.D. (1), she noted a lack of controlled studies of patients undergoing cosmetic procedures. I would like to report a sample (unpublished 1980 thesis) of 20 patients drawn from a waiting list for cosmetic rhinoplasty who were compared to a control group on measures of psychiatric morbidity and body image tests. Both groups were administered structured psychiatric interviews and psychological self-report measures. The patients were significantly more disturbed on measures of psychiatric morbidity than the control subjects and scored higher on measures of neuroticism and social anxiety and lower on measures of extroversion. Most patients were rated as having moderate to severe personality disorders (Schneiderian sensitive and insecure types). No patients were psychotic.

A second group of tests concerning body image perception were also administered. These included subjective and objective measures of degree of deformity as well as specific tests of perception of nose size, utilizing both drawing and visual magnification techniques. Objective observer ratings of deformity for both groups were similar and within the minimal to mild range, although patients saw themselves as significantly worse than did control subjects. Thus, the patient group arguably fulfilled one of the essential criteria for *DSM-III-R* body dysmorphic disorder: the preoccupation with some imagined defect in appearance in a normal-appearing person, or one with a slight physical abnormality, where the concern is grossly excessive.

The main hypothesis of the study was that the experimental patients would have a less accurate perception of their nose size than the control group. The main finding was that the experimental group in fact had a more accurate perception of nose size according to two independent measures of nose size estimation. Furthermore, from the small number of postsurgery assessments following the same protocol, there was evidence that after surgery, patients' estimation of nose size became less accurate and fell within the range of the normal control subjects.

The role of cosmetic surgery in altering body image perception in these patients remains controversial, although clearly a number of uncontrolled studies do indicate significant positive changes, at least in the short term. Some recent studies of behavioral desensitization (2, 3) to dysmorphic symptoms suggest the possibility of a cognitive-behaviorial approach for some patients with this disorder. One plausible explanation in the case of cosmetic surgery would be that these sensitive personalities cognitively overfocus on the dimensions and shape of their noses, in comparison to normal persons, by spending excessive amounts of time looking at themselves in mirrors. This was reported by all patients in this study and is quite different from the mirror avoidance behavior of anorexic patients. Intuitively, this would give some basis for their more accurate perception of organ size in comparison to the control subjects. After surgery, the nose is heavily bandaged for a number of weeks; therefore this "overscanning" of the nose is no longer possible. These findings are also compatible with cognitive overfocusing as an aspect of an obsessive-compulsive disorder, one component of which is the compulsive examination of the nose and associated obsessive ruminations about it, with the accompanying increase in accuracy of nose size perception found in the experimental group. Further exploration of these body-size estimation techniques may be of value in defining more effective treatment approaches for these patients.

DR. LAURENCE JEROME
*London, Ont., Canada*

## Dr. Phillips Replies

SIR: Dr. Jerome's study is interesting and adds to the literature on body image perception and psychological and psychiatric assessment in cosmetic surgery patients. However, as is the case with most studies of cosmetic surgery patients, it is difficult to determine whether his findings apply to body dysmorphic disorder, as it is not clear that the patients described had this specific disorder. Although many patients with body dysmorphic disorder seek and obtain cosmetic surgery, it cannot be assumed that all patients seeking cosmetic surgery have body dysmorphic disorder. Presumably, most cosmetic surgery patients simply want to improve their appearance and do not necessarily have an intense, distressing, time-consuming, pervasive, and impairing preoccupation with an imagined physical defect.

This issue highlights the need for diagnostic instruments and more specific diagnostic criteria to aid in the diagnosis of body dysmorphic disorder. The addition of a new criterion to this disorder's proposed *DSM-IV* definition should be useful in this regard; this criterion specifies that to meet criteria for body dysmorphic disorder the preoccupation with the imagined physical defect must cause marked distress or significant impairment in social or occupational functioning (1). It is hoped that this criterion will help differentiate body dysmorphic disorder patients from individuals with "normal" concern over appearance and from those who seek cosmetic surgery but do not have body dysmorphic disorder.

I would also add that although Dr. Jerome mentions the potential benefits of cosmetic surgery in body dysmorphic disorder, much of the literature (2,3) and my and my colleagues' work (4) suggest that surgery is generally not helpful to these patients over the longer term; they often develop more intense or new preoccupations and may have repetitive, unsuccessful surgical procedures in their disappointing search for a physical solution to a psychiatric problem.

## Long-Term Effects of Incest

SIR: We read with great interest the article by George R. Brown, M.D., and Bradley Anderson, M.D. (1) about psychiatric morbidity in patients with abuse experiences. We have also carried out research on the prevalence and the consequences of incest in patients with mental disorders and in more than 1,000 male and female nonpatients. We think that our findings (2, 3) confirm and supplement Dr. Brown and Dr. Anderson's results. Like other investigators (4–6), we found various psychopathological conditions and no definite, dominating clinical picture, no typical "incest syndrome." However, self-injurious behavior, anxiety symptoms, and forced sexual behavior proved to be the main symptoms of sexually abused patients.

Some differences can be determined in family risk variables between the sexually abused psychiatric patients and the nonclinical sample with experience of sexual abuse in childhood. Multiple impulsive personality disorder and alcohol abuse in fathers and depression in mothers could be found in the first group. Mothers of sexually abused psychiatric patients were often not accepted as confidantes or protectresses because of their own emotional and social deficits or disturbance, and thus were not experienced as supportive. The familial situations of the nonclinical sample were frequently characterized by financial problems, by a mother with a physical illness or drug abuse, and by an impulsive or helpless father.

JOHANN KINZL, M.D.
WILFRIED BIEBL, M.D.
*Innsbruck, Austria*

## Dr. Brown Replies

SIR: The work of Dr. Kinzl and Dr. Biebl, published subsequently to ours, indeed supports some of our conclusions, especially with respect to the central role of suicidality in adults with abuse histories. The distinction between a "patient" and a "nonpatient" is often tenuous and associated with economic issues and other factors influencing access to psychiatric care in the United States. Therefore, we are not surprised to see confirmatory findings in the European studies by Dr. Kinzl and Dr. Biebl. Their work, studying women referred to a psychosomatic clinic, found high rates of somatoform disorders (33% of 33 abused women) and sexual dysfunction (90%), which was not supported by our work with unselected, consecutively admitted inpatients.

The notion of an "incest syndrome" is compelling but largely unsupported by empirical research with our large group of inpatients and, now, with a comparably sized nonclinical sample in the work of Drs. Kinzl and Biebl.

The role of alcohol use disorders in fathers appears to be pivotal in the family histories of adults abused as children irrespective of the source of the study population. We believe the primary and secondary prevention aspects of this finding are critical.

Dr. Kinzl and Dr. Biebl speculate on the etiology of maternal contributions to the abusive environment. This remains an understudied phenomenon, complicated by the beliefs of some clinicians that abusive families are composed of an "offending parent" (father or stepfather) and a "nonoffending parent" (mother). For example, while serving on the U.S. Air Force Task Force on Child Sexual Abuse, I learned that this terminology was in widespread use by mental health care professionals assigned the duties of case finding, evaluation, and treatment of child abuse in the military environment. The extent to which mothers are aware of abuse perpetrated by others and fail to acknowledge this or intervene on behalf of the abused child may itself be an independent factor in the expression of adult psychopathology.

Although Drs. Kinzl and Biebl report that they have studied both male and female students, their published work to date has focused on findings in women. We look forward to their future analyses that may help to address the virtual absence of information regarding the contributions of abuse to adult male psychopathology (i.e., boys and men as victims).

## Dissociation and Suicide in the Young

SIR: Herbert Hendin, M.D. (1) has stressed the important theme that attention to the psychodynamics of suicidal patients is essential for proper therapy. Given this, it is curious that he did not mention it in multiple personality disorder, the group of patients with perhaps the highest suicide attempt rate of all mental disorders. Ross (2) found 72% had made suicide attempts. Their common psychodynamics help in understanding not only their suicidal behavior but also posttraumatic stress disorder (PTSD), conditions which manifest a high degree of dissociative experiences (3) and symptoms (4). Dissociation was the primary psychodynamic in the suicide attempt of a 37-year-old American Vietnam veteran with symptoms of PTSD (5). Dissociation phenomena do not appear to be included in the author's considerations of cognition and meaning of suicide and psychodynamics. Does the author consider dissociation in his overall scheme of psychodynamics of suicide attempts, or does he reject it and regard it as irrelevant?

GORDON D. JENSEN, M.D.
*Sacramento, Calif.*

## Dr. Hendin Replies

Sɪʀ: Although there is some evidence suggesting that suicide attempts may be associated with dissociative disorders, there is to date no evidence that dissociative disorders are associated with a high incidence of actual suicide. There is therefore no reason as yet to regard patients with dissociative disorders as being at high risk for suicide.

There is evidence that PTSD is associated with suicide attempts, but dissociative experiences have not been found to be the major predictive factor of suicide attempts in Vietnam veterans with PTSD. In our study of 100 veterans with PTSD, 20% had reliving experiences that could have led to their being diagnosed as having a dissociative disorder. Suicide attempts were not a significant factor in this group (1, 2).

The case in the literature referred to by Dr. Jensen concerns dissociative experiences in a Vietnam war veteran suffering from schizophrenia and PTSD. Since patients with both disorders are at higher risk to make a suicide attempt, one can not conclude too much from such a case. The case does underline the need to look beyond a diagnosis for an explanation of suicide, since a majority of patients with diagnoses that have a high risk for suicide, such as depression, alcoholism, and schizophrenia, do not kill themselves.

A psychodynamic formulation of the case cited would need to account for the patient's delusions that a conspiracy existed to prove him homosexual, for his belief that odors emanating from his hemorrhoids repelled women, and for the fact that after a fight with his parents he shot himself when being pursued by the police while walking with a shotgun toward the home of a girlfriend. His dissociative episodes appear to have been an important part of the defensive system he erected to protect himself against his conflicts.

Splitting as a defense, of which dissociation is an extreme form, is important in suicidal patients, since one part of the self is often being attacked by another. The psychodynamics of suicide include an understanding of why such an attack is necessary and why, for some, death is the only acceptable resolution.

## Depression After the Death of a Spouse

Sɪʀ: Sidney Zisook, M.D., and Stephen R. Schuchter, M.D. (1) studied men and women whose spouses had recently died and described the frequency of depressive syndromes during the first 3 months thereafter. I will criticize a few of the less central statements made in this fine, welcome, and lucidly described study. First, I remind readers that of the 350 spousally bereaved subjects, 24% met the *DSM-III-R* criteria for depressive episodes 2 months after the death, 23% at 7 months after the death, and 16% at 13 months after the death, in comparison to 4% of a comparison group. My comments concern the focus only on a diagnosis of depression.

The diagnosis of posttraumatic stress disorder (PTSD) was not included in the article although 125 subjects experienced the sudden death of a spouse, an event that is outside the ordinary experience of most of such subjects. The non-*DSM-III-R* diagnosis of pathological grief reaction was also not considered. Some depressions may be pathological grief reactions, others may be cyclical depressive disorders brought forward by the experience of a stressful life event in a predisposed person. It is very important in understanding cases and diagnoses to consider such parameters. In future studies it would be a good idea to assess the signs and symptoms of PTSD, including intrusion and avoidance symptoms, as well as to assess depressive signs and symptoms.

In research such as that on the consequences of losses, it is important to formulate each case and also to make every diagnosis that is appropriate to the subjects. To focus on one diagnosis may ignore the multifaceted nature of pathological grief, which may present as increased anxiety symptoms, increased depressive symptoms, psychosomatic disorder, increased mixtures of anxiety and depressive symptoms, and PTSD symptoms such as those of unduly prolonged or intense intrusion or denial.

The authors stated that "one of the long-range goals of the San Diego Widowhood Project is to develop treatment strategies based on a sound understanding of the natural history and course of bereavement." They cited several treatment modalities, including the brief psychodynamic-cognitive therapy for stress response syndromes developed at the University of California, San Francisco. They stated, "None of these is specifically geared to treat or prevent depression in the bereaved." As it happens, the University of California, San Francisco, treatment was developed in the context of treating subjects with traumas and/or pathological grief reactions. Depression is not the only diagnosis from *DSM-III-R* that applies to pathological grief reactions, and the treatment should be applied to the etiology, not the descriptive, formal diagnosis.

I think this is an outstanding study, a forward-moving effort in the study of the consequences of bereavement. I do think that study of treatment for a subtypology such as the combination of bereavement and major depressive disorder without PTSD or other diagnoses will be useful. I only wish to point out our present problem of how to "officially" diagnose pathological grief. Our present nomenclature has no set of categories for disorders caused by serious life events combined with dispositional factors. Of interest, in this domain we may soon be able to move from descriptive to etiological classifications.

*San Francisco, Calif.*

### Dr. Zisook and Dr. Schuchter Reply

SIR: We fully agree with Dr. Horowitz that grief is multifaceted and that our field needs to develop more valid and reliable ways of defining pathological grief reactions. Dr. Horowitz correctly points out that we did not include the diagnosis of PTSD in our study. However, our reading of the *DSM-III-R* criteria for PTSD is that spousal bereavement generally does not satisfy criterion A (p. 250). The boundaries between "uncomplicated bereavement" and some of the potential complications of bereavement, such as PTSD and major depressive disorder are not as well demarcated as we hope they will be by the time future editions of *DSM* come along. We also agree with Dr. Horowitz that depression is only one of several possible pathological outcomes of loss and that in future studies it would be a good idea to assess signs and symptoms of PTSD as well as symptoms of other anxiety disorders. An ideal outcome study would include not only the Impact of Events Scale (1) but also comprehensive diagnostic interviews with detailed past histories, personal resources, and intercurrent life events, and matched married control subjects. Such a study could substantially help clear up some of the aforementioned boundary problems.

Dr. Horowitz's comments prompted us to do an additional analysis. We divided the sample into subjects whose spouses' deaths were "sudden and unanticipated" (N=121) and those whose spouses' deaths were "prolonged and unanticipated" (N=168); outcome measures included depression as well as scores on nine subscales of the Hopkins Symptom Checklist (HSCL) (2) 2 months after the loss. There were no significant differences between groups in the percentage of subjects who met criteria for a depressive syndrome (24% versus 23%) or on the interpersonal sensitivity, hostility, obsessive-compulsive, paranoid, psychotic, or somatization subscales of the HSCL. On the other hand, the group whose spouses died suddenly and unexpectedly had significantly higher mean scores on the subscales for depression (1.87, SD=0.61, versus 1.70, SD=0.50; $\chi^2$=6.50, df=1, p=0.01), anxiety (1.7, SD=0.66, versus 1.55, SD=0.55; $\chi^2$=6.87, df=1, p=0.009), and phobia (1.34, SD=0.50, versus 1.19, SD=0.32; $\chi^2$=8.95, df=1, p=0.003). Thus, there are differences in outcome based on the type of death; when death occurs suddenly and unexpectedly, it is likely to be experienced as more traumatic, subsequently evoking more depressive, anxiety, panic-like, and avoidant symptoms.

We are in less agreement with Dr. Horowitz's statement that treatment should be applied to the etiology, rather than the descriptive, formal diagnosis, in pathological grief reactions. There are some data to suggest that major depressive syndromes, even when they occur in the context of bereavement, may respond well to antidepressant medication. In such cases, phenomenology may be at least as important as etiology in the selection of treatment, although neither should be ignored. However, we also feel that only well-designed, controlled studies comparing the major treatment options and combinations thereof will resolve this issue.

### Depression in Borderline Patients Who Split

SIR: Updating an earlier report on the comorbidity of borderline personality disorder and depression, John G. Gunderson, M.D., and Katharine A. Phillips, M.D. (1) considered several hypotheses relating the two pathologies, then concluded that "a surprisingly weak and nonspecific relationship exists between these disorders." In essence, they maintained that depression and personality disorder are somewhat distinct phenomena and not psychologically or biologically linked. I propose that, at least for borderline patients who use the splitting defense (2), depression and personality structure are indeed related and that the link is most likely both psychological and biological.

Why are borderline patients, particularly those who split, so prone to severe, debilitating depression, sometimes leading to mood-driven psychosis, in the face of negative experience? In part, most likely, because splitting makes it difficult for these patients to acknowledge a disappointment or loss for what it is and work it through. By creating a split self unit and a split object (other person) unit, by "dis-integrating" the ambiguity of self and other—i.e., their reality—it is possible to keep polar opposite representations of self and other separate in consciousness and so sidestep the anxiety of having to deal with the "whole" situation all at once.

To come to terms with a loss or disappointment, the initial meaning of what was lost must first be acknowledged and lived. But this is precisely what splitting borderline patients cannot do, because it requires accepting the ambiguity of the situation in lived consciousness. Attempting to deal with a loss, these patients continue to oscillate between positive and negative meanings of it, perceiving the lost possibility or object first as all good, then as all bad, embracing only half the reality in each oscillation. Such defensive maneuvering, skating around any stable meaning, makes coming to terms with the lost possibility or object impossible.

It seems likely that the way the world is perceived in response to negative experience is a more complex phenomenon for a splitting borderline patient than for someone without this pathology and that the consequent depression of the borderline patient would be more profound and difficult to reverse. Differences in the nature of depression in borderline and nonborderline patients have been noted, and the latter group is known to be less responsive to antidepressants and lithium (1). Adding to all this the possibility that borderline splitting may itself have a neural basis (3), it seems reasonable to leave open to further empirical test the question of whether depression in borderline patients who split is psychologically and biologically related to the personality disorder.

## Borderline Personality Disorder and Depression

SIR: A recent article by John G. Gunderson, M.D., and Katharine A. Phillips, M.D. (1) overstated the differences between borderline personality disorder and depression. Specifically, the overlap between borderline personality disorder and certain forms of nonendogenous or atypical depression received insufficient attention. While the authors mentioned hysteroid dysphoria, a form of atypical depression, they failed to note several important findings. Parsons et al. (2) showed that atypical depressive subjects who also met borderline personality disorder criteria were more selectively responsive to monoamine oxidase inhibitors (MAOIs) than those who did not, and that phenelzine response rates in the former group were in the 90% range. Also, Liebowitz et al. (3) found that borderline personality features per se in atypical depressive subjects improved to a significantly greater extent with the MAOI phenelzine than with the tricyclic imipramine or placebo, suggesting that borderline features in this population are affectively mediated.

In general Dr. Gunderson and Dr. Phillips are correct that borderline personality disorder can be readily distinguished from melancholic or endogenous forms of depression that are highly responsive to tricyclics. However, the relationship of borderline personality to more specifically MAOI-responsive atypical forms of depression is still uncertain, and the overlap appears substantial. To minimize this is to risk undertreatment of potentially MAOI-responsive borderline patients.

## Dr. Gunderson and Dr. Phillips Reply

SIR: "The practical hazard of hypothesis III [that borderline personality disorder and depressive disorders coexist but are otherwise unrelated] is that patients with the borderline syndrome sometimes respond partially and occasionally respond dramatically to antidepressants, suggesting that clinicians should not rule out use of this treatment" (p. 974 of our article). We made this statement despite the overwhelming data indicating that there is no relationship between these disorders because, from a clinical and conceptual standpoint, we favored a more complex interactive model with its possibility of shared etiologic sources. In this regard, we are grateful for Dr. Liebowitz's letter, buttressed by two references of which we were unaware, in which he offers some substantiation of our preferred model.

On a different level, Dr. Liebowitz's letter should be seen as expressing the concern of a psychopharmacologically oriented psychiatrist who fears that the subgroup of borderline patients who may respond to MAOIs will go unrecognized and be unnecessarily mistreated. This widely acknowledged concern has its battered counterpart in the concern that, in the search for a pharmacological cure, the majority of borderline patients (who show only modest or even no response to medications) will be misguided by an expectation for rapid change and deflected from recognizing the importance of the psychosocial sources of their difficulties (e.g., neglect and abuse) and the possible value of psychosocial treatments (e.g., psychotherapy, Alcoholics Anonymous, family therapy). However undocumented their effectiveness, such psychosocial treatments address the issues essential to the longer-term welfare of borderline patients.

A naive reader might conclude from Dr. Liebowitz's letter that it has now been established that MAOIs have substantial benefits for many, even most, borderline patients. Yet, Cowdry and Gardner (1), who conducted the only direct test of MAOIs on a rigorously defined sample of borderline patients (unlike the two references cited by Dr. Liebowitz), reached a far more modest conclusion: "It is critical that the medication trials be a collaborative effort between patient and physician and that the medication be understood by all as an adjunctive treatment modality that is likely to be of limited benefit rather than a magic potion or panacea" (p. 118).

## ECT Response in Catatonia

SIR: Michael Smith, M.D., and Breck Lebegue, M.D. (1) described a man with severe chronic catatonia who did not respond to 20 ECTs or sequential trials of several pharmacological agents but who showed clinical improvement on a regimen of 20 mg/day of lorazepam. The lack of response surprises us in view of the reported experience (2, 3) of the successful treatment of catatonia with ECT. Further details of the ECT are needed. Specifically, we need to query whether the treatments were adequate, by examining such elements as concurrent medication (especially benzodiazepines), electrical dosage, seizure threshold, electrode placement, and duration of the seizures (4).

Unless seizures are monitored for adequacy there is no assurance that "treatment" was actually done. The APA task force report (5) argues that if the response to six to 10 treatments is insufficient, modification of ECT technique should be considered, including "switching from unilateral to bilateral ECT, increasing stimulus intensity levels, and using medications to potentiate the ictal response" (p. 103). Additionally, early workers used percent time in slow wave EEG activity or sedation threshold as an index of treatment efficacy (6).

Thus, until the reader is assured that the ECT in this case was adequately administered, the expressed view that a catatonic patient failed to respond to ECT should be questioned, as the evidence for efficacy of ECT in this syndrome is compelling.

## Dr. Smith Replies

SIR: I thank Drs. Francis and Fink for underscoring an important consideration in the treatment of catatonic schizophrenia.

In answer to their query, the following information is provided. Mr. A had a total of 20 ECTs, 11 of which were with bilateral lead placement. The total seizure time, as determined by observed tonic-clonic muscle activity, was 661 seconds, with an average seizure time of 33 seconds. The longest seizure was 54 seconds, the shortest was 20, the standard deviation was 11 seconds. Additional parameters included a pulse width of 1.5 msec, stimulus duration of 2.0 seconds, and a frequency of 70 Hz. The treatments were given over a 49-day period, averaging one treatment every 2.5 days. At the time of the first ECT, Mr. A was being treated with lorazepam (1 mg/day), as well as haloperidol (10 mg/day). The lorazepam was discontinued after the second treatment and was reinitiated after the ninth treatment, as a result of Mr. A's increasing agitation, at a dose of 3 mg/day. It was continued at that dose through the remaining ECTs. Seizure-enhancing medications (e.g., caffeine) were not utilized.

## GABA-Benzodiazepine Receptors

SIR: I would like to compliment Charles F. Zorumski, M.D., and Keith E. Isenberg, M.D., on their elegant article (1). The authors provided a thorough review of the relationship of centrally acting benzodiazepines to the $GABA_A$ macromolecular complex and associated ion channel. As the title suggests, they incorporated considerable insight into the possible mode of action of GABA-related compounds and provided cogent explanations of, and support for, the functional significance of cited observations. Despite the article's eloquence, there was an error, possibly stemming from an apparent oversimplification regarding drug actions at benzodiazepine receptor subtypes, which warrants attention and correction. The original studies of the $BZ_1$ selectivity of CL 218872 (a triazolopyridazine) suggest that $BZ_1$ receptors are primarily associated with an anxiolytic response as opposed to other benzodiazepine-related effects (e.g., sedative-hypnotic). These conclusions, however, remain largely unsubstantiated and may reflect the unique properties of CL 218872 more than a general action mediated by $BZ_1$ receptor sites. Other classes of compounds such as the imidazopyridines (zolpidem) and the pyrazoloquinolines are also $BZ_1$ receptor selective but are known for their sedative-hypnotic as opposed to anxiolytic characteristics. The only $BZ_1$ selective sedative-hypnotic currently available is quazepam (2–6).

Quazepam is marketed under the trade name Doral. Drs. Zorumski and Isenberg erroneously employed quazepam as an example of a $BZ_2$ selective agent. Clearly, this is not the case. Although molecular biological studies indicate there are more than just two central benzodiazepine receptor subtypes, quazepam still relates more closely to what has been classically defined as $BZ_1$ rather than $BZ_2$ receptor activity. The theory that $BZ_1$ receptor activation is exclusively involved in sleep mechanisms is likely to prove to be an oversimplification as well, but, as pointed out by Drs. Zorumski and Isenberg, such hypotheses serve as heuristic starting points for the development of effective therapeutic agents with fewer side effects. As a scientist committed to elucidating quazepam's activity at central $BZ_1$ sites, and on behalf of my colleagues working in this area, I hope that this inaccuracy will be corrected.

*Fargo, N.D.*

## Dr. Zorumski and Dr. Isenberg Reply

SIR: Dr. Wamsley raises an interesting and important point regarding drug actions at the $GABA_A$-benzodiazepine receptor. He contends that quazepam is selective for the benzodiazepine $BZ_1$ subtype of receptor. An important goal of current pharmacological research, as Dr. Wamsley notes, is to elucidate the site at which drugs exert their effect on the $GABA_A$ receptor. A purpose of our review was to indicate to readers the surprising number of GABA receptor subunits, all of which could function as sites of action for various drugs. Other reviewers, noting the proliferation of $GABA_A$ receptor subunits, calculate the potential magnitude of receptor complexity (1). Current pharmacological typing underestimates actual receptor complexity. Future work, integrating pharmacological and physiological approaches with molecular techniques, will better define the site of action of currently available drugs as well as offer the promise of more specific agents for the treatment of psychiatric disorders.

## Mania and AIDS

SIR: The article by Karl Kieburtz, M.D., and his colleagues (1) described eight AIDS patients who developed mania at some point after HIV infection. The authors stated, "No cause for a secondary affective disorder other than HIV infection was identified." However, they did not mention how they determined that the manic episode was not due to zidovudine (five patients were taking zidovudine prior to admission) or to antidepressant therapy (four of five patients with histories of depressive disorder were treated with antidepressants), both of which are known to cause manic symptoms (2, 3). Since this population is known to have more frequent and severe side effects from standard pharmacotherapies, clarification of this point would be helpful.

In addition, because primary affective disorders can occur at any age, it is possible that some patients could have been at higher risk for developing a mood disorder regardless of, or in addition to, any physical disorder. Information regarding any family psychiatric history may help substantiate or refute the likelihood of such an occurrence.

VALERIE F. HOLMES, M.D.
*Durham, N.C.*

SIR: Dr. Kieburtz and associates suggested that AIDS causes mania. Additional mechanisms might explain the increased prevalence of mania in their AIDS population and would also predict an increased prevalence of HIV infection among patients with manic presentations. First, crack and intravenous cocaine abuse, which increase the risk for HIV and syphilitic infection (1), can themselves present as mania and can exacerbate preexisting mania (*DSM-III-R* and 2). Mania from cocaine, affective illness, or a combination of these can persist even after urine testing for recent cocaine use has become negative. False negative urine testing can also occur. Recent users of large amounts of cocaine were locked into a drug-free unit and given two types of urine tests. Thirty-seven percent had a negative urine test preceded and followed by a positive test on one or both tests (3). Second, mania as a primary disorder is associated with the behaviors of hypersexuality and substance abuse (*DSM-III-R* and 2), which are risk factors for HIV and syphilis. Substance abuse has been repeatedly linked to sexual risk-taking behaviors that increase the risk for sexually transmitted diseases, including HIV infection (1). Neurosyphilis, which is possibly on the increase, is associated with HIV infection and it can present with mania. Symptomatic HIV infection gives serum syphilis tests a higher false negative rate (4).

Since the presence of HIV risk factors is often denied, we propose strong consideration of HIV testing in manic presentations, especially when the patient is 30 years old or older or presents with hypersexuality, even when a urine test for detecting cocaine use is negative. Thirty is the minimum age for stronger consideration of HIV testing on the basis of the epidemiology of cocaine abuse and affective illness and the average age of 37 for Dr. Kieburtz and associates' patients. Cocaine abuse usually begins in a patient's teens or 20s (*DSM-III-R*), so by age 30 many crack or intravenous cocaine abusers will have used these drugs long enough to increase their HIV risk. Bipolar and schizoaffective disorders can present in adolescence, although usually their onset is in the third decade (*DSM-III-R*). Therefore, many bipolar and schizoaffective patients will have had enough previous manic episodes by age 30 for the hypersexuality and substance abuse of mania to increase their HIV risk. We suggest that other etiologies for the mania associated with HIV infection be considered before concluding that HIV itself causes mania.

## Dr. Kieburtz and Dr. Caine Reply

SIR: These letters reflect the difficulty in establishing the cause of a secondary affective disorder. As we described in our article, we chose to follow specific a priori criteria for establishing that in these patients a manic syndrome was secondary to HIV infection. These criteria included the fact that the patients presented with a characteristic manic syndrome and demonstrated coexisting or emerging cognitive impairment. Additionally, there was laboratory evidence of active cerebral disease, as well as evidence of active immunosuppression. Furthermore, we evaluated the patients comprehensively for other causes of secondary mania, although given the space limitations we did not describe all the negative testing or unrevealing assessments. We could identify no well-established cause of a secondary affective disorder other than HIV infection in these patients. This search included consideration of prescribed medicines, over-the-counter medications, and substances of abuse. Additionally, secondary infections and other medical causes of mania were excluded.

Regarding the comments by Dr. Holmes, zidovudine has not been convincingly shown to cause a secondary mania. The reference cited by Dr. Holmes was a letter to the editor that presented two case reports. It would be difficult to establish a causal relationship based on these limited data. In our patient, there was certainly no temporal relationship between zidovudine therapy and the development of manic symptoms. Additionally, the one patient who began taking zidovudine during hospitalization for the manic syndrome showed no adverse effects from this medication. In response to Dr. Holmes' other question, five patients had a prior history of an affective disorder, as stated in the article. Four of these patients had been treated with antidepressants in the past, but at the time of their manic syndromes none of the patients was receiving such therapy. Four of these same five patients also had family histories of affective disorder, with depression in three families and a history of bipolar disorder in one.

Regarding the comments by Dr. Whitefield and associates, all patients were screened for drugs of abuse. Similarly, all patients were tested for the presence of syphilis. Admittedly, these tests may be imperfect; however, the laboratory tests were only one element in our clinical evaluation of each subject. On the basis of our examination and knowledge of these patients, we could find no evidence that their mania was caused by cocaine abuse or syphilis. All of these patients were well known either by colleagues or the authors before their psychiatric inpatient admission, or they were followed after discharge. No clinical data have substantiated an abuse-related etiology for their mania. Furthermore, the likelihood of these tests being falsely negative for the entire group of eight patients was particularly unlikely.

Our data did not support the recommendation that patients with mania be tested for HIV routinely. All of the patients we described had progressed to AIDS by the time their mania developed. Their primary diagnosis of HIV infection was obvious due to their opportunistic diseases. It has not been our experience that the manic syndrome occurs early in HIV infection or in otherwise asymptomatic patients.

We also strongly advocate the vigorous search for other secondary causes of mania before concluding that a patient with AIDS has mania due to HIV infection. It has been our experience that there is usually additional evidence supporting this diagnosis, e.g., meningeal enhancement on magnetic resonance imaging or emerging cognitive impairment. Thus, patients should fulfill the full array of criteria for establishing a secondary syndrome before concluding that their mania is due to HIV infection.

## Blunting of Clonidine-Stimulated Growth Hormone Release in Mania

SIR: In their excellent article showing blunted growth hormone (GH) stimulation in response to desipramine, Timothy G. Dinan, M.D., M.A., and associates (1) stated that to their knowledge, GH reponses to noradrenergic challenges have not been previously investigated in mania. In fact, my colleagues and I have already shown a similarly blunted GH response to clonidine (0.15 mg i.v.) in seven drug-free manic patients age- and sex-matched to seven inpatients with major depression and seven with minor depression (2). The mean GH peak was similar in the manic patients (3.2 ng/ml, SD=2.4) and in the patients with major depression (3.2 ng/ml, SD=2.4) and significantly lower than in the subjects with minor depression (13.2 ng/ml, SD=8.7).

Results of these two studies support the hypothesis that $\alpha_2$-receptor abnormalities represent a trait marker for affective disorder. Another important consideration in interpreting these results is that the increased receptor sensitivity hypothesized to be related to mania (3) would be expected to peak in the later phases of bipolar depression before the "switch" to mania and to attenuate after the onset of the manic episode as receptors down-regulate in response to increased catecholaminergic availability. In fact, the only suggestion of augmented GH responses to clonidine challenge has been found in bipolar depressed patients (4). Therefore, the results of these two studies do not suggest sustained increases in $\alpha_2$-adrenergic receptor sensitivity in mania but cannot address the apparently more physiologic hypothesis advanced by Bunney et al. (3) that receptor increases precede the "switch" to mania, since the patients were evaluated at least several weeks after the onset of the manic episode. Obviously, the evaluation of the "switch" hypothesis needs longitudinal studies of bipolar patients.

## Challenge for Psychiatry

SIR: The editorial by Allan Beigel, M.D. (1) was timely. It brought to our attention how our profession can be used by government for motivations other than patients' care. The beauty of the editorial, if I understood it correctly, is that while recognizing the plight of our colleagues in Eastern Europe who worked for years under the Communist ideology, it also called for our attention to problems of a similar nature in this country.

Dr. Biegel mentioned the dilemmas faced by psychiatrists in the United States who are asked to work in less than satisfactory conditions and to abide by ideologies that do not always make patients' care the first priority. I am thinking here of the public psychiatrists in America, often foreign medical graduates without many options of employment, who must accept impossible case loads of patients housed in totally improper therapeutic environments and even who are pressured to discharge these patients to the streets, to become homeless. I am also thinking of the psychiatrists in the private sector who , in order to survive economically, are being asked to abide by an "ideology of the brain" that is robbing the American psychiatric patient of his or her soul.

I have nothing against psychiatrists in the United States extending a hand to help our Eastern European colleagues to move to a different political system. But let us not forget that charity begins at home and that maybe now is the time for American psychiatrists to lose their fears of speaking out against policies, government or private, that are contrary to the promotion of mental health.

# Position Statement on Day Care for Preschool Children

*This statement was prepared by the Task Force on Day Care for Early Pre-School Children[1] of the APA Council on Children, Adolescents, and Their Families. It was approved by the Assembly of District Branches in November 1991 and by the Board of Trustees in December 1991.*

The American Psychiatric Association recognizes that the early development of children has a profound impact on later psychological development and the potential of individuals. Practicing psychiatrists are confronted directly and indirectly with questions related to child care through their involvement with families. The psychiatrist, as physician, is able to integrate the knowledge and skills needed in understanding the biopsychosocial dimensions that arise for all concerned with child day care. The Task Force on Day Care for Early Pre-School Children is cognizant of the debate on the merits of day care, the controversy about its impact on development, and the absence of comprehensive criteria to assess day care quality.

Research indicates that the infant-parent relationship is a fundamental cornerstone of infant development: a secure attachment to ongoing caregivers (most often parents) has been identified as a necessity for psychological and emotional development. Infants who are securely attached to their caregivers are more socially competent than infants who have not developed secure attachments.

Other research indicates that when parents can take advantage of leave from work, infant-parent attachment is enhanced. Demonstration of those findings required a minimum of 4 months of leave, but further research may be able to better pinpoint the crucial developmental times when such added parental presence is particularly helpful. Clearly, whether parents are in professional or occupational training or in the general work force, special considerations are vital to support parenting functions.

There is evidence that good-quality day care for preschool children in vulnerable populations has a *positive* developmental outcome. Additional research has documented that poor-quality care has detrimental developmental consequences for infants and young children. Better working conditions for child care providers correlates with stability of staff and continuity of day care offered to the children, both important variables in quality care.

Often child care by persons other than parents is not a matter of choice. Thus, both government and the private sector must respond to this reality. To assure the well-being of children and the facilitation of the family, the developing body of information about the influences on health development must be considered. Whether traditional family care or child day care, it is the quality of care that is crucial.

Primary developmental issues are significant throughout the preschool years, and they increasingly involve not only the parents but also other caregivers and peers. At the same time that interpersonal relationships increase in complexity, maturing youngsters also solidify their intrapsychic development. Day care provides a special opportunity for enhancement of or interference with development. Good preschool day care incorporates attention to all health care issues, alertness to hazards of traumatic experience (including abuse), and special attention to individual needs related to physical illness, handicaps, and cultural and ethnic uniquenesses. As psychiatrists, we are particularly aware that the absence of attention to these important factors in child development can lead to psychopathology, both in childhood and in adult life. Therefore, the American Psychiatric Association adopts the following policies:

1. The American Psychiatric Association, with other national organizations, shall advocate for the right of children to have developmentally appropriate care in a safe and caring environment.
2. The American Psychiatric Association believes that the assurance of quality care through a variety of means is essential for the healthy development of children. The adoption of developmentally appropriate day care standards is integral to the achievement of quality care.
3. The American Psychiatric Association will work with other professional organizations and consumer groups to help inform parents and other utilizers of child care about the issues of quality day care.
4. The American Psychiatric Association and its district branches, with other appropriate groups, will work to recognize the professional role of child care workers and the importance of appropriate compensation and provision of career incentives. The continuing development of training curricula for child care workers, with sensitivity to cultural diversities, is essential.
5. The American Psychiatric Association recognizes that certain populations may require special consideration in the development of day care standards. Additional educational and supportive services may be desirable to provide adequately for the care of, for example, children of single parents or two-job employees or children who are mentally or physically disadvantaged.
6. The American Psychiatric Association urges the adoption of policies, by all appropriate parties, that will allow the type of parental leave options, including part-time training and employment, that will enhance mother-infant bonding and the facilitation of the family. The absence of appropriate parental leave policies places children and families at risk for adverse psychological development.
7. The American Psychiatric Association urges increased research on the impact of day care on preschool children. Research is needed within the ecology of day care, not only focusing on the child per se but also extending to the potential consequences for the family system and for our society.

# Gender Differences in Pharmacokinetics and Pharmacodynamics of Psychotropic Medication

**Kimberly A. Yonkers, M.D., Judith C. Kando, Pharm.D., Jonathan O. Cole, M.D., and Susan Blumenthal, M.D., M.P.A.**

*Objective: This review explores the theoretical background for and empirical evidence supporting gender-related differences in pharmacokinetics and pharmacodynamic properties of psychotropic medications. Method: The authors reviewed all English-language articles on this topic that involved original research using human subjects. Results: Limited evidence suggests that young women seem to respond better to and require lower doses of antipsychotic agents and benzodiazepines than young men. The administration of exogenous hormones interacts with medications, changing plasma levels and possibly conferring greater risks for toxicity. Young women may have an enhanced response to nontricyclic antidepressants. Conclusions: Too little basic and clinical research has been conducted on sex differences in therapeutic effects and side effects of psychopharmacological treatments. Addressing these differences as well as similarities will lead to safer and more effective treatment for all patients.*

(Am J Psychiatry 1992; 149:587–595)

As effective pharmacological treatments are found for many psychiatric disorders, psychiatrists have become acquainted with the nuances of prescribing such treatments. Pharmacological research is a guide for psychiatrists as they weigh therapeutic effects against side effects or potential adverse reactions. Research reveals sources of variability in therapeutic properties and adverse effects of medications (pharmacodynamics) and the amount of drug available for therapeutic action after administration (pharmacokinetics). One important source of variability to be considered is the sex of a patient. Phase I studies, which determine therapeutic doses, are conducted with male subjects, but women seek treatment and receive psychotropic medication more frequently than men (1, 2).

There are theoretical reasons to suggest gender-related drug effects, and there are limited clinical data to support such hypotheses for different psychopharmacological agents. In this paper we explore the theoretical reasoning behind sex differences in pharmacokinetics and pharmacodynamics of psychotropic agents. We then summarize the literature on this topic as it pertains to psychotropic medications. It is our hope that this summary will disseminate what is known about gender-related differences in psychopharmacological agents and encourage thought for areas of future exploration.

## POTENTIAL SEX DIFFERENCES IN PHARMACOKINETICS

### *Absorption and Bioavailability*

The percentage of drug that is absorbed from the gastrointestinal tract depends on the acid base and lipophilic properties of the drug as well as the physiology

---

Received March 18, 1991; revision received Oct. 23, 1991; accepted Nov. 12, 1991. of the gastrointestinal tract. The degree to which a drug is ionized affects its solubility. It has been suggested that women secrete less gastric acid than men, leading to potential gender differences in absorption (3). There are also several studies indicating such differences in gastric emptying. Wald et al. (4) examined gastrointestinal transit time in women during the menstrual cycle, once in the follicular phase, when progesterone levels are low, and once in the early luteal phase, when progesterone levels rise. They found that transit time was prolonged significantly in the luteal phase. However, a study using a different method conducted by Horowitz et al. (5) yielded conflicting results. Horowitz et al. concluded that progesterone caused slowing in the small intestine during the luteal phase. Datz et al. (6) undertook a study to determine if nonpregnant women empty solids and liquids differently from men. They found that women empty both solids and liquids more slowly. The mechanism for the difference is unknown, but Datz et al. proposed that it is the effect of progesterone and estradiol on the gastrointestinal tract.

These findings suggest that gonadal hormones may play a role in changing absorption rates, which can affect bioavailability. Bioavailability is the fraction of administered dose that reaches the patient's systemic circulation (7). If the bioavailability of a drug given to women is substantially altered, the dose will need adjustment in order to achieve a comparable concentration in the plasma.

Given the many variables that need to be considered, it is difficult to determine the specific effect of less gastric acid secretion and slower gastric emptying. One can speculate about several possibilities, however. For example, most absorption occurs through the intestinal mucosa. A smaller degree of absorption occurs in the acidic stomach, where enzymatic and mechanical activities digest and break down larger compounds. Since enzymes can denature proteins, an increase in the speed of gastric emptying generally decreases exposure to enzymes and increases the opportunity for absorption in the intestine (8). Thus, a lower gastric emptying rate during the luteal phase, as suggested by Wald et al. (4), would ultimately decrease the amount of drug absorbed. However, if transit time is prolonged in the intestine, as Horowitz et al. (5) suggested, the opposite would occur.

By maintaining the necessary acidic environment for enzymatic action, gastric acid secretion adds an additional variable to the absorption equation. For weak acids, an acidic environment establishes a nonionic state. This enhances their absorption because compounds require neutralization in order to be absorbed through a nonpolar lipid bilayer. Conversely, if the acidic environment is maintained, absorption is decreased for weak bases because they remain ionized. A decrease in gastric acid secretion, as noted in the study of Grossman et al. (3), may decrease enzymatic action and decrease the absorption of weak acids but increase absorption of weak bases.

These possibilities are simplified and provide just an outline of hypothetical sex-related or menstrual cycle variations in absorption. These effects are complicated and may counterbalance one another; ascertainment of gender-related differences in bioavailability will ultimately require empirical studies of different compounds.

### *Distribution*

The physical and chemical properties of a drug determine its distribution. These properties include acid base, water and lipid solubility, and affinity for binding proteins (9). Changes in vascular volume and tissue volume also alter the distribution of a drug (8). If the volume of distribution of a drug is changed, the loading dose and the dosing interval during therapy might have to be modified.

The ratio of lean body mass to adipose tissue mass can also affect a drug's disposition. In general, females have a lower ratio of lean body mass to adipose tissue (10). Drugs with a high affinity for adipose tissue (e.g., diazepam), would be expected to demonstrate a greater volume of distribution in females. Other factors that affect the volume of distribution include differences in blood volume, cardiac output, and organ size (8). Drugs that have a greater volume of distribution would probably have a lower serum concentration when first administered. Over time, however, the potential for storage of medication in adipose tissue is higher. Thus, half-life may become prolonged and serum levels may be greater in patients with less lean body mass. The effect of sex on these factors in relationship to specific drugs has not been adequately studied.

### *Metabolism*

The hepatic drug metabolizing enzymes play an important role in the removal of many drugs from the systemic circulation. Drugs may undergo either phase 1 or phase 2 metabolism. Phase 1 metabolism consists of oxidation, reduction, and hydrolysis; phase 2 metabolism consists of glucuronidation and sulfation. Hepatic extraction is the amount of medication that is removed from the systemic circulation by the liver. Drugs with a high hepatic extraction ratio are sensitive to hepatic blood flow rather than hepatic enzyme activity. Antipyrine, a substance with a low hepatic extraction ratio, is often used to evaluate the oxidative function of the liver (11). Studies examining the effect of gender on the plasma half-life of antipyrine have produced conflicting results. Riester et al. (9) and Fraser et al. (12) found no difference between men and women, but O'Malley et al. (13) found that the antipyrine half-life was 30% longer in men than women, thus supporting a gender-specific difference in oxidative function for this drug. However, O'Malley et al. did not control for smoking and menstrual cycle effects and Riester et al. did. This probably accounts for these discrepancies. Studies examining gender differences in phase 1 and phase 2 metabolism are needed to clarify this issue.

The liver is also responsible for first-pass metabolism. The first-pass effect occurs when a drug is absorbed from the gastrointestinal tract into the portal circulation. Drugs are then extensively metabolized in the liver before they reach the systemic circulation (7). The systemic clearance of drugs that undergo extensive hepatic metabolism are sensitive to changes in hepatic blood flow. Studies examining gender differences in hepatic blood flow are lacking.

### *Menstrual Cycle Effects*

There are several possible menstrual-phase-specific changes such as those involving gastric motility. Although studies confirming changes in weight across the menstrual cycle are inconsistent, a subgroup of women do experience water retention (14). Potential changes may include increases and decreases of the volume of distribution. One study found evidence of menstrual phase changes in transcapillary fluid dynamics, resulting in fluid shifts between intravascular and extravascular spaces (14). Again, empirical studies are lacking, but an increase in fluid retention may dilute the concentration of medications, resulting in lower plasma levels. Of course, the amount of fluid retained would have to be quite large. The opposite would occur if fluid shifts favor extravascular volume increases.

Changes in the activity of hepatic microsomal oxidase systems may occur depending on the cycle phase and levels of progesterone and estrogen (15). Monamine oxidase activity may be decreased by estrogens and increased by progesterone (16, 17). There is also evidence that exogenous ovarian hormones affect the metabolism of medications. In a study looking at women's capacity to complete cognitive and behavioral tasks (e.g., driving an automobile), Ellinwood et al. (18) found that women taking oral contraceptives and a standard dose of diazepam throughout the menstrual cycle were relatively "intoxicated" during the menses. By showing that the same oral dose of a benzodiazepine had a more potent effect during one part of the menstrual cycle, these authors demonstrated that the pharmacodynamics of the benzodiazepine changed across the cycle. This highlights the importance of establishing menstrual cycle phase when investigating pharmacodynamic as well as pharmacokinetic properties of psychotropic medications.

## SEX DIFFERENCES IN PSYCHOTROPIC AGENTS

### *Antipsychotic Agents*

The literature analyzing pharmacokinetics, pharmacodynamics, and side effects of psychotropic agents by sex is the most substantial for antipsychotic drugs (table 1). Several researchers have found higher plasma levels of antipsychotics in female subjects (20, 21). Simpson et al. (20) found higher fluphenazine levels in women despite comparable dosing and similar age and weight characteristics. Chouinard et al. (21) investigated fluspirilene, a long-acting injectable neuroleptic, and found that women required roughly half the doses required by men despite similar weight and age characteristics. In this trial, the prescribed doses were titrated to therapeutic efficacy. Unfortunately, serum levels were not reported.

Antipsychotic drug levels were reported in another recent study that explored the relationship among thiothixene levels, demographic variables, and drug interactions (22). Men had significantly higher oral clearance than women; clearance did not necessarily correlate with body weight. The authors also found a reduction in clearance for subjects over the age of 50. They did not say whether factors of smoking and concurrent use of enzyme-inducing drugs overrode these demographic variables.

Rather than using explanations based on pharmacokinetics, several authors have suggested that properties of ovarian hormones may modify and improve the efficacy of antipsychotic treatment in women. Chouinard and Annable (19) found that women had greater improvement than men after treatment with pimozide and chlorpromazine. The weights of the men and women were equivalent, as were the doses prescribed. Chouinard and Annable (19) hypothesized that the greater efficacy in young women was due to the presumed antidopaminergic effect of estrogen (27, 28).

Several authors (23, 24) invoked antidopaminergic properties of estrogen to explain why young women are prescribed lower average doses of antipsychotics than are young men. These researchers assumed that the level of medication prescribed reflects the amount of medication required for a therapeutic response. Given that assumption, these authors suggested that premenopausal women receive additional antipsychotic benefit. In addition to the possibility that estrogen's dopamine-receptor-binding activity contributes to antipsychotic efficacy, it has recently been shown that progesterone may have a role in inducing behavioral changes (29). Several major metabolites of progesterone bind to the $\gamma$-aminobutyric acid receptor complex (29). Depending on the metabolite, they provoke agonist and antagonist activities.

The possibility of gender differences in the actions of antipsychotic medications is also implied by the variable expression of antipsychotic-induced side effects. It has been suggested that the incidence of tardive dyskinesia is greater in women (25, 26, 30). Smith et al. (25, 30) found that the severity of tardive dyskinesia was far greater in women over the age of 67. Chouinard's group (26) also reported that young men in their sample had a higher prevalence of severe dyskinesias than women. In a subsequent letter (31), they explained this discrepancy by suggesting that postmenopausal status and loss of estrogen-induced supersensitivity may favor the development of tardive dyskinesia in postmenopausal women. If estrogens were acting in some way at dopamine receptors, it would be consistent with a protective effect for premenopausal women.

The literature comparing the action and side effects of antipsychotic agents supports gender-related dissimilarities in plasma levels and side effects as well as the possible therapeutic advantage of these agents. Again, the assumption that the dose prescribed is the required

therapeutic dose for an individual may not be accurate. Further, estrogen has not been directly tested as an antipsychotic agent in humans; therefore, the binding capacity of estrogen may not be equivalent to antipsychotic efficacy. Thus, these studies do not confirm hypotheses about gender-related differences in therapeutic effect. However, several areas of further investigation are suggested by these findings. It is clear that age needs to be considered when looking at gender differences because of the critical interactions between gender and age. In addition, studies need to carefully define menstrual status, cycle phase, weight, and exogenous hormone administration in their subjects. Finally, it will be important to test some of the hypotheses regarding the psychotropic effects of ovarian hormones that are suggested by basic science research.

### *Benzodiazepines*

Whereas research on antipsychotic agents investigated possible gender-related variations in efficacy, research on benzodiazepines has looked more closely at pharmacokinetic issues (table 2). Few of these studies evaluated gender differences in therapeutic effects and

side effects. Greenblatt et al. (32) found that diazepam, a benzodiazepine which is oxidatively metabolized, has a higher clearance in younger women than in men. The statistical significance of this difference disappeared in women who were 62–84 years old. MacLeod et al. (33) found that women metabolized the drug more slowly than men regardless of age (33).

Oral contraceptives have been found to decrease the clearance of benzodiazepines (34, 35). Ellinwood's group (18) postulated that oral contraceptives decrease the rate of absorption of diazepam, leading to a slower peak in levels. Cognitive and psychomotor tasks were more impaired during the week off hormones in women taking oral contraceptives because benzodiazepines peaked more quickly. This suggested that change in absorption rates for the week off hormones led to a dose of benzodiazepine which suddenly became intoxicating.

No sex differences in metabolism have been found for triazolam, a benzodiazepine that is also oxidatively metabolized (36). Nitrazepam, a drug metabolized by reduction, has not been found to have gender-related or menstrual-cycle-related differences in clearance (15). However, higher steady-state levels of this drug have been noted in oral contraceptive users (15).

Temazepam and oxazepam, benzodiazepines that undergo glucuronidation, had slower clearance rates among female subjects in several studies (36–38). This difference was apparent regardless of age (36). The methodology used in studies examining gender-related differences in the pharmacokinetics of benzodiazepines makes their generalizability provisional. The interindividual differences were large. In addition, researchers did not control for the enzyme-inducing effects of cigarette smoking (8) or autoinduction of enzymes over time, variables that could obscure or evoke sex-related differences. However, the preponderance of evidence suggests that benzodiazepines which are conjugatively metabolized have slower elimination rates in women than in men. Oral contraceptives seem to inhibit clearance and decrease the rate of absorption. Only one study looked at menstrual cycle effects (18), and it found no significant cyclic changes. Given the relationship between exogenous hormones and benzodiazepines, it would be worthwhile looking more closely for menstrual cycle effects. In addition to measuring plasma levels, it would be interesting to test physiological response throughout the menstrual cycle, as was done by Ellinwood et al. (18).

### *Antidepressant Agents*

Given the literature citing the higher prevalence of depressive disorders in women (39), the paucity of studies addressing sex-specific medication effects is surprising (table 3).

Hamilton et al. (40) investigated gender-specific neuropharmacological responses to antidepressant drugs. When men and women were treated with clorgyline, a negative correlation between changes in anxiety and activation was found for men but no such link existed for women. When amphetamine was administered, the negative correlation between antidepressant response and anxiety existed for both sexes, but only women showed a link between anxiety and depression.

A study by Davidson and Pelton (41) evaluated the efficacy of tricyclic antidepressants and monoamine oxidase inhibitors (MAOIs) by gender in three types of atypical depression. Their data showed that depressed women with panic attacks had a more favorable response to MAOIs than to tricyclic antidepressants, whereas men who were depressed and had panic attacks responded more favorably to tricyclic antidepressants.

By reanalyzing data from an earlier study, Raskin (42) attempted to define gender-specific antidepressant effects. He found that young women (younger than age 40) responded less well to imipramine than did older men and women. Raskin hypothesized that the activating and energizing properties of imipramine exacerbated hostility in young women. Young men responded better to chlorpromazine, perhaps because of its sedating properties, but responded less well to phenelzine than younger women.

A study by Halbreich et al. (43) examined *d*-amphetamine-induced changes in mood and activation in postmenopausal women and young men. They found that postmenopausal women became dysphoric and sedated, but young men experienced euphoria and an increase in alertness with *d*-amphetamine treatment.

Little research has been undertaken examining differences in pharmacokinetics of antidepressants. Ziegler and Biggs (44) found no significant gender differences in plasma levels of amitriptyline and nortriptyline. Burrows et al. (45) had similar findings. Moody et al. (46) found that women had higher plasma levels of imipramine than men. In 1985 Preskorn and Mac (47) found that women and older subjects had higher plasma levels of amitriptyline than did young male subjects. These elevated levels in women may have occurred because these studies (46, 47) allowed co-administration of other medications, including oral contraceptives, which could affect tricyclic antidepressant plasma levels. Abernethy et al. (48) assessed concurrent use of imipramine and oral contraceptives and found that the latter inhibited hepatic metabolism of intravenous imipramine, resulting in lengthened half-life. When imipramine was given orally, this effect was counterbalanced by the change in oral availability and decreased apparent oral clearance. Not only does this illustrate the impact of co-administering oral contraceptives, it illustrates that mode of administration can potentially affect plasma levels differently in male and female subjects.

Finally, Greenblatt et al. (49) made important contributions to the investigation of sex differences in psychotropic agents by analyzing the pharmacokinetics of trazodone. They found that the volume of distribution was greater in women and the elderly, but clearance was significantly reduced only in older men.

### *Lithium*

Lithium carbonate has been the subject of several case reports suggesting menstrual cycle effects on serum levels. In at least two case reports (50, 51), lithium levels were found to be higher in the postmenstrual phase than in the premenstrual phase. Although this may have been attributable to increased water retention, this was not reported. However, a recent study of 14 women without bipolar disorder given lithium during follicular and luteal phases failed to show a difference between the mean lithium levels in the two phases (52). However, several individuals in this group did show a phasic difference. This illustrates that meaningful differences can be obscured by relying only on averages. Further, in this instance it would be important to look for phasic differences in women undergoing chronic lithium treatment. Since some women with mood swings complain of worsening during the late luteal phase of the menstrual cycle, it may be helpful to correlate lithium levels to symptoms throughout the menstrual cycle.

Adverse reactions to lithium may occur more frequently in women (53–55). Lithium-induced hypothyroidism predominates in women, just as thyroid disease is more common in women (56). Further, rapid-cycling bipolar illness, which some suggest is more prevalent in women (57), is associated with thyroid abnormalities (56). The importance of the hypothalamic-pituitary-adrenal (HPA) axis in women with affective illness is further suggested by studies of thyroid augmentation of antidepressant therapy; the potentiating effect may be largely confined to younger women (58).

## CONCLUSIONS

This paper has reviewed the theoretical basis for potential sex-related differences in pharmacokinetics and pharmacodynamic effects of psychotropic agents. A

[a] Two studies. For study 1, N=24; for study 2, N=12. For study 1, the mean age was 41 years; for study 2, the mean age was 33 years. For study 1, the medication was clorgyline; for study 2 the medication was amphetamine.

[b] Two groups, one of women aged 46–62 years and one of men aged 24–31 years.

[c] No other medication given.

[d] Two groups, one of men with a mean age of 43 years and one of women with a mean age of 38 years.

[e] Other medications were allowed.

[f] Two groups of women, one taking oral contraceptives (mean age=25 years) and a control group (mean age=29 years).

[g] Two groups, one with an age range of 18–40 years and one with an age range of 60–70 years.

major finding of our search through the literature on this topic is the paucity of experimental data directly addressing this issue. As intriguing as hypotheses about gender-based differences are, the interactions among body weight, fat distribution, hormone fluctuations, and the actual neuroanatomical substrates are very complex. Thus, findings from one drug may or may not be generalizable to other types of drugs or even to drugs in its own class. In our review of data-based articles, small sample sizes and confounding factors such as smoking and lack of attention to menstrual cycle phase complicate the findings. However, despite these limitations, there is evidence suggesting that there are gender-related variations. Some of the clearest findings include 1) the potential for women to have higher plasma levels of psychotropic drugs (especially when given with oral contraceptives) and 2) greater efficacy of antipsychotic agents and a greater likelihood of adverse reactions such as hypothyroidism and, in older women, tardive dyskinesia. These suggested sex-related differences clearly require more extensive investigation.

# The Debate on Treating Individuals Incompetent for Execution

Kirk Heilbrun, Ph.D., Michael L. Radelet, Ph.D., and Joel Dvoskin, Ph.D.

*The question of whether to provide mental health treatment to prisoners under death sentence who have been judged incompetent for execution presents a powerful ethical dilemma for mental health professionals. Arguments that favor or oppose the provision of treatment are discussed in the context of the nature of the disorder to be treated, the type of treatment to be provided, the goals of treatment, and the relevant legal standard for determining competency for execution. Arguments against treating the incompetent include 1) the need to avoid harming those who are treated, 2) the risk that disclosures in therapy will be used for assessment purposes, 3) the need for paternalism when sufficient harm is necessary, 4) the adverse impact on the clinician, 5) the potential undermining of patient and public perceptions of mental health professionals, and 6) the poor allocation of limited resources. Arguments for treating the incompetent include 1) respect for the wishes of the prisoner, 2) the need to clarify the values underlying the refusal to treat, 3) the low risk of harm from some forms of treatment, and 4) the adverse impact on the milieu stemming from failure to treat. The authors conclude that treating incompetent prisoners may not violate ethical standards under some circumstances, and that some forms of treatment will require the informed consent of the prisoner.*

(Am J Psychiatry 1992; 149:596–605)

In recent years, the issue of competency for execution has become a hotly debated clinical/legal question. This surge of interest has occurred despite the fact that this form of competency is based in common law and dates back to the thirteenth century (1–4). There appear to be at least two reasons for the renewal of the debate. First, the number of prisoners under death sentence in American jurisdictions has grown rapidly and, as of January 1991, exceeded 2,400 individuals (5). Second, the U.S. Supreme Court, in *Ford v. Wainwright* (6), held that executing the mentally incompetent would violate the Eighth Amendment prohibition against cruel and unusual punishment.

Currently, the issue of competency for execution has significantly more implications for mental health professionals than ever before. Firmly entrenched in statutory and common law and now with a constitutional basis, the concept of this form of competency is solidly established in our criminal justice system. Moreover, with the rapidly increasing population under death sentence, it seems inevitable that increasing numbers of mental health professionals will be asked to become involved in cases concerning an individual's competency to be executed. Even for clinicians who will never be involved with inmates under death sentence, the competency issue is useful as a heuristic device with which to explore issues such as trust and beneficence. The approach we take to weighing competing considerations and developing a position could also be used for situations in which the need for treatment competes with other demands, such as retribution and public safety.

There are two separate avenues to mental health professionals' involvement with inmates who have received the death sentence. The first is assessment, either before or after a formal finding of incompetency for execution. The second is the provision of mental health treatment for prisoners who have been found incompetent. The question of whether mental health professionals can ethically provide an assessment of competency for execution has been debated by many, including the present authors (3, 7–13). The parameters of how such assessment should be provided, if done at all, have also been discussed (12, and paper by S.L. Brodsky presented at the annual meeting of the American Psychological Association, Washington, D.C., 1986). The distinction between preadjudication and postadjudication assessment has been discussed; the latter presents ethical questions of even greater complexity (12).

The issue of treating a condemned inmate found incompetent for execution raises perhaps the most troubling questions, as the prisoner will have received a stay of execution pending restoration of competency. The

primary focus of this article is on the ethical aspects of providing mental health treatment under such circumstances. (The constitutional questions raised by the issue of involuntary administration of one kind of treatment—antipsychotic medication—to prisoners who are incompetent for execution were before the U.S. Supreme Court in *Perry v. Louisiana* [14]. The Court remanded the case back to Louisiana for reconsideration in light of their holding in *Washington v. Harper* [15]. It is possible that the U.S. Supreme Court will eventually rule on the constitutionality of involuntary medication of prisoners incompetent for execution, but it appears unlikely to the attorneys involved in arguing the case [presentations by K. Nordyke and R.I. Salomon at the annual conference of the Forensic Mental Health Association of California, Pacific Grove, 1991]). While elsewhere we have argued that the best solution to these dilemmas is to commute the death sentences of incompetent inmates to life imprisonment (3, 12), here we focus on the ethical dilemma regarding treatment in cases in which commutations have not been made. One of our important points is that this is a powerful ethical dilemma because it occurs in the context of capital cases. "Death is different," an axiom that has long been recognized within the criminal justice system, will apply as well to the involvement of mental health professionals in this process.

Most states provide for transfer to some kind of secure psychiatric hospital for inmates found incompetent for execution (4, 16). For example, an inmate in Florida who is found incompetent for execution shall be "committed to a Department of Corrections mental health treatment facility" where "he shall be kept . . . until the facility administrator determines that he has been restored to sanity" (Florida Statutes, 922.07, subsections 3 and 4). Such a procedure is consistent with that recommended in the American Bar Association's *Criminal Justice Mental Health Standards* (17). One clear expectation in transferring an incompetent prisoner to a secure mental health facility is that the individual will receive mental health treatment. In this article we discuss whether and under what circumstances mental health treatment should be provided to such an individual, since one consequence of treatment may be restoration of competency and subsequent execution of the prisoner. (Because arguments about treating the incompetent for execution can be, in our view, closely bound up with feelings and values related to capital punishment, we offer the following statement of personal values, endorsed by each of us: we are not convinced by any existing data that capital punishment, as practiced historically or presently, actually deters crime [18]. We are convinced that the death penalty as currently applied has strong liabilities, including racial bias [19, 20], costliness [21], and the possibility of executing the innocent [22]. Our experience with death row inmates has led us to conclude that there are few individuals who, by their wanton disregard for human life, their willful and measured decision to kill, and their believable promises to kill again, have effectively given up their right to continue living. Unfortunately, our criminal justice system is not able to distinguish accurately between those who meet these criteria and those who do not. Nor does any conceivable incremental benefit of execution over life imprisonment seem to justify capital punishment in light of these difficulties. Thus, while we may debate the merits of the death penalty in theory, we are opposed to the way it is currently practiced. These values may affect the discussion that follows.)

## HISTORICAL BACKGROUND OF COMPETENCY FOR EXECUTION

Extensive discussions of the history of competency for execution are available elsewhere (1–4) and thus will not be detailed here. Some of the early justifications for excluding the incompetent from execution were religious (executing incompetent individuals does not allow those persons to put their spiritual affairs in order and prepare to "meet their Maker"), humane (madness is punishment in itself), and normative (executing severely disturbed individuals reflects badly upon society). More recent justifications for excluding the incompetent from execution have included the retributive aspect (individuals are not fully punished if, due to mental disturbance, they do not fully understand the implications of their death), the incompetent person's inability to assist counsel with last-minute appeals, and the psychological aspect (the individual cannot go through the "stages of dying" necessary for a humane death).

Empirically, the construct of competency for execution is important because the vast majority of individuals under death sentence are removed from death row for reasons other than execution. (From 1972 through December 1990, 143 prisoners were executed in the United States. During this same period, however, a total of 1,078 prisoners under death sentence were removed from death row for reasons other than execution: dismissal of indictment, reversal of judgment, commutation, resentencing, and natural death [5]). The capacity to work with counsel on collateral appeals is thus more important than it might seem.

Case law prior to 1986 had established that the "evolving standards of decency" of a civilized society forbade suffering beyond that which is "necessary . . . to extinguish life humanely" (23) under the provisions of the Eighth Amendment. In the more recent *Ford* decision (6), the Supreme Court held that executing the incompetent would, for several reasons, also violate the Eighth Amendment. The majority opinion questioned the retributive value of executing a person who does not understand the reasons for being executed. It described the abhorrence of killing a person who has "no capacity to come to grips with his own conscience or deity" and who experiences "fear and pain without comfort of understanding." Finally, the majority asserted that such executions would "simply offend humanity" and should be prohibited to "protect the dignity of society itself from the barbarity of exacting mindless vengeance." (Alvin Ford, still on death row in Florida and never having been judged incompetent for execution, died of natural causes on Feb. 28, 1991.)

## CONTEXT OF TREATING PERSONS INCOMPETENT FOR EXECUTION

Three broad positions on the involvement of mental health professionals in the treatment of individuals incompetent for execution have been described: always treat, sometimes treat, and never treat (7, 8). The first position (always treat) is held by clinicians who maintain that they are responsible for treating severe mental illness whenever possible, without regard for consequences. Severe psychosis is a painful condition which they cannot ethically refuse to treat when they are in a position to provide relief. Adopting such a position does not necessarily imply endorsement of capital punishment but, rather, separates the delivery of clinical services (which is in the realm of mental health professionals) from the administration of punishment (which lies within the domain of judges and corrections officials). It is also possible that the refusal to treat actually represents a concealed protest against the death penalty (13).

An intermediate position (sometimes treat) is taken by those who would provide treatment to individuals incompetent for execution, but only when the latter want to be treated. An important consideration for those holding this position is whether the benefits of treatment would outweigh the risks under such circumstances. This stance does, however, create another problem: it is quite possible that an individual who is incompetent for execution might also be incompetent to consent to treatment. Potential solutions to this dilemma may involve a "living will," allowing the prisoner (while competent) to express a preference regarding treatment if he or she should become incompetent for execution, or the use of a "next friend" to make the treatment decision (8, 24).

The third position (never treat) holds that the relief of suffering is not sufficient justification for providing treatment, as such treatment is provided with the goal of making possible the infliction of even greater harm. Would it not be more humane, such proponents ask, to allow someone to suffer with psychosis than to administer a treatment that might restore competency and terminate life? Several commentators have forcefully articulated this position (11, 25).

Each of these positions provides a valid perspective on the ethical dilemmas created by the prospect of treating persons incompetent for execution. However, none of the positions is very specific. Treatment is not defined; at times one author seems to mean psychotropic medication, while another may include both medication and psychotherapy. The nature of the disorders that might result in an adjudication of incompetency for execution is not specified. "Psychotic" is the most often cited description of such conditions; this may be both too vague and too narrow. The goals of treatment are insufficiently specified. Finally, the nature of competency itself is discussed globally rather than specifically. In the following discussion we address the ethical issues in these more specific aspects.

### *Relevant Disorders*

"Competency" is a legal term, not a medical or psychological term, so some translation is necessary. There appear to be three major classes of *DSM-III-R* disorders that might render an inmate incompetent for execution. Functional psychotic disorders such as the schizophrenias, mood disorders with psychotic features, delusional disorder, and psychotic disorders not elsewhere classified (schizoaffective disorder, schizophreniform disorder, and atypical psychosis) would constitute the first class. The second class would include certain organic mental disorders, such as delirium, dementia, amnestic disorder, organic delusional disorder, organic hallucinosis, and organic mood disorder, in which the symptoms are of a nature and severity sufficient to impair the individual's competency for execution. The third class would be mental retardation. It is noteworthy that previous commentators, in discussing "psychosis," were probably referring to the first class and parts of the second. Mental retardation has been addressed less frequently but is perhaps even more likely to yield cognitive deficits impairing competency for execution (26). While the mentally retarded may still be considered incompetent for execution if they meet state statutory requirements, the U.S. Supreme Court has made it clear that mental retardation in itself is insufficient to bar execution under the Eighth Amendment (27).

### *The Nature of Competency*

Any kind of legal competency implies tasks. The individual must be able to understand, know, believe, or do something related to the competency construct (28); there must be the ability to understand relevant concepts and act at a minimally acceptable level of skill on the basis of that understanding (29). In the case of competency for execution, the two most frequently cited elements within the standard are "understand" and "assist." The former refers to an individual's capacity to understand the nature of the death penalty and the reasons why this punishment is to be inflicted. The latter describes the capacity to assist legal counsel in ongoing appeals.

According to the *Criminal Justice Mental Health Standards* of the American Bar Association (17), the standard for competency for execution is that an individual should not be executed if "as a result of mental illness or mental retardation, the convict cannot understand the nature of the pending proceedings, what he or she was tried for, the reason for the punishment, or the nature of the punishment. A convict is also incompetent if, as a result of mental illness or mental retardation, the convict lacks sufficient capacity to recognize or understand any fact which might exist which would make the punishment unjust or unlawful, or lacks the ability to convey such information to counsel or the court" (p. 290). Of the 37 jurisdictions in the United States that have a death penalty and a relevant law relating to competency for execution, only two have standards that conform to the "understand" element, and another eight have "understand and assist" standards. Two states define competency for execution in terms of "mentally ill and need for treatment"; the remaining states use only a brief, unelaborated definition (e.g., "insane," "incompetent," "unfit") (16). The U.S. Supreme Court had the opportunity in the *Ford* case (6) to provide a single standard for this competency, as it had done for competency to stand trial (30). It did not do so, although Justice Powell, in his concurring opinion, did conclude that the test of incompetency for execution should be whether the prisoner is aware of his or her impending execution and of the reason for it. As a result of the failure to define a standard for competency in the *Ford* majority opinion and the lack of specificity in their pre-*Ford* statutes, most states do not provide specific guidance regarding the necessary tasks for determining competency for execution. The states that offer more explicit guidelines differ about what these are.

In an effort to help construct a consensual definition of competency for execution, we offer the following three tasks as potential components: 1) understanding the nature of capital punishment and the reasons for its imposition, 2) assisting counsel in ongoing collateral appeals, and 3) spiritually and psychologically preparing for death. While the latter does not appear in any of the statutes or case law, it has been proposed (31). We include it because clinicians need to address all possible dimensions unless or until the definition of incompetency is restricted by appellate courts.

### *Treatment and Treatment Goals*

The types of mental health treatment that might be provided to prisoners incompetent for execution also need further specification. Psychotropic medication is one such treatment, but we will refer to two other types as well. The first is psychotherapy; the second involves a combination of education, skills training, and behavioral therapy that might best be described as psychiatric rehabilitation (32, 33).

Such treatments might be delivered with a number of goals in mind. In any forensic setting, a primary purpose of treatment involves assisting an incompetent patient to regain legal competency. Some would argue that competency for execution is no exception and that a major reason for treating such an individual would involve promoting the recovery of competency. This treatment might be indirect (e.g., removing a disability, such as an actively psychotic condition, and thereby allowing the capacities to perform competency tasks to reemerge) or direct (e.g., enhancing the capacity to interact effectively with counsel through communication skills training). There are, however, other goals that therapists could pursue as well. These include relief of suffering brought on by a psychotic condition, provision of comfort and support and the opportunity for catharsis, enhancement of the individual's capacity to fight effectively for legal rights, and provision of an opportunity to prepare psychologically for death. While the last two goals may arguably relate to the individual's competency status in some jurisdictions, the first two are largely situation-independent treatment goals.

## ARGUMENTS AGAINST TREATING THE INCOMPETENT

### *First, Do No Harm*

The notion that psychiatrists and psychologists providing treatment should not harm patients is probably more of an implicit understanding than an explicit ethical canon of either profession. *Primum non nocere* (first, do no harm) is a long-established tenet of the medical profession, although it is no longer a part of the American Psychiatric Association's *Principles of Medical Ethics* (3, 34). Psychologists are ethically obligated to "protect the welfare of the people and groups with whom they work" (35, 36). This sets a similar tone, and the ethical issue here is the same for psychiatrists and psychologists. Mental health professionals are helpers, with a primary obligation to assist and not harm those who receive their services.

### *Risk That Disclosures in Therapy Will Be Used for Assessment Purposes*

The establishment of an effective treatment relationship depends on whether the individual receiving treatment can trust the professional who is rendering it. This would seem particularly true for psychotherapy with persons who are incompetent for execution. Being under death sentence can have a powerful polarizing effect on a prisoner's perceptions: others are seen as either friends or enemies. There is thus the temptation to view the therapist in one of these two roles. It is not clear whether the prisoner can be accurately informed that information provided in therapy will not be disclosed except in instances involving an increased risk of violence by the patient toward another individual or himself or instances of escape. There is the very real possibility that psychotherapy with a prisoner who is incompetent for execution could result in the use of confidential disclosures for the purpose of assessing the person's competency for execution. In many inpatient settings, disclosures made during therapy are shared within a "circle of confidentiality" that may include supervisors in the chain of clinical responsibility, social workers, nurses, and other treatment team members (37). The risk that disclosures made during therapy will be used for assessing competency for execution is particularly acute under this model and when there is not a strict separation between treatment and assessment functions (3, 12).

### *Paternalism Is Necessary When Significant Harm Is Possible*

There are times when it is necessary to decide that the potential risks of treatment sufficiently outweigh the benefits, so that treatment should be withheld whatever the wishes of the patient or the external demands. Surely, the treatment of those incompetent for execution must be among such cases. Psychotropic medication, which may have an immediate impact on the symptoms rendering an individual incompetent for execution, is the best example. The physician must weigh the potential gain from this form of intervention against the risk that the individual will quickly have a remission of symptoms, regain competency, and be executed.

There is certainly the possibility that an individual who is incompetent for execution might also be incompetent to consent to psychotropic medication (7). This must be considered in any decision to prescribe medication. While the legal right to refuse medication may be limited in prison (14, 15), there are also ethical considerations confronting a physician under these circumstances. Given the potential consequences that could follow a medication-induced improvement in mental condition, the ethics-induced demand for the necessary level of competency to consent to this particular treatment should be very stringent.

### *Adverse Impact on the Clinician*

A clinician attempting to administer any kind of treatment to an individual who is incompetent for execution can experience powerful feelings of confusion, anger, and ambivalence. The awareness that the application of one's craft may result in the death of another human being, even indirectly, creates a situation in which a clinician can feel strong pulls in two directions. On one hand, it is very difficult to be in proximity to someone who is suffering from a mental disturbance, and who may even be asking for help, and not render help. Such a decision, in our experience, is far easier to make in the abstract than in the clinical situation. On the other hand, the awareness that death could ensue soon after treatment is enough to give almost any clinician pause. This conflict is exacerbated by personal contact with the inmate.

In one recent instance, the feelings of clinicians were described in these terms, and they unanimously voted against repeating the entire process, having failed "by bitter experience" to resolve the difficult emotional dilemma created by this situation (25). (The dilemma has never been resolved. The prisoner was transferred from the forensic service at Florida State Hospital to the Corrections Mental Health Institution in 1985 as a result of a change in state statute. After having been evaluated by the Corrections Mental Health Institution treatment team, he was returned to Florida State Prison 2 years later. The team did not express a clear opinion with regard to the prisoner's competency for execution. They did state that he apparently understood the nature of his legal situation at the time of the report—although given the nature of his mental illness, it would be hard to tell on any given day in the future whether he would understand—and had also obtained maximum benefit from treatment. Following his transfer to Florida State Prison, the prisoner refused to cooperate when a new team of three psychiatrists attempted to assess his competency for execution. The stay of execution that had been granted because of his incompetency was therefore vacated by the governor. The prisoner remained on death row as of February 1992.) There have been no other cases in which an individual has been judged incompetent for execution. However, the emotional impact upon clinicians from this single case provides an ominous foreboding of things to come.

### *Undermining Patient and Public Perceptions of Mental Health Professionals*

The professions of medicine and psychology are multifaceted. Both include scientific, professional, and public policy components. However, the facet involving direct patient services is arguably the most visible and the most prominent in the public eye. Actions that run counter to the "healing profession" image may thus have a disproportionately large impact on these professions as a whole. There can be little doubt that there will be widespread dissemination of information about the actions of psychiatrists and psychologists in cases of incompetency for execution. The avid public interest in death penalty cases, fueled by intense media scrutiny, is a potentially volatile situation. The spectacle of the smiling, white-coated doctor, syringe in one hand and hangman's noose in the other, may be quickly dismissed as outrageous hyperbole—until it appears in a national magazine (38) or on the editorial page of a prominent newspaper.

### *Poor Allocation of Limited Resources*

The supply of mental health professionals is far outstripped by the demand, particularly from forensic and correctional facilities (39, 40). Treatment (of whatever form) provided to an inmate who is incompetent for execution can be extremely time-consuming. Because of the high visibility of the case, intense media interest, heightened concern for security, other institutional concerns, ethical issues, and personal reactions of the clinician, such a case can require more clinical resources than even presentencing capital punishment cases of comparably high visibility. Treating prisoners incompetent for execution is simply a poor way to spend valuable resources, from an individual clinical standpoint, from a psychiatric institutional standpoint, and as a matter of public policy.

## ARGUMENTS FOR TREATING THE INCOMPETENT

### *Respect for the Wishes of the Prisoner*

The strongest argument for treating persons incompetent for execution is that they have a right to such treatment if they want it. "Informed consent" followed by delivery of mental health service is an ethical cornerstone of both psychiatry (34) and psychology (36) that arguably applies in many forensic contexts (41, 42). A situation analogous to the treatment of incompetent prisoners involves the ongoing legal appeal process following a death sentence. There are some prisoners who wish to discontinue collateral appeals, presenting a similar dilemma for the attorney: abiding by the expressed wish of the client may hasten his or her death, yet there is a compelling argument that this respect for the client's wishes actually enhances the dignity and humanity of the client (8, 24).

The question of whether consent to mental health treatment under these circumstances can be validly given is clearly a difficult one. In the civil commitment context, there are three essential elements to determining the validity of consent to treatment: disclosure, competency, and voluntariness (43, 44). It may well be that competency to consent to such treatment could always be questioned under such circumstances (45) and that such competency should be assessed broadly and include both the rationality and informed nature of the decision (10). Thus, a large percentage of prisoners who are incompetent for execution might also be incompetent to consent to treatment. However, if it can be assumed that valid consent to some forms of treatment can be obtained in some cases of incompetency for execution, then we are left with a clearly stated, competently given preference to receive treatment.

There are also other ways in which competent consent might be obtained: 1) from the prisoner before the incompetency issue is ever raised (comparable to the living will), 2) from the prisoner after a brief trial of medication designed to restore competency to consent, and 3) from a "next friend" appointed by the court. (Keith Nordyke, the attorney representing Michael Perry in *Perry v. Louisiana* [14], filed a motion for his own appointment as Perry's "next friend" for the purpose of deciding about the administration of psychotropic medication. This motion was granted by the trial court, and Perry's medication was stopped when Nordyke refused permission for its administration. The trial court removed this decision-making authority from Nordyke after 6 months. This points to a practical difficulty in applying the "next friend" concept: a trial judge inclined toward or against the death penalty can greatly influence the medication decision by appointing a "next friend" who is similarly inclined.) When competent consent can be obtained, by whatever means, it seems reasonably clear that any subsequent refusal to treat would be simply a substitution of the clinician's values for those of the prisoner.

### *Confusion of Values*

The second argument for providing treatment is based on the notions that 1) refusing to treat is a veiled protest against the death penalty and 2) the principles of beneficence (doing good) and nonmaleficence (doing no harm), so clearly important in nonforensic treatment situations, are far less applicable in a forensic treatment context. The first point has been made by Mossman (13), who gives the example of a mentally disordered convicted murderer serving a life sentence who is subsequently transferred to a mental hospital. Few mental health professionals would have qualms about providing treatment under those circumstances, although it might "bring about" punishment by returning the individual to prison. A comparable example might be that of individuals who are charged with first-degree or life-sentence felonies but are incompetent to stand trial on these charges. To our knowledge, nobody has cited ethical difficulties in treating under these circumstances, even though treatment might again facilitate the administration of punishment through restoration of competency to stand trial.

Since it is not the administration of punishment per se but rather the punishment by death that creates the ethical difficulties, this argument concludes that such difficulties are really a protest against the death penalty under the guise of professional ethics, a conclusion also reached by Bonnie (9). While there is no doubt that mental health professionals should, like any other citizens, be free to express their opposition to capital punishment, some would argue that such opposition should be presented in an intellectually honest way: openly and in their roles as citizens rather than as professionals.

Further, a strong argument has been made that the principles of beneficence and nonmaleficence are not central to forensic ethics (46). When there is not a promise that such principles will govern the relationship, as in cases of evaluation for the purpose of court testimony to advance the general interests of justice, then they arguably do not attain primacy. While Appelbaum (46) draws a distinction between forensic and treatment procedures, it is not clear whether treatment for the purpose of regaining a prisoner's criminal competency is serving the needs of the state (by advancing the general interests of justice) or of the individual (by diminishing suffering). It can be argued that it is largely the needs of the state which should be addressed in the context of competency for execution and that treatment decisions should not be made solely on the basis of the interests and needs of the incompetent prisoner.

### *Some Forms of Treatment Have Low Risk of Harm*

Much of the discussion about treating persons incompetent for execution seems to assume a strong causal connection between treatment and regaining competency. This assumption may not be accurate, at least for some forms of treatment. The clearest connection between treatment and psychotic symptoms occurs in regard to antipsychotic and mood-stabilizing medications. In cases of schizophrenia, affective disorders, and organic mental disorders with psychotic symptoms, the prescription of appropriate medications can directly ameliorate symptoms such as perceptual disturbances, severe communication disturbances stemming from formal thought disorder, and disturbances in thought content, such as delusions. These kinds of symptoms in turn may have a direct impact on an individual's ability to understand the nature of death and the reason it is being inflicted upon him or her. Within the broader view of competency for execution, such symptoms could also have an adverse impact upon an individual's ability to work productively with counsel on collateral appeals and could impair the capacity to prepare for death. On the other hand, medication would not have an effect on the cognitive deficits stemming solely from mental retardation.

Other forms of treatment may present a different picture. The evidence shows that psychotherapy or counseling alone, in the absence of other forms of treatment, is not effective in alleviating the biologically based "positive" symptoms of schizophrenia, affective disorders, and organic mental disorders (47). Psychotherapy could therefore be delivered to an individual found incompetent for execution with the assumption that the risk of harm stemming from improvement would be low. The comfort, catharsis, and support from such psychotherapy would be valuable, and the therapist might assist the individual in preparing for death with as much dignity and humanity as possible under the circumstances, if this were not part of the competency criteria.

Psychosocial rehabilitation involves teaching a mentally ill patient the additional skills to permit him or her to behave and interact in a relatively nonpathological manner, despite the continued existence of the underlying illness (48). The connection between this kind of treatment and competency-relevant behavior seems potentially strong. In effect, one might be teaching an individual to behave "as if" he or she understood the nature of the death penalty and the reasons for its being administered. One might also be teaching the individual to communicate more effectively, which could improve the ability to interact with counsel. Other skills, however, such as stress management techniques, could theoretically improve the person's coping ability without having a direct effect on competency-relevant capacities. It therefore makes a difference which skills are taught and which deficits are to be remediated. Clinicians could conceivably deliver certain kinds of psychosocial treatment to individuals incompetent for execution without the concern that such treatment would immediately make it more likely that competency would be regained.

### *Adverse Impact of Failure to Treat on the Milieu*

Since most states provide for the transfer of an incompetent prisoner to a high-security mental health institution (16), we must consider the impact of selective refusal to treat certain patients within such facilities. What will happen to incompetent prisoners who are not treated in any way? Will they be confined to their rooms and ignored by the staff? Will they interact with the direct care staff but not the treatment staff? What impact would such selective treatment refusal have on the other patients and on the therapeutic milieu? It seems likely that it would increase the sense of isolation and estrangement of incompetent prisoners and exacerbate the confusion and mistrust of the staff that may already be exhibited by acutely disturbed patients in an inpatient setting. Both kinds of effects are antithetical to the goals of an effective inpatient milieu: to increase patients' sense of security and interpersonal trust and diminish their isolation and confusion. To the extent that the therapeutic milieu is an important element in the effectiveness of inpatient treatment, the selective refusal to treat one patient could damage the treatment prospects for more than that single individual.

## SYNTHESIS

The arguments presented in this article primarily encompass the ethical and moral considerations relevant to treating persons incompetent for execution. Legal considerations have been relatively less emphasized; while they are neither mutually exclusive of nor synonymous with ethical concerns, it is possible to envision a constitutional analysis that reaches a different set of conclusions.

Despite this caveat, however, the arguments we have presented help clarify the ethical issues involved in the provision of mental health treatment to prisoners who are incompetent for execution. The decision about whether to provide such treatment should depend on the nature of the treatment to be provided, the goals of treatment, the standard for competency for execution, and determination of the prisoner's ability and willingness to consent to the treatment.

Specificity is important because one of the major objections to providing treatment concerns the possibility that a treated individual will be put to death if the treatment is successful. Some kinds of treatment have a low causal connection with improvement in competency-relevant capabilities but may nevertheless "help" under some circumstances. Psychotherapy or counseling is the class of mental health treatment for which there is the lowest causal connection between treatment and competency-relevant behavior. Certain kinds of psychosocial education interventions—in the area of stress management, for example—are also unlikely to affect an individual's ability to understand or assist in relevant ways. Cognitive deficits experienced by the mentally retarded are unlikely to be altered with either medication or therapy, although perhaps the relevant understanding could be improved through certain kinds of training.

On the other hand, the administration of antipsychotic or mood-stabilizing medications is much more likely to effect a change in the competency-relevant thinking and behavior of individuals with schizophrenia, organic mental disorders with psychotic features, and affective disorders with psychotic features. It is in these cases that the importance of informed consent to treatment becomes paramount. The importance of obtaining consent—informed, voluntary, and competent—thus varies according to the kind of treatment being considered. For treatments having a strong therapeutic link to competency-relevant symptoms (e.g., psychotropic medications) and thus presenting a high risk to the prisoner, there appears to be an ethical demand to obtain informed consent prior to delivery of treatment. For other forms of treatment (e.g., milieu, psychotherapy) having a weaker link to competency-relevant symptoms but potentially providing other benefits (e.g., support, catharsis, contributing to the broader milieu), the demand for fully informed consent seems less compelling, and the threshold for consent should be lower.

Even with medication, however, if informed consent can be obtained, then there is an argument for providing the treatment requested by the patient. Respect for the prisoner's autonomy versus the need for paternalism under compelling circumstances are the considerations that must be weighed against each other. A legal analogy would be the predominant position of the courts regarding the insanity defense for defendants who refuse to invoke it when it would be worthwhile. Until recent years, in order to preserve the "moral integrity" of the law, this defense was interposed by the court against the defendant's wishes (for example, *Whalem v. United States* [49], in which the Circuit Court of Appeals for the District of Columbia appeared to establish a duty for trial judges to impose an insanity defense when it would be likely to succeed, regardless of the defendant's wishes.) Now, however, the prevailing view seems to involve honoring the decision of a competent defendant to avoid using this defense (8, 44, and several post-*Whalem* decisions by the U.S. Supreme Court, including *North Carolina v. Alford* [50] and *Faretta v. California* [51], and by the District of Columbia Court of Appeals in *Frendak v. United States* [52]).

It is crucial, however, to verify that consent is indeed valid under circumstances of competency for execution. It is possible that an incompetent prisoner might be treated with medication only to the point that he or she is able to make a competent decision about further treatment, although this would increase the risk of alleviating competency-relevant symptoms. It is possible to assume that an individual who is both incompetent for execution and incompetent to consent to treatment would not, if competent, give consent to be treated. The preferable course here would seem to involve having a "next friend" (a role played by a relative or advocate rather than the defense attorney or mental health professional) weigh these possibilities in order to make a substituted judgment. It has been argued that there is probably no legal right for a prisoner to refuse treatment under these circumstances (8), a position that is consistent with the U.S. Supreme Court's recent decision in *Washington v. Harper* (15). However, we would conclude that there is an *ethical* demand for mental health professionals to abstain from the involuntary treatment of someone who is incompetent for execution, at least with treatments likely to alleviate competency-relevant symptoms. On the other hand, it would not appear unethical to integrate an incompetent inmate into a therapeutic milieu, even without the prisoner's consent, because of the potential benefits to the prisoner and the other patients and the relatively low risk of "harm."

The atmosphere surrounding the death penalty is powerfully charged. One's position on capital punishment can play a large role in determining whether to treat individuals who are incompetent for execution. Reluctance to provide any kind of treatment can be a veiled protest against the death penalty, although not necessarily against punishment itself. "Above all, do no harm" is not necessarily a relevant principle for treating individuals in the criminal justice system, if one includes criminal sanctions under "harm." There are two reasons why this dictum is not applicable. It does not offer a distinction between evaluations of competency for execution and presentencing evaluations, and it would also condemn other kinds of clinical evaluation in the postsentencing phase of the criminal justice system that have never been seen as problematic by those who accept any kind of clinical forensic involvement in the criminal justice system (8). However, the close temporal proximity to drastic harm, even if it is an indirect rather than a direct consequence of treatment, can create intense difficulty in the treatment of persons who are incompetent for execution. This is the mental health variant of considering punishment by death as "different," something that has been recognized within the criminal justice system for some time (8, 53).

The entire question of treatment for persons incompetent for execution presents a "lose-lose" situation for mental health professionals. It is difficult to abstain from treating a person in need. It is equally difficult to provide treatment to an individual under these circumstances. The personal consequences are also difficult. In addition, the potential loss of public esteem for the profession, stemming from the public's perception that treatment professionals are closely involved with capital punishment, may be a powerful consideration.

## CONCLUSIONS

One of the recommendations made elsewhere (12) is that mental health professionals should consider very carefully the decision about whether to participate in the assessment of competency for execution. This recommendation seems equally apt for the decision about providing treatment. Clinicians should carefully weigh any decision to participate under these circumstances. However, it also seems appropriate to conclude that such a decision should be made on an individual basis rather than as a profession. We have argued that any decision about treating persons incompetent for execution should involve a variety of considerations. A blanket recommendation against participation does not seem indicated on ethical grounds.

There are, however, some unresolved questions about how to participate that might be usefully addressed by the professional psychiatric and psychological associations. To what extent is treatment of incompetent prisoners a clinical situation, emphasizing the principles of beneficence and nonmaleficence, and to what extent is it a forensic situation, in which the needs of society may be weighed more heavily than those of the individual? Clearer answers may await our professions' responses to Appelbaum's call (46) for the development of a comprehensive set of forensic ethical standards.

Competency for execution presents a very complex set of ethical and moral problems for mental health professionals involved with these cases. The discussion in this article leads us to conclude that there is no single, ethically proper position on the treatment of persons found incompetent for execution. It appears unethical to administer against the prisoner's wishes treatment that is highly relevant to competency, such as antipsychotic medication for psychotic disorders. It may not be unethical if the prisoner consents to receiving such medication, although there are problems in determining what constitutes "consent." If the treatment is unlikely to affect competency-relevant symptoms, however, then it is not unethical to provide it. Finally, the circumstances of each case will influence some of the treatment decisions for which there are no clear ethical mandates. We hope that these conclusions, and the discussion on which they are based, will introduce more shades of gray into a debate that has often been treated in black and white.

# An Overview of Sport Psychiatry

Daniel Begel, M.D.

Objective: *Although the application of psychiatric methods and principles to sports is relatively unsystematic at this time, athletic behavior presents several issues of interest to psychiatry. The aim of this paper is to provide a framework for understanding the developmental, occupational, pathologic, therapeutic, and research aspects of sport psychiatry.* Method: *Studies in psychiatry, psychology, and psychoanalysis provide the basis for this overview, and nonscientific works are cited where they illuminate various issues. Illustrative case examples are also reported.* Results: *It is proposed, but not proven, that athletes undergo phase-specific development and that they may suffer impairments in adapting to the athletic context. This context may also modify treatment modalities.* Conclusions: *There is a need for more clinical studies of athletes, especially in the realms of childhood traumas, competitive issues, and mental illnesses. Because of the close relationship of mental and physical phenomena in sports and because athletic behaviors are often precisely measurable, athletics may constitute a fruitful area for psychiatric research.*

(Am J Psychiatry 1992; 149:606–614)

In the 1920s, an educational psychologist at the University of Illinois, Coleman Griffith, first applied the principles of psychology to sports (1). His work stood alone for several decades, until sport psychology was again taken up by Ogilvie (2) and others (3–5). Today, sport psychology is a comprehensive discipline, with journals (*Journal of Sport and Exercise Psychology, International Journal of Sport Psychology*), graduate programs (6), national and international societies (7), and numerous textbooks (8–10).

Compared to psychology, psychiatry has so far devoted rather little attention to sports. Beisser's pioneering case studies of athletes in therapy (11), published in 1967, raised interesting questions regarding the psychotherapy of athletes and the impact of athletics on the personality. Arnstein (12), in 1976, discussed some of the emotional problems of adolescent athletes. More recently, psychiatrists have published work on such topics as clinical guidelines (13), the conceptual underpinnings of sport psychiatry (14), obligatory running (15), and the psychiatric effects of anabolic steroid use by athletes (16, 17). These papers are few, however, and while they highlight several psychiatric issues in sports, they do not constitute a systematic body of knowledge.

One related area receiving greater attention by psychiatrists is the use of exercise as a therapy for anxiety and mood disorders (18–20). Both individual case studies (21) and efficacy trials (20) have been reported. However, according to Morgan (22, 23), who has reviewed this work, the therapeutic benefits of exercise cannot as yet be claimed with certainty. Altshul (24) came to the same conclusion on clinical grounds. In any case, exercise therapy for psychiatric disorders does not represent an application of psychiatric methods to the field of sports per se, so in this respect it is peripheral to the field of sport psychiatry. As Massimino said, "The primary role of the sport psychiatrist must be a clinical one: to prevent, diagnose, and treat the psychiatrically related medical issues confronting the athlete" (13, p. 56).

In principle, psychiatry may contribute to sport medicine. Ours is a science that studies mind-body relationships. Our biopsychosocial perspective may lend itself to the study of such problems as recovery from injury, healthy and unhealthy aspects of competition, the relationships between psychological functioning and athletic performance, and the effects of athletic activity on neuroendocrine function.

For example, several studies (25, 26) have shown a significant correlation between life stress and the frequency of athletic injury. In one report (27), the personality characteristics of hysteria and hypochondriasis, as measured by the MMPI, adversely affected recovery from knee surgery. The role of parental influence in the genesis of competition anxiety in children participating in sports has also been pointed out (28–30). The behavioral, analgesic, and cardiovascular effects of exercise have been linked with

endogenous opioid systems in rats (31), and in humans the calming effect of aerobic training may be reversed by naloxone (32). The cognitive variable of field dependence/independence has been related to performance in basketball players (33). All of these findings are suitable for further study from a psychiatric perspective.

In the last decade, psychiatric involvement in sports appears to have grown. Faced with drug abuse, professional sports has sometimes sought the help of psychiatrists (34). Psychiatrists have also been called on to facilitate performance (13). The American Academy of Sports Physicians has established a sport psychiatry committee, and one medical school has set up a formal program in the field within its department of psychiatry (35). These are appropriate developments for sport medicine, especially since the services of sport psychology are often administered by practitioners with little or no clinical training (36).

In this overview I attempt to integrate the findings and ideas of various observers of sports with the basic principles of clinical psychiatry. Although sport psychiatry is in its infancy, this heuristic attempt to define its boundaries is meant to facilitate and encourage further work in the field.

## DEVELOPMENTAL PERSPECTIVE

The epigenetic theorem of behavioral science states that the capacities of the human being unfold in a sequence of stages, each stage building on the preceding ones and providing a foundation for the stages that follow. This theorem has been elaborated by Freud, for libidinal development (37); Erikson, for identity formation (38); Piaget, for cognition (39); and Lidz, for personhood (40). For athletic development, similar epigenetic schemes have been proposed (14, 28). Although these schemes are preliminary constructs with little empirical validation, they aim to place athletic activity within the context of normal human development.

A hypothetical first stage, from birth to approximately age 3 years, is thought of as the age of emergent body narcissism, in which the future athlete discovers the body's potential as an instrument of pleasure, experiment, and discovery (14, 28). Children's spontaneous motor behavior, as well as the enjoyment of such passive activities as swinging, inversion, and the like, promote an appreciation of physical play (28). Although children may imitate aspects of sporting behavior before age 3, they do not yet understand the rules of society's games (28).

A hypothetical second stage, corresponding to the Oedipal years, is thought to be important for the emergence of competitive strivings (14). The pre-Oedipal child's struggles of will evolve toward an interest in competition for its own sake. Although at this age children enjoy beating opponents in quasiathletic contests, they may not as yet be concerned with winning as it is defined in true sports, as the following example illustrates.

*Case 1.* A group of 4- and 5-year-olds ran a 50-meter race. One child, running faster than the others, looked behind her for a rival. She slowed down to allow the rival to catch up to her, whereupon she resumed running fast and pulled ahead. She then looked for another opponent, and then another. In this way, moving side to side as well as forward and back, she achieved several victories in a single race. Although she came in second by standard measures, this did not appear to dampen her satisfaction.

In a third stage of athletic development, corresponding to the latency years, children spontaneously organize their own athletic contests (14). The progress in athletics during latency is thought to depend on cognitive maturation (14), specifically the development of concrete operations (39), which enable the child to understand such notions as position, follow-through, and generalized rules (14).

For example, to run past a finish line, rather than stop just at the line, as preoperational children tend to do, children must possess a notion of "reversibility" and understand that their actions after a race is over affect the outcome of the race itself (14). Similarly, achieving a notion of "conservation" (39) enables latency-age soccer players to maintain position, rather than swarm to the ball, as preoperational children often do.

On the whole, latency is thought to be a crucial time for the athlete's learning about how things work, including basic techniques, rules, and social roles (28). Latency has therefore been termed the age of "playground conditioning" (14). Because it is the age in which children first understand true sports, it is the age that is most studied in the field of youth sports (10, 41, 42).

During the next hypothetical stage of development, adolescence, athletics become imbued with passion and idealism (14, 28). Although preadolescents are happy about winning and disappointed about losing, they may not yet experience the emotional upheavals of teenage athletes (12). In particular, sexuality and self-esteem become especially important for athletes in adolescence (12).

The development of body narcissism, competitive strivings, playground conditioning, and passion and idealism prepare the person for athletic maturity (14). For those who reach this final stage, athletic training appears to become more systematic and creative than it had been before (14).

These hypothetical stages await experimental verification, but they help us to understand certain frequently noted problems in youth sports. Martens (43), Lewthwaite and Scanlan (29), and others (28, 42) have called attention to the potential of sports for generating unwelcome anxiety in young people. Often this is said to result from inappropriate adult behavior. From a developmental perspective, this behavior may represent a premature insistence on athletic attitudes for which the child is not yet ready. Latency-age children may be expected to summon the fervor of adolescence. Five-year-olds may be subjected to mature training methods. The following case illustrates that attitudes appropriate to athletes in adolescence may be encouraged in children as young as 3.

*Case 2.* Although Max, a football coach, was a basically gentle man, he continually urged his players to display a "killer instinct." Max frequently brought his son Benjy, who had just turned 3, to practice. Although the child ran and played freely with various people at the field, he never smiled and always maintained an expressionless face.

At home with his family, Max played with his son after dinner. As he did with his players, Max persistently urged Benjy to "look mean" and modeled an angry face. The child appeared confused by the command, but after several tries adopted a distorted look that was part grimace, part fright. He appeared confused about the expressive functions of his facial muscles.

The developmental perspective may also help us to think about the impact of adults' increasing organization of youth sports. In the last 25 years there has been a major shift in athletic settings for children, from self-organized playground games to leagues organized by adults (44). Although youth sport leagues provide many opportunities for youngsters and their families to participate, spontaneous games provide opportunities of a special kind.

We know the importance of latency for socialization processes (40). In their spontaneous games, youngsters experiment with solutions to such problems as how to deal with winning and losing, how to adapt to a displacement in the social hierarchy, and how to resolve conflict. When play is disrupted by a heated dispute over the rules—for example, whether or not a given action constitutes a foul—it may be unwise for an adult to quickly resolve the matter in the interest of resuming play. As Piaget explained in his study of morality (45), for which he used as subjects children playing marbles, in disputing the rules the contestants are constructing them by refining and comparing their personal notions with the notions of their peers. The problem of how to preserve spontaneity and opportunities for psychological growth within organized youth sport leagues is one that sport psychiatry might well consider.

## PSYCHODYNAMIC FACTORS IN SPORTS-RELATED PROBLEMS

Although sport psychiatry is too young for a formal nosology, the sports-related problems that have been identified may be divided into five categories. These are 1) sudden performance failure ("choking") (46, 47), 2) prolonged performance failure (slump) (48), 3) emotional factors that contribute to injury (25, 26) or prolong recovery from injury (27), 4) interpersonal problems with coaches and teammates (2), and 5) training problems of various kinds, including those relating to retirement (11, 49).

This division is one of convenience, and there seems to be a degree of overlap. For example, Nicholi (50) reported how interpersonal problems can prolong the poor performance of a team, and Ogilvie and Tutko (2) observed that a "choking" athlete may come in conflict with a coach. A severe injury may bring retirement issues to the fore (51). Since there have been no epidemiologic studies of these problems, it is impossible to say how prevalent they are among athletes.

Mahl (52) elucidated the role of psychological conflict and defense in the genesis of a wide variety of behaviors. The person in conflict "is prompted simultaneously by incompatible response tendencies" (52, p. 20). The various defenses result in "avoiding or decreasing the aversive motivational state" and "avoiding or mitigating a perceived or anticipated danger situation" (52, p. 40). Ogilvie and Tutko pointed to the role of an unconscious fear of success in some cases of athletic failure (53), and as Mahl (52) pointed out, defenses may also serve to mitigate objectively painful situations. The following case illustrates how psychodynamic conflict may lead to a sudden performance failure.

*Case 3.* An 18-year-old high school senior was playing second base for his baseball team in the state championship game, the last game of his high school career. With his team ahead by one run in the bottom of the ninth inning, with runners at first and second bases and two outs, he fielded an easy ground ball. He elected to throw the ball to his shortstop, covering second, for the out that would have ended the game and given his team the championship. Although it was a throw he had completed countless times in his life, this time he threw the ball over the shortstop's head, into left field, enabling one runner to score. On the next play the opponents scored again and won the game.

As he had prepared for this game, the athlete's conscious focus had been wholly devoted to achieving victory. But because he possessed only average talent, he could not look forward to playing in college, and therefore, as he laced his shoes, practiced batting, and ate his pregame meal for the last time, he was inwardly grieving the loss of the sport he loved. To complete the crucial throw was equivalent to ending his career, something he would not do without conflict.

The following example illustrates how psychodynamic factors may prolong recovery from an injury.

*Case 4.* A college sprinter, in her second year of school at an institution far from home, was discouraged by the failure of her hamstring injury to heal in spite of standard rehabilitation measures. She was thinking of quitting her sport, but if she did she would lose her college scholarship, and she felt that her mother would then be angry with her. She reported that a friend of hers had had "the same thing" happen in the previous year, and the friend had quit and returned home. When asked, the sprinter reported that the friend's mother had been happy to have her daughter home. She then admitted, with some relief, that her own mother missed her and she missed her mother and that a reunion would be a welcome event. This athlete's longing for her mother conflicted with her desire to return to training.

Psychodynamic factors may also contribute to problems between coaches and athletes. The coach may be perceived as a surrogate parent by the athlete (54). In individual sports especially, the athlete-coach relationship may be among the most intimate in the lives of both parties. The intense consideration given to the functioning of the athlete's body may kindle transferences not unlike those in psychotherapy, except that these transferences are usually unexamined. According to Freud, "Psycho-analytic treatment does not create transferences, it merely brings them to light" (55, p.

117). Both sexual acting out and outbreaks of unmanageable hostility sometimes occur.

As always, it is advisable to evaluate each instance of sports-related difficulty before coming to a diagnosis (13). Not all performance syndromes are related to psychodynamic factors, as the following case illustrates.

*Case 5.* A basketball player who too frequently committed senseless fouls and made poor passes at crucial moments appeared to have no motive for doing so. He was happy with his team, his coach, and his general circumstances. It was observed that on one occasion he did precisely the opposite of what his frantic coach instructed from the sideline. Upon further history it was revealed that, until his late teens, this athlete needed to reverse his shoes before putting them on, in order to perceive, concretely, which of two possible arrangements was the best one. He also suffered from symptoms of dyslexia in speech and writing. When the coach said, "Don't foul" or "Don't throw it away," the athlete was confused by the negative construction. The coach was advised to use positive linguistic framing, which quickly alleviated the difficulty.

Nicholi (50) and Collins et al. (34), among others, have mentioned the reluctance of athletes to acknowledge emotional vulnerability. Defensive denial of the psychological sources of trouble may take the form of euphemisms, such as "head case" and "brain lock," or excuses. The following is an example of such a case.

*Case 6.* A distance runner explained her repeated slumps as being due to a series of hard-to-diagnose physical conditions: ferratin-deficiency anemia, diffuse intravascular candidiasis, and "overtraining." With each diagnosis came a torrent of bitter recrimination at the medical community for failing to diagnose her problem earlier.

The athlete in a slump may resort to magic and superstition (56), reflecting a belief, akin to our own, that the source of the trouble lies outside conscious control. Perhaps, as Beisser suggested (11), it is the intangibility of thought, an opponent against which no concrete action can be taken, that leads to athletes' reluctance to acknowledge psychological sources of failure. But this question has not been well studied, and it is not known whether athletes' attitudes toward their own psychological dynamics are any different from those of nonathletes. For the time being, it seems best to treat the athlete's skepticism with the same consideration we have for any resistance (57).

The psychodynamic aspects of sports-related problems may be similar to those that contribute to some defined mental disorders. For example, "choking" may be analogous to panic disorder, and adjustment disorder may present as a slump. Without further study, the construction of a formal nosology in sport psychiatry is premature.

## POSSIBLE OCCUPATIONAL SYNDROME

Lay observers have asserted that society exerts a harmful influence on the personality of the exceptional athlete, fostering tendencies toward violence, promiscuity, and grandiosity. Telander (58) and Bissinger (59) documented in journalistic works the effects of corruption and degradation on young star athletes. As long ago as the fifth century B.C., Euripides opined, "Of all the countless evils throughout Hellas none is worse than the race of athletes. Slaves of their belly and their jaw they know not how to live well. . . . I blame the custom of the Hellenes who, honoring useless pleasures, gather to see such men" (60).

In a thoughtful account of his life in professional basketball, Bill Bradley (49) discussed society's tendency to both worship and condemn its athletic heroes, and he said that as a result the athlete's "sense of identity is insufficient" (49, p. 123). Similarly, I have referred to the "hollow identity" of some professional athletes (14).

Although Ogilvie and Tutko (61), in a nonreviewed publication, expressed the view that whatever personality traits successful athletes display are the result of a "ruthless selection process" (61, p. 61), occupational psychiatry has known since the work of Sherman in 1927 (62) that an individual's adaptation to his or her job is a complex process. There may be a number of factors within the biopsychosocial matrix of an exceptional athlete's life that promote aggressivity, promiscuity, and narcissistic vulnerability.

Nicholi (50) mentioned the struggles of his professional football players with unmanageable aggression, citing violent nightmares as a symptom. He attributed this to a kind of posttraumatic stress disorder, although in his subjects it may also have been a consequence of the use of anabolic steroids, which sometimes promote aggressive behaviors (17). It is also possible, as Bradley seemed to suggest, that in adapting to idolatry the athlete becomes increasingly grandiose and in adapting to degradation he becomes increasingly insecure.

An additional factor may be the fact that the social pressures on professional athletes act within a particular phase of the life cycle. At an age when, according to Erikson (38), a young adult is establishing methods for handling the dilemmas and commitments of intimacy, the professional athlete is also thrust forward into complicated tasks normally characteristic of the later stage of generativity. The predictable apprenticeship that young adults initially enjoy in their professional lives is a luxury denied the professional athlete, whose career depends on immediate output. This condensation of stages may be overwhelming to the person, as Nicholi described (50), and as a result the athlete may remain mired in regressive patterns of behavior that one former athlete called "terminal adolescent syndrome" (63, p. 6).

Another possible factor is athletic training itself. The training that characterizes athletic maturity is strongly narcissistic. The extreme devotion to one's body ensures this. It is possible that athletic training, which is ego-syntonic, shapes other aspects of behavior as a kind of inappropriately applied template, promoting grandiosity and entitlement in human relations and a preoccupation with physical satisfaction. The result of such a process is illustrated by the following example.

*Case 7.* A recently retired professional baseball player returned to his alma mater to carry out certain obligations as a prominent alumnus. A religious man, he was married to an attractive professional woman and worked in the field of human services.

In the evening, he went with some old friends to a nightclub, where his presence was announced from the stage. From his seat he fastened a hard, predatory stare on a woman sitting at a neighboring table with her male companion. After what appeared to be a wordless, visual rape continued for some time, the boyfriend rose from his chair to approach the athlete's table. Instead of the challenge that the whole gathering expected, the boyfriend asked for the athlete's autograph and shook his hand. Afterward the athlete explained his practice of compulsive seductivity as something he learned in professional baseball. The sanctioning of his behavior in the nightclub repeated a pattern that occurred many times over, in various ways, during his career.

In the *Iliad,* Homer provided a vivid description of a narcissistically wounded athlete (64). Achilles, the great runner, was described as a ruthless, arrogant killer. He was the sacker of 12 cities and king of the Myrmidons, known not only for their violent and rapacious inclinations but also for their love of sports. His only vulnerable spot was his heel, by which his mother had held him when she dipped him in the river Styx.

When King Agamemnon took away one of his female prizes, Achilles sulked, refusing to join the battle for Troy, nursing his grudge, and repudiating offers of amends. It was not because of longing for the woman that he pouted—he had women by the score—but rather because of his wounded pride and "bitter humiliation" (64, p. 171). As Achilles pouted, his savage but idle Myrmidons played sports: archery, discus throwing, and chariot racing.

Without further research we are not yet in a position to say whether the problems of professional athletes represent anything more than cluster B personality variants (*DSM-III-R*). But if it turns out that a constellation of aggressivity, promiscuity, and narcissistic grandiosity and vulnerability is in some way an occupational hazard for professional athletes, as lay observers tend to believe, we may somewhat whimsically term this constellation "the Achilles complex" after that ancient athletic king.

## MENTAL ILLNESS IN ATHLETES

Several reports have addressed mental illness among athletes. Beisser (11) reported in detail seven cases of severe illness. Coleman (65) discovered more than 70 cases of suicide among active and retired professional baseball players. In a presentation at the 1987 National Conference of Sport Psychology sponsored by the United States Olympic Committee, James McGee, Ph.D., estimated that 34% of the 250 athletes in one professional sport organization qualified for a substance abuse diagnosis according to *DSM-III-R* criteria.

An attempt to distinguish mental illness among athletic individuals from mental illness among nonathletes was made by Little (66). In a series of 72 men consecutively referred to an outpatient psychiatric clinic, he found that patients who scored high on a scale of athleticism differed from those who did not in several respects. Compared with the nonathletic group, the athletic group displayed more somatic symptoms, better premorbid mental health, and more disorders precipitated by injury or physical illness.

In all of the reports except McGee's the preponderance of subjects were past their athletic prime. There may be several reasons for this. First, it has been suggested (11) that for some people athletic participation may serve as a defense against problems of self-esteem, which become apparent when the athlete retires. The palliative effects of sports may underlie their use as a therapeutic modality in hospitals (67) and their possible effects on mood (21).

Second, athletic behaviors sometimes resemble symptoms of mental disorder and thereby confound recognition of illness. Endurance athletes, for example, pay scrupulous attention to diet and leanness, are relatively hyperactive, and, in the case of some women, experience amenorrhea; for these reasons, they may resemble patients with anorexia nervosa (15). Like Binswager's patient Ellen West (68), endurance athletes often keep detailed diaries. It is possible that coaches of anorexic athletes misinterpret a person's pathological behavior as devotion to training. A preliminary study of body image among marathon runners (69), however, failed to show body image distortions such as those seen in the disease.

A third possibility is that a tendency to idealize athletics leads observers to deny the existence of psychiatric symptoms. One psychiatrist failed to observe any signs of anxiety among a group of professional football players in treatment for drug abuse (34). In his treatise *Sport: A Philosophic Inquiry,* Weiss defined athletes as "excellence in the guise of men" (70, p. 17). To the extent that such a definition is unconsciously shared by clinical observers, it may be expected to interfere with the perception of signs of illness.

Until more case studies of athletes are reported, it will be difficult to draw conclusions about the possibility of distinguishing pathological characteristics among various athletic populations.

## TREATMENT ISSUES

Although published accounts of the treatment of athletes are few, the treatment modalities that have been used are diverse. In 1928 Deutsch (71) reported a psychoanalysis with an athlete, in which she attributed the patient's talent for ball games to unresolved castration anxiety. Psychotherapy (11), group therapy (34, 50), a family systems perspective (72), and pharmacotherapy (73) have been applied. In addition, behavior therapies developed by sport psychology to enhance athletic performance have been used by psychiatrists (13, 50). A nonclinical but interesting phenomenologic approach to training was reported by the philosopher Herrigel (74).

Since the literature is meager, it is not possible to formulate at this time which modalities are appropriate for which problems under various conditions. But our treatment approach may be modified on occasion by the athletic context. For example, an episode of anxiety that might be relatively minor if it occurred in the context of another activity might require urgent attention if it occurred in an athlete facing imminent competition. In providing consultation to teams, it may be necessary to conduct interviews in unusual settings, such as on the sideline or on the team bus (75) and to be respectfully aware of the informal "treatment" that coaches often give players on athletic teams.

The effects of medication on athletes in training is an uncharted area, and caution should be used in prescribing some psychotropic medications because of their effects on vision, coordination, and cardiac function (76). For example, medications that affect visual accommodation may be safe for an interior lineman in football but hazardous to a baseball player.

The psychiatrist should also consider performance variables in prescribing medications. In addition to ECG effects, there have been reports of negative inotropic responses to phenothiazines and tricyclics (77). Thus, these medications may be expected to impair performance in endurance sports in which cardiac output is maximal. One report (78) indicated that cardiovascular performance assessed during treadmill exercise testing is not affected by long-term lithium therapy. Buspirone, which is minimally sedating, may be a useful choice in treating anxiety. Finally, it should be kept in mind that some medications are illegal in some sports. Beta blockers, for example, are forbidden in archery.

Therapeutic eclecticism is sometimes appropriate for the treatment of sports-related problems. The following example illustrates how psychodynamic principles were used in constructing a behaviorist script.

*Case 8.* A recreational downhill skier was troubled by his inability to ski freely down the fall line and his tendency to ski laterally back and forth in great controlled loops. He found this particularly embarrassing on ski trips with corporate colleagues, feeling that it revealed a lack of manliness and courage. He requested instruction in relaxation and rehearsal techniques.

As a youngster he had been discouraged from skiing by his father, who regarded it as an "upscale," "WASP" sport that was inappropriate for his son. Further examination of his history revealed troubling competitive themes, and this psychodynamic information was used in constructing behavioral rehearsal scripts. He was told to imagine himself sharing a lift with a confident, blond Adonis figure who, on the ride, ridiculed skiers taking broad, transverse loops. As his anxiety rose, he was asked to imagine himself giving his companion a karate chop to the Adam's apple, throwing him off the lift, and whisking by his crumpled figure on the way down. His joyful indulgence of this fantasy in the office seemed to loosen his inhibition on the slope.

It might be expected that competitive themes would be prominent in psychiatrists' psychotherapeutic relationships with some athletes. The frequency of such themes is not known, but the following example illustrates a therapist's experience of feeling played with.

*Case 9.* A baseball pitcher sought therapy for, he said, "a problem I am having." He did not say explicitly what this problem was, but over the course of four sessions he threw out various tantalizing suggestions, each of which was followed up by the psychiatrist, without result. After four meetings the patient ended the work. The psychiatrist still had no idea of why the athlete had come to see him and felt as if he had been thrown a series of difficult verbal pitches.

Countertransference issues may also be influenced by the athletic context. A psychiatrist who is a sports fan may derive vicarious gratification from the exploits of the patient. A psychiatrist may prescribe controlled drugs in the interest of enhancing performance (75), may give pregame pep talks (50), and may appear at press conferences to explain a patient's treatment (79). The psychiatrist may overidentify with the athlete in ways the athlete does not appreciate, as suggested by the following example.

*Case 10.* A divorced champion Olympic discus thrower was returning to training after several years of retirement. He consulted a psychiatrist to discuss his feelings about being single again after a number of years of marriage and his anxieties about dating.

One day, in a discussion of his training, the athlete mentioned certain problems he was having with "bending and blocking." The psychiatrist compared these problems with his own difficulty in bending over to field ground balls in his softball games. "Bending" and "blocking" are technical terms in discus throwing, and the patient felt the doctor was seeing a similarity between them that did not exist. He felt misunderstood and in response stopped his therapy.

In adapting treatment to the athletic context, it is important not to forget basic principles. If one important clinical task in general psychiatry is to listen empathetically to the patient's troubles, then we should do so in sport psychiatry. Skilled listening is one feature that distinguishes our work from that of other areas of sport medicine. An interesting account of the importance of listening to athletes can be found in one of the earliest works of Western literature.

In the *Odyssey* (80), Homer described how King Alcineus, observing the tears of Odysseus during a welcoming banquet, suggested that the gathering engage in sports to lift the mood of his athletic guest. Although Odysseus quickly became playful and energetic during the games, his bleak mood soon returned when they were over. Perceiving his "relapse," Alcineus then tried what psychiatrists try first: "Explain to us," he said, "what secret sorrow makes you weep . . . for a sympathetic friend can be quite as dear as a brother" (80, p. 138).

## DISCUSSION

Although an estimated $4 billion is spent annually on sport medicine services (81), the study and treatment of athletes by psychiatry is still in its infancy. A significant contribution of sport psychiatry to sport medicine will depend on an expanded clinical literature. Of particular interest are cases in which children have been traumatized and cases in which adult athletes have suffered sports-related problems. Cases in which athletes are treated for psychiatric disorders are important for integrating sport psychiatry into the mainstream of clinical practice. In addition, consulting work with athletic teams, whose primary mission is to win, needs to be reported on and understood in the context of community psychiatry and group therapy.

The question of how psychodynamic factors influence performance is also of interest. The full expression of aggression seems to be essential for athletic success (82). But we sometimes observe that a particularly good competitor—that is, one who is not merely competitively disposed but, rather, performs best in the most important competitions—feels respectful and friendly toward the opponent. Such feelings were revealed in a private tape-recorded conversation between two heavyweight boxing champions, who were opponents but expressed a warm, admiring relationship (83). If it turns out that such an attitude is characteristic of other champion competitors, this finding could be of interest to our competitive society.

It is also possible that sport psychiatry may someday contribute to the understanding of mind-body relationships. In his book *Mind, Brain, Body,* Reiser pointed to a need for "conceptual templates" (84, p. 17) to link the study of neurotransmission and neuroendocrinology with psychoanalysis. He offered several hypotheses to explain how meanings may be transduced into biological effects, focusing especially on signal anxiety and the psychophysiology of stress (84). Even an advocate for "autonomous disciplines" as rigorous as Edelson can hope for an "eventual rapprochement between neuroscience and psychoanalysis" (85, p. 156).

In 1973 one of the pioneers of sport medicine, Ernst Jokl, discussed the "physical structure of mind" and concluded that "in as far as it encompasses the search for attachment of mind to the body, science tells us nothing" (86, p. 16). Since then, our understanding of the biological basis of mental disease has advanced greatly, but it is perhaps fair to say that the integration of this knowledge with such psychoanalytic concepts as primary and secondary process, unconscious conflict and defense, and psychic structure awaits the appropriate conceptual templates.

Since Jokl's work, sport science has continued to touch on the possible connections between symbolization and biology. Morgan (87), for example, found that hypnotically induced perceptions of effort during exercise altered some aspects of cardiovascular function even when actual effort was invariant. Suinn (88), building on the work of Jacobson (89), observed electromyographic correlates of skiers mentally rehearsing their runs. In neuroendocrine research (90) it has been shown that circulating β-endorphin levels may under some circumstances rise in anticipation of an athletic event.

While these results do not define conceptual templates, they suggest that athletics may constitute an appropriate experimental field for studying the problem. If it were possible, for example, to identify some biological concomitants of such phenomena as "choking" and slump, and if it were also possible to elucidate some symbolic processes involved, then we might be on a useful scientific path. This is because in sports it is often possible to measure the performance effects of "choking" and slump quite precisely and in a well-defined context. But all of this for now is merely a hope that someday sport psychiatry, in its research, will contribute to the convergence of psychologic and neural science.

# Can Mildly Depressed Outpatients With Atypical Depression Benefit From Antidepressants?

Jonathan W. Stewart, M.D., Patrick J. McGrath, M.D., and Frederic M. Quitkin, M.D.

*Objective: The authors' goal was to explore the efficacy of antidepressant medications in outpatients with mild depression. Method: Four hundred one outpatients were diagnosed as depressed by* DSM-III *criteria. Atypical Depression Diagnostic Scale criteria were also applied to these patients; these criteria require reactivity of mood plus two of four associated features, including hypersomnia, hyperphagia, leaden paralysis, and pathological sensitivity to rejection. All patients were then randomly treated for 6 weeks with up to 300 mg/day of imipramine, up to 90 mg/day of phenelzine, or placebo. Outcome at 6 weeks was determined by clinical global improvement ratings. The outcomes of patients with entry Hamilton Rating Scale for Depression scores in the low (scores of 12 or lower), medium (scores of 13–15), and high (scores above 16) range were compared. Results: The majority (N=332, 83%) of the 401 depressed patients had definite or probable atypical depression. Among the 140 patients who had low pretreatment Hamilton scale scores, 19 (33%) of 57 given placebo, 25 (60%) of 42 given imipramine, and 34 (83%) of 41 given phenelzine responded. Each of the antidepressants was superior to placebo. Similar findings applied to the patients with medium and high Hamilton scale scores, except that the rates of placebo response were lower (29% and 10%, respectively). Conclusions: These data support the use of antidepressant medication for some mildly depressed patients, at least if they have atypical depression. Too few patients were included who did not have atypical depression to draw conclusions about such patients.*

(Am J Psychiatry 1992; 149:615–619)

Antidepressant medications have often been reserved for more severely depressed patients, while psychotherapy is advocated for individuals having "low-grade" depression (1, 2). The pharmaceutical industry has essentially accepted this dictum by requiring a minimum pretreatment score on a standard rating scale in their applications to the Food and Drug Administration. Typically, studies of new antidepressants require a minimum score of 18 or 20 on the Hamilton Rating Scale for Depression (3). Some support for this position may be found in the National Institute of Mental Health (NIMH) Treatment of Depression Collaborative Research Program, which compared two psychotherapies with imipramine and placebo and found a treatment effect for imipramine only among depressed patients who had pretreatment Hamilton depression scale scores of 20 or higher (4). This has been interpreted (5) as indicating the usefulness of supportive psychotherapy for more mildly depressed patients, although, strictly speaking, this is an unwarranted assumption because none of the treatments used was demonstrated to be effective for patients with Hamilton depression scale scores lower than 20. We have previously reported failure to demonstrate the efficacy of desipramine in patients with major depression who had low Hamilton depression scale scores (6) as well as in patients with nonmajor depression (7).

We wondered whether the wisdom of requiring high

Hamilton depression scale scores for entry into antidepressant trials was warranted. Therefore, we have included in our studies of antidepressants any otherwise eligible patient who met *DSM-III* criteria for major depression or dysthymia, regardless of their pretreatment scores on rating scales such as the Hamilton depression scale. This allowed us to investigate whether "mildly" depressed patients can benefit from antidepressant medication. This report consists of a reanalysis of outcome data from patients entering two studies designed to test our hypothesis that phenelzine is more likely to benefit patients with atypical depression than is imipramine. These studies included 401 patients. We arbitrarily grouped these patients into thirds on the basis of their pretreatment Hamilton depression scale scores. Here we will focus on the 140 patients in the third of the group with the lowest scores, 12 or less, using for comparison purposes the 261 patients from the same study who had higher baseline scores.

## METHOD

### *Patient Sample*

Patients included the majority of outpatients with nonmelancholic depression who sought treatment at a depression evaluation service clinic between October 1979 and May 1987. One hundred forty-three of the patients eligible for the two studies described here were entered instead into trials of investigational medications. These trials generally required nonfecund patients for entry. Nine patients entered a study requiring major depression and Hamilton depression scale scores of 18 or greater, 93 entered into two studies (one with N=71 and one with N=22) requiring Hamilton depression scale scores of 10 or greater, and 41 entered a study having no minimum Hamilton depression scale score. Patients were entered preferentially into one of the investigational drug studies if eligible and agreeable, although none of these investigational studies ran for the entire length of time of the two studies reported here. The two studies reported here ran consecutively from October 1979 through May 1987; data from these studies from a variety of perspectives have been reported (8–12). Patients who dropped out or responded during a 10-day placebo washout period are not included in this report.

Patients had to be 18–65 years of age, physically healthy, meet criteria for a *DSM-III* diagnosis of affective disorder, be considered able to follow a tyramine-free diet, and provide informed consent. Patients with a history of psychosis or mania and patients currently abusing drugs or alcohol were excluded. The Atypical Depression Diagnostic Scale was administered to all patients to determine the presence of atypical depression (8). This instrument assesses presence or absence of the required feature of mood reactivity plus the four hypothesized associated features of atypical depression—hypersomnia, hyperphagia, leaden paralysis, and pathological sensitivity to interpersonal rejection. Mood reactivity plus two associated features are required for definite atypical depression, and mood reactivity plus one associated feature are required for probable atypical depression.

### *Procedure*

Baseline evaluations included a clinical interview to determine *DSM-III* diagnoses as well as administration of the 21-item Hamilton Rating Scale for Depression, the Clinical Global Impression (CGI) (13), and a variety of other measures that will not be reported here. Patients were then treated single-blind with placebo for approximately 10 days and reevaluated. Those who had not responded (response is defined in the next paragraph) were then randomly assigned to receive 50 mg of imipramine, 15 mg of phenelzine, or placebo in gradually increasing doses to a maximum dose of 300 mg/day of imipramine, 90 mg/day of phenelzine, or six capsules of placebo. Patients were seen weekly, and CGI ratings were obtained. After 6 weeks, CGI and Hamilton depression scale scores were again obtained and response was determined. Patients were instructed to follow a low-tyramine diet throughout the study.

### *Definition of Response*

The CGI global improvement score was used to determine response or nonresponse after single-blind administration of placebo and 6 weeks of randomized treatment. A score of 1 ("very much improved") or 2 ("much improved") defined responders. Patients with scores of 3 ("minimally improved") or higher ("unchanged or worse") were nonresponders. We used this scale conservatively, so that patients who were less depressed but still symptomatic would be considered minimally improved and classified as nonresponders.

### *Statistics*

Categorical differences among drugs (response versus nonresponse) were tested for differences for patients grouped according to pretreatment Hamilton depression scores by using two-by-three chi-square. Similarly, differences in response rates among patients grouped by Hamilton scores were tested for each drug.

## RESULTS

Of the 401 patients, 140 had pretreatment Hamilton depression scale scores of 12 or less (low scores), 126 had scores of 13–15 (medium scores), and 135 had scores of 16 or greater (high scores). The table shows their rates of response. Patients with low baseline Hamilton depression scale scores responded to both imipramine and phenelzine significantly more often than to placebo. The most striking difference between the patients with low Hamilton depression scale scores and

[c] Two-by-three $\chi^2$=4.76, df=2, p=0.09; low versus medium score, n.s.; low versus high score, $\chi^2$=3.74, df=1, p=0.05; medium versus high score, $\chi^2$=2.74, df=1, p=0.10.

those with higher pretreatment Hamilton scores was in their higher rate of response to placebo. Patients with high Hamilton depression scale scores had a very low rate of response to placebo. The trend toward less of a response to phenelzine among patients with high Hamilton depression scale scores appears to be accounted for by their lower rate of nonspecific response, as estimated by placebo response. That is, the response rate appears to consist of a combination of nonspecific response (i.e., they improved for reasons other than the specific effects of the medication) and specific response (i.e., they needed the medication in order to improve). Since the patients with higher Hamilton depression scale scores seemed to have a lower rate of nonspecific response (as estimated by placebo), their apparent drug response might have been less inflated by nonspecific response. An estimation of rate of "true" drug response, then, is the difference between response rates to medication and placebo and yields an estimate of what percent of the patients "needed" the drug to improve, as opposed to getting better despite having taken a medication. This estimated "true" drug response rate was 27%, 19%, and 38% for imipramine, and 50%, 52%, and 54% for phenelzine in the groups with low, medium, and high initial Hamilton depression scale scores, respectively. Since these drug-placebo differences were similar for the three groups and did not show up as a significant drug by severity interaction, we appear to have demonstrated differences in placebo (i.e., nonspecific) response but no difference in "true" drug response among the groups with different Hamilton scale scores.

One might suspect that less severely depressed patients would tolerate side effects less well than more severely depressed patients. If so, then patients with low Hamilton depression scale scores who were not experiencing a remission in their symptoms might drop out of the study, artificially leaving only those patients who had improved. This would result in an apparent drug effect that in reality would be due to unimproved patients dropping out. In fact, no more patients with low pretreatment Hamilton depression scale scores dropped out on drug than on placebo ($\chi^2$=3.52, df=2, n.s.), and there was no difference between patients with low and high Hamilton depression scale scores in rate of dropouts overall or in each drug group ($\chi^2$=0.11, df=2, n.s.). There is thus no suggestion that differential dropout rates artificially produced the results shown.

## DISCUSSION

These data support the utility of antidepressant medication in depressed patients with mild symptoms (at least as measured by the Hamilton depression scale). The most striking difference between patients with low and high Hamilton depression scale scores was the somewhat greater placebo response in the more mildly depressed patients. Once this nonspecific improvement was taken into account, the responses accounted for by specific effects of the medication (drug response minus placebo response) did not differ across groups with different Hamilton depression scale scores.

Since the pharmaceutical companies often require Hamilton depression scale scores in the upper range for entry into their investigational protocols, what are the implications for subsequently giving antidepressants to patients who would not have been eligible for the studies that demonstrated the drug's efficacy? At least for imipramine and phenelzine, it appears that the likelihood of benefit from these agents over and above what may be expected from placebo effects does not differ between the patients with high Hamilton depression scale scores (likely to be eligible for a pharmaceutical company trial) and those who are too "mildly depressed" for entry into these trials. By limiting their trials to the more severely depressed, however, the companies may be unnecessarily limiting their available pool of potential patients and limiting the generalizability of the results of their efficacy studies.

Results of this study run counter to an earlier report of efficacy of desipramine in more severely depressed patients but not in those with mild depression (i.e., those with a Hamilton depression scale score lower than 14) (6). We feel that the discrepancy occurred because of the small number of patients in that study with low Hamilton depression scale scores (N=32). The current study included approximately four times the number of patients, resulting in much narrower confidence limits and less likelihood of asserting no difference when one exists.

The NIMH Treatment of Depression Collaborative Research Program also failed to demonstrate efficacy of imipramine in mildly depressed outpatients with major depression. Although not explicitly stated in the published results, it appears that among 22 patients with Hamilton depression scale scores lower than 20, 55% responded to imipramine, compared with 38% of 21 placebo-treated patients. Although this was not a significant difference between drug and placebo, it is similar to our own results, but with less than half the sample size. Power analysis suggests that if our own imipramine results are accurate the NIMH study only had a 52% chance of finding a significant result with the sample size they used. They may have erroneously asserted the null hypothesis.

Another issue is the seemingly low rate of placebo response in the patients in the current study. Typical rates of placebo response seen in pharmaceutical trials are in the range of 25%–35%. This was the rate of patients who began with low and medium Hamilton depression scores. Patients with scores of 16 or higher, in the range of patients usually included in pharmaceutical trials, had a significantly lower rate of placebo response—10%. We have several possible explanations for this. First, we may be somewhat more conservative in our use of the Hamilton depression scale and the CGI. If so, our Hamilton depression scale scores and response rates may be somewhat lower than other investigators would obtain with the same patients. Second, 83% of the patients reported here had definite or probable atypical depression (8, 9), a hypothesized form of depressive disorder characterized by reversal of the endogenous features that the Hamilton depression scale captures. Hence, the severity of their disorders may not have been adequately reflected by the Hamilton depression scale, and their rate of placebo response might differ from that of patients with other types of depression. Finally, we rate responses on the CGI conservatively, so that a patient must have improved enough that residual symptoms were minimal or absent. We assume that our conservative approach to judging response decreases the likelihood that nonspecific changes in symptoms would be considered positive responses. This conservative approach might yield a lower rate of placebo response in our patients than others would find. The practical result is that the power of a study to demonstrate effectiveness of a drug would be increased. That is, for a study of a given size, the likelihood of finding a difference between drug and placebo is greater if the placebo response rate is lower. Alternatively, fewer patients are needed to have a given likelihood, say 80%, of showing the difference to be significant.

Some skewing of results may have occurred due to the siphoning off of patients into other studies. For example, the patients accepted into these competing studies included a predominance of men and postmenopausal women, while approximately half of the current group included women of childbearing age. We do not believe that the results were skewed because only one small study involving nine patients required Hamilton depression scale scores of 18 or greater. The other studies required Hamilton depression scale scores of 10 or greater (N=93) or had no Hamilton depression scale score requirement (N=41). Thus, sex and age may have been skewed, but we have not found these to affect medication response, and the Hamilton depression scale data seem not to have been skewed.

Although hypotheses of differential placebo response must remain conjectural at present, the current data seem convincing that antidepressants can be effective in mildly depressed outpatients. The majority of patients with atypical depression who have mild depressive symptoms can benefit from antidepressant medication.

# White Matter Hyperintensity Signals in Psychiatric and Nonpsychiatric Subjects

Frank W. Brown, M.D., Richard J. Lewine, Ph.D., Patricia A. Hudgins, M.D., and S. Craig Risch, M.D.

*Objective: As part of an ongoing study investigating the relationship between brain morphology/function and neuropsychological performance in psychopathology, the authors conducted brain magnetic resonance imaging (MRI) studies to investigate the prevalence and psychiatric significance of white matter hyperintensity signals. Method: Brain MRI acquisition was done with 0.5 and 1.5 Tesla Philips scanners. Psychiatric subjects (N=229) and normal volunteers (N=154) were recruited by newspaper and local advertising and by physician referral.* DSM-III-R *criteria were used. White matter hyperintensity signals were rated on a 4-point scale of severity. Prevalence rates and risk ratios were calculated. Results: Prevalence rates of hyperintensity signals in all psychiatric subjects (mean age=34 years, SD=9) and normal volunteers (mean age=34, SD=10) were 6.6% and 9.1%, respectively (a nonsignificant difference). When all psychiatric subjects, subjects under age 45, and subjects age 45 and over in a diagnostic category were considered, there were no statistically significant differences between them and normal volunteers in the same age groups in prevalence of schizophrenia, schizoaffective disorder, bipolar disorder, major depression, and obsessive-compulsive disorder. A significant difference existed between the severity of deep white matter hyperintensity signals in subjects with major depression and normal volunteers. Older age was correlated as a risk factor for white matter hyperintensity signals for psychiatric subjects. Conclusions: These results do not support previous findings of greater prevalence of hyperintensity signals in bipolar disorder. Significantly higher prevalence rates of hyperintensity signals were seen in subjects with major depression only when severity of the deep white matter hyperintensity signals was considered. Older age is an indirect risk factor for the presence of white matter hyperintensity signals, probably as a result of vascular changes associated with concurrent medical illnesses.*

(Am J Psychiatry 1992; 149:620–625)

Magnetic resonance imaging (MRI) using spin-echo pulse sequences has permitted the identification of previously undetected phenomena, one of these being increased signal intensity within deep and periventricular white matter. Increased signal intensity on $T_2$-weighted brain MRI may be caused by numerous processes including hydrocephalus, demyelinating diseases, flow enhancement in slowly flowing vessels, a linear signal from penetrating cortical vessels, sulci, edema, or dilated perivascular spaces (1–8). Many hyperintensity signals remain unexplained, thus giving way to the use of such terms as unidentified (ubiquitous) bright objects, leukoencephalopathy, and subcortical encephalomalacia. This paper will refer to these unexplained increased signals as white matter hyperintensity signals.

Studies have begun to examine white matter hyperintensity signals in a variety of psychiatric populations including depression (9–14), obsessive-compulsive disorder (15), bipolar disorder (16–19), schizophrenia (20–23), panic disorder (24), and dementia (1, 25–31; unpublished 1985 study of G.R. Cherryman et al.). Data to date indicate that patients with bipolar disorder are more likely than age-matched control subjects to have white matter hyperintensity signals (16–19), that subjects with late-onset schizophrenia have a greater prevalence rate of white matter hyperintensity signals than control subjects (18, 21, 22), and that a subcortical arteriosclerotic process may account for the greater prevalence of white matter hyperintensity signals in depression (9–14, 32–34).

The purpose of this paper is to present recent prevalence data on white matter hyperintensity signals in a large group of psychiatric subjects and normal volunteers. Comparisons will be made to earlier studies when appropriate, and a discussion of etiology and implications will be presented.

## METHOD

As part of an ongoing study investigating the relationship between brain morphology/function and neuropsychological performance in psychopathology, we conducted brain MRI studies to investigate the prevalence and the psychiatric significance of white matter hyperintensity signals. Brain MRI acquisition was performed with 0.5 and 1.5 Tesla Philips scanners (Shelton, Conn.). Spin-echo sequences, employing multiecho technique, in the axial plane with long repetition time (2000/50–100 msec/1: repetition time/echo time/acquisition), were used. Slice thickness was 7 mm except for three MRI scans which used 5-mm and 6-mm slice thickness that showed focal 4–6-mm white matter hyperintensity signals. All scans were done at a university hospital. Eighty-three percent of the normal subjects (N=128) and 54% of the psychiatric subjects (N=124) had 0.5 Tesla MRI scanning. Because of overnight stays for the psychiatric subjects, additional use of the 1.5 Tesla MRI scanner was possible during off hours. More normal subjects had 0.5 Tesla MRI scanning because most normal subjects were scheduled as outpatients.

Psychiatric subjects (N=229) and normal volunteers (N=154) were recruited by newspaper and local advertising and by physician referral. Detailed informed consent was obtained from all subjects. Normal subjects were medically and psychiatrically healthy. Comprehensive screening laboratory tests (SMA-22, CBC, urinalysis, thyroid function) were done, including a urine drug screen, ECG, MRI, and physical and neurological examinations. Normal subjects had to have the following to be included in the study: a negative urine drug screen, normal ECG as read by a cardiologist, normal results on physical examination, no history of diabetes or untreated or uncontrolled hypertension, normal results on neurological examination, normal electrolytes, normal CBC, normal urinalysis, and normal thyroid tests. Normal subjects could not have any Research Diagnostic Criteria lifetime diagnosis except for normal brief depressive episodes after situational loss. All subjects were administered the Schedule for Affective Disorders and Schizophrenia-Lifetime Version (SADS-L) and an extensive neuropsychological battery, and most had a lumbar puncture performed during a short inpatient stay on a research unit. Diagnosis was based on *DSM-III-R* criteria using the SADS-L.

Brain MRI scans were initially read once by one of three university neuroradiologists to determine the presence of white matter hyperintensity signals. One neuroradiologist read 46% of the scans; the remainder were equally divided between the other neuroradiologists. Rating scales were not incorporated for the initial MRI reading. The neuroradiologists were aware only of the subject's age and that the subject was in a research study investigating white matter hyperintensity signals; specific information such as type of psychiatric disorder or comparison status was not made available. Dictated MRI findings were kept of each subject with emphasis concerning white matter hyperintensity signals. Neuroradiologists would comment as to known or unknown etiology of white matter hyperintensity signals. Neuroradiologists randomly reviewed MRI scans from psychiatric and normal subjects as well as 0.5 and 1.5 Tesla MRI scans. Interrater reliability and intraindividual drift were not assessed for the first MRI reading.

From August to December 1990, one neuroradiologist (P.A.H.), unaware of diagnosis, reviewed all scans for which the dictated findings indicated the presence of white matter hyperintensity signals from any cause and an age-matched psychiatric and normal comparison group. A 4-point severity rating scale, modified by Coffey et al. (9), was used that allowed for severity and location of periventricular and deep white matter hyperintensity signals to be noted. Subcortical lesion size and location were also described. This second reading of MRI scans was intended to allow a measure of reliability of repeat readings between raters and to rate severity, size, and location of white matter hyperintensity signals. Prevalence rate was based on the second reading of MRI scans.

An etiological approach to determining a white matter hyperintensity signal was incorporated by the neuroradiologist (P.A.H.) in reading the MRI scans the second time. In essence, if a focal white matter hyperintensity signal was felt to represent a deep cortical sulcus, high signal within a cortical vessel, or any other normal structure, the neuroradiologist did not count it as a white matter hyperintensity signal. Any white matter hyperintensity signal that was felt to be due to a known cause was noted to allow comparison to the previous reading. A total of 36 MRI scans with white matter hyperintensity signals and 33 comparison scans were reread to assess interrater reliability.

Risk ratios were calculated as the prevalence rate among persons with white matter hyperintensity signals in a diagnostic group divided by the prevalence rate among normal comparison subjects in the same age group. Point prevalence rate was calculated as the number of subjects with white matter hyperintensity signals divided by the group size. Tests for significance were based on the Z test for the difference between two proportions, two-tailed analysis, and the Z test for the difference of the means in two groups, two-tailed analysis. Interrater reliability for the presence or absence of white matter hyperintensity signals was assessed by using the kappa statistic for measurement of reliability between the first MRI readings by the three neuroradiologists and the second reading of 69 MRI scans by one neuroradiologist. Simple agreement was calculated as total scans in agreement divided by the total group (N=69).

**TABLE 1. Relation of Diagnosis and Age to Prevalence of White Matter Hyperintensity Signals**

| *DSM-III-R* Diagnosis and Age Group | Age (years) Mean | SD | N | Prevalence of White Matter Hyperintensity Signals (%)[a] | Risk Ratio[b] |
|---|---|---|---|---|---|
| Schizophrenia | 33.2 | 9.0 | 114 | | |
| <45 years | 30.9 | 6.1 | 103 | 2.9 | 0.4 |
| ≥45 years | 52.2 | 6.3 | 11 | 9.1 | 0.6 |
| Schizoaffective disorder | 38.2 | 9.1 | 21 | | |
| <45 years | 35.0 | 6.3 | 17 | 0.0 | 0.0 |
| ≥45 years | 52.0 | 5.6 | 4 | 25.0 | 1.8 |
| Bipolar disorder | 37.7 | 7.6 | 22 | | |
| <45 years | 34.5 | 5.2 | 17 | 5.9 | 0.9 |
| ≥45 years | 48.4 | 3.4 | 5 | 0.0 | 0.0 |
| Major depression | 40.3 | 10.5 | 28 | | |
| <45 years | 33.8 | 5.5 | 18 | 5.5 | 0.8 |
| ≥45 years | 52.5 | 5.6 | 10 | 30.0 | 2.1 |
| Obsessive-compulsive disorder | 33.6 | 9.2 | 9 | | |
| <45 years | 32.2 | 8.2 | 8 | 0.0 | 0.0 |
| ≥45 years | 48.0 | | 1 | 0.0 | 0.0 |
| Organic personality disorder | 37.5 | 13.4 | 2 | | |
| <45 years | 28 | | 1 | 0.0 | 0.0 |
| ≥45 years | 47 | | 1 | 100.0 | 7.0 |
| Brief reactive psychosis | 24.5 | 9.2 | 2 | | |
| <45 years | 24.5 | 9.2 | 2 | 50.0 | 7.4 |
| ≥45 years | | | 0 | | |
| Normal volunteers | 34.0 | 9.5 | 154 | | |
| <45 years | 31.1 | 6.2 | 133 | 6.8 | |
| ≥45 years | 52.3 | 5.7 | 21 | 14.3 | |

[a] Number of individuals with white matter hyperintensity divided by total number in diagnosis and age group.

[b] Prevalence within diagnosis and age group divided by prevalence among appropriate normal volunteers.

**TABLE 2. Severity of White Matter Hyperintensity Signals in Major Depression**

| Rating of Severity | Patients With Major Depression | Normal Volunteers |
|---|---|---|
| Periventricular white matter hyperintensity signals | | |
| 0 | 27 | 148 |
| 1 | 0 | 5 |
| 2 | 0 | 0 |
| 3 | 1 | 1 |
| Deep white matter hyperintensity signals[a] | | |
| 0 | 24 | 145 |
| 1 | 3 | 8 |
| 2 | 0 | 1 |
| 3 | 1 | 0 |

[a] The difference between the two groups was significant (Z=2.45, p<0.03, Z test for two proportions, two-tailed).

## RESULTS

Interrater reliability between the original MRI reading and the follow-up reading (69 scans) gave a kappa of 0.68 (84.1% simple agreement). Sex, race, and magnetic field strength (0.5 versus 1.5 Tesla) did not correlate with the presence or absence of white matter hyperintensity signals. Age correlated with the presence or absence of white matter hyperintensity signals for the psychiatric group ($Z=3.4$, $p<0.001$) but only approached significance for the normal group ($Z=1.6$, $p=0.10$). The mean age for the psychiatric group with white matter hyperintensity signals was 42.8 years (SD=10.4), and for the normal group with white matter hyperintensity signals it was 37.8 years (SD=11.2). Prevalence rates of hyperintensity signals in all psychiatric subjects (mean age=34, SD=9) and normal volunteers (mean age=34, SD=10) were 6.6% and 9.1%, respectively (a nonsignificant difference).

Prevalence rates and risk ratios of normal volunteers and subjects in seven psychiatric diagnostic categories are listed in table 1. In each diagnostic category, results are listed for subjects under age 45 and age 45 and older. When all subjects (under age 45 and age 45 and over) in a diagnostic category were considered, there were no statistically significant differences between them and normal comparison subjects in the same age groups for schizophrenia, schizoaffective disorder, bipolar disorder, major depression, and obsessive-compulsive disorder. For organic personality disorder and brief reactive psychosis, meaningful comparisons were difficult because there were only two subjects in each category.

For major depression, when severity of *periventricular* white matter hyperintensity signals was considered (table 2), no significant difference existed between normal volunteers and subjects. A significant difference existed between the severity of *deep* white matter hyperintensity signals in subjects with major depression and normal volunteers.

## DISCUSSION

This study is unique in that it used a large group of subjects and assessed multiple psychiatric populations for the prevalence and risk of white matter hyperintensity signals. Data in table 1 indicate nonsignificant differences in prevalence rates of white matter hyperintensity signals in the comparison and psychiatric subjects when severity of the white matter hyperintensity signals is not considered. Our findings do not show an association between the presence of white matter hyperintensity signals and a diagnosis of any psychiatric disorder. Organic personality disorder and brief reactive psychosis were each diagnosed in only two subjects; thus, significance is difficult to assess.

It is interesting that these results do not support previous findings of significantly greater prevalence of white matter hyperintensity signals in bipolar and major depression samples. In fact, for bipolar disorder, a reverse trend, while not significant, was evident (risk ratio=0.58, $Z=0.307$) when the entire bipolar group was considered. Subjects with major depression and schizophrenia and normal subjects over the age of 45 had a nonsignificantly higher prevalence rate of white matter hyperintensity signals than those subjects under age 45; this finding may reflect, in part, age-related brain vascular changes. For the entire psychiatric group, age correlated significantly with the presence or absence of white matter hyperintensity signals ($Z=3.4$, $p<0.001$), while for the normal group, this correlation approached significance ($Z=1.6$, $p=0.10$). We feel that this finding is consistent with previous studies (5, 35, 36). If age-related brain vascular changes account for a greater prevalence of white matter hyperintensity signals, then reducing potential risk factors for vascular disease would lower the potential risk. Our normal group excluded patients with known neurological or physical illnesses including diabetes and untreated or uncontrolled hypertension. The stringent selection criteria for normal subjects probably account for the nearly significant correlation between white matter hyperintensity signals and age in this group. Psychiatric subjects did not have to meet these stringent exclusion criteria.

Making comparisons among different studies is difficult because of different methodologies and population sampling techniques. Periventricular capping was not included for analysis in this study unless the neuroradiologist on the second reading felt that it was of greater prominence than what is normally seen in all populations (37, 38). This represents determination of the clinical significance of white matter hyperintensity signals instead of a strict description of the presence or absence of white matter hyperintensity signals. Previous studies have reported one or the other (9, 13, 16, 18). However, when severity of deep white matter hyperintensity signals was considered (table 2), a significant difference ($Z=2.45$, $p<0.03$) existed between subjects with major depression and normal individuals. This significant finding has been reported in previous studies (9, 13).

Interrater reliability for the study of white matter hyperintensity signals has been reported in other studies. Coffey et al. (9, 13) reported a simple agreement of 93% between two MRI raters; no kappa was reported. Rabins et al. reported an interrater reliability using the interclass correlation coefficient of 0.85, which represented good reliability (39). Coffey et al. (personal communication, March 1991) and Rabins et al. have used rating scales that incorporate standard photographs depicting the various severity stages of white matter hyperintensity signals for all of their determinations of severity. For our study, simple agreement was 84.1% with a kappa of 0.68. Of 69 MRI scans reviewed, 58 were in agreement as to the presence or absence of deep white or periventricular white matter disease (36 scans with white matter hyperintensity signals and 33 scans without white matter hyperintensity signals). It is felt that this reliability would have been greater if rating scales using pictorial guidelines had been incorporated.

There are methodological concerns from this study. The use of two different MRI scanners can potentially alter data interpretation. Eighty-three percent of normal and 54% of psychiatric subjects received 0.5 Tesla MRI scanning, while the rest received 1.5 Tesla MRI scanning. Outpatients randomly received either 0.5 or 1.5 Tesla, while inpatient subjects more often received 1.5 Tesla MRI. Of 28 subjects (13 normal and 15 psychiatric subjects) who received 0.5 Tesla MRI and 1.5 Tesla MRI scanning in follow-up after 1 year, there were no differences in scan interpretation, which indicates that no new or previously undetected white matter hyperintensity signals were found. Five subjects had white matter hyperintensity signals on both 0.5 Tesla and 1.5 Tesla MRI. The use of three neuroradiologists to perform the initial MRI reading without interrater reliability is of concern. Due to project limitations, this was not feasible. However, all neuroradiologists were board-certified, evaluated subjects randomly on 0.5 Tesla and 1.5 Tesla MRI, and used the same guidelines for evaluation. The second MRI reading was done by one neuroradiologist using a rating scale. The second rater used an etiological approach to white matter hyperintensity signals. If white matter hyperintensity signals that were explained by known or highly suspected cause are considered, 11 additional subjects would be added, to give a modified prevalence rate of white matter hyperintensity signals from any cause of 9.2% for psychiatric subjects and 12.3% for normal comparison subjects (a nonsignificant difference).

The significance of this large study is that white matter hyperintensity signals, when coded as present versus absent, failed to differentiate psychiatric patients and normal comparison subjects. Significantly greater rates were seen in subjects with major depression only when severity of the deep white matter hyperintensity signals was considered.

Possible explanations for this association include the following: 1) white matter hyperintensity signals (perhaps through vascular changes) are markers for conditions that predispose individuals, especially those with late-onset depression, to the expression of depressive disorders, 2) depressive disorders predispose individuals to the development of white matter hyperintensity signals (i.e., induced hypoperfusion), and 3) an underlying disease process predisposes individuals both to the development of depression and white matter hyperintensity signals. We believe that white matter hyperintensity signals represent subtle anatomical changes that occur as a result of vascular insults, producing an expression of psychiatric symptoms that is determined by location of the vascular insult. Many late-onset psychiatric disorders may in fact be a direct result of such injury. Previous studies support this theory (10, 11, 32). Determination of white matter hyperintensity signals may well represent a noninvasive approach in assessing the likelihood of development of psychiatric symptoms or disorders.

There is a need for continued research in psychiatric populations that uses standardized rating scales with pictorial guidelines for hyperintensity signals that will allow comparisons between levels of severity. The decision to include all hyperintensity signals independent of presumed cause (versus only unexplained hyperintensity signals) remains a controversial issue that can easily influence reported prevalence rates. Studies must define the specific methodologies used to define white matter hyperintensity signals. Studies need to continue to incorporate neuropsychological testing, especially complex tasks and attentional tasks; if, in fact, white matter hyperintensity signals represent anatomical changes that produce psychiatric symptoms, then subtle neuropsychological findings should be evident, as some earlier studies suggest (17, 40).

## CONCLUSIONS

In this assessment of large psychiatric and comparison groups, we found no significant differences in the prevalence rate of white matter hyperintensity signals. A significant difference existed between severity of deep white matter hyperintensity signals in subjects with major depression and normal comparison subjects, as has been reported in earlier studies (9, 13).

## New Policy Regarding Letters to the Editor

Effective immediately, Letters to the Editor critical of an article published in the *Journal* must be received within 6 weeks of the article's publication. Letters received after the deadline will not be considered and will be returned unreviewed.

# Psychotherapy With Mexican-American Patients

Elisa G. Sanchez, M.D., and Paul C. Mohl, M.D.

*Objective: The authors sought to determine whether 20 years of cultural change have altered the clinical lore and earlier findings that Mexican-Americans are more resistant to psychotherapy than other ethnic groups and less likely to be referred for it. Method: All charts of patients seen on a university hospital psychotherapy service since its inception in 1979 were reviewed in three separate studies. The charts of all cases closed as of 1984, the charts of all active patients during 1985, and the charts of all patients screened for therapy in 1986 were included. Ethnic background, age, sex, education, income, treatment modality recommended, duration of therapy, and outcome (interrupted versus completed therapy) were recorded for each patient. Results: There were minor significant differences between the Mexican-American patients and the Anglo-American patients in age and education. No other significant differences were found. Conclusions: Because of cultural change, altered psychiatric perspectives, and/or the effects of socioeconomic status as a confounding variable in previous studies, the accepted clinical lore and earlier findings about psychotherapy with Mexican-Americans may no longer apply.*

(Am J Psychiatry 1992; 149:626–630)

In the main, our knowledge of psychotherapy with Mexican-American patients has been derived from studies of low-income, poorly educated patients who have sought psychiatric treatment in public mental health facilities. The findings of these studies have been applied to all Mexican-American patients without regard for the distinctiveness of subgroups. According to these studies, Mexican-American patients, as compared to "Anglo" patients, are often chosen for supportive, nonintensive psychotherapies. They also have higher rates of dropping out of treatment and have difficulties in treatment that arise from cultural differences between them and their therapists.

The purpose of this investigation was to reexamine some of these earlier findings. There has been limited research on patients with higher incomes and educational levels. We reviewed data on Mexican-American patients with these characteristics and compared them with a similar group of Anglo-American patients.

Since a large majority of Mexican-Americans belong to lower socioeconomic classes, they have mostly been grouped with low-income patients of different ethnic and racial groups in research on treatment. It has long been noted that patients in the lower social classes are more apt to receive short-term supportive psychotherapy or pharmacologic or other somatic therapies (1). They are believed to be more apt to seek only relief of symptoms, to have a poor understanding of the psychotherapeutic process, and to lack a desire for psychotherapy (2).

Yamamoto et al. (3) found that minority-group patients at a large metropolitan county hospital were more often seen in supportive follow-up therapy. The percentages of Caucasian, Mexican-American, and African-American patients who were offered either individual or group psychotherapy were 50%, 40%, and 33%, respectively. Seventy-eight percent of the Caucasians remained in treatment beyond the 9-month period of the study, compared to 14% of the African-Americans, 51% of the Mexican-Americans, and 3% of the Oriental patients. The interpretation was that Caucasian patients were more popular among therapists because they shared with them values and attitudes that facilitated empathy.

Karno (4) found that what he called "old Americans" were more often offered psychotherapy (25 of 65 patients) than were Mexican-Americans (four of 22) and African-Americans (six of 30). Also, the duration of treatment was longer for the old Americans (21 sessions) than for the Mexican-Americans (14.5 sessions) and the African-Americans (14 sessions). When social

class was taken into consideration, old Americans were accepted in psychotherapy in higher numbers than the patients of the ethnic groups of the same social classes. This was interpreted as proving that differences in treatment between the old Americans and the ethnic groups were related to ethnicity rather than social class.

The life orientation of low-income and minority patients has been described as less concerned about the way they relate to life and as wanting immediate answers to their needs. They give little importance to verbalization and greater emphasis to action and expect resolution of their psychological distress in the immediate future (5). Consequently, it has been recommended that therapy be limited to segments of six or fewer visits at a time. Afterward, therapy may be renegotiated to maintain specific short-range goals. Role preparation has also been advised for patients beginning therapy (6).

Goin et al. (7) studied the expectations about treatment among a group of low-income patients. They found that a surprisingly large proportion (62%) wanted to talk about their feelings rather than have the doctor do something to make them feel better. This apparent wish for a more dynamically oriented psychotherapy did not correspond, however, to the number of sessions they expected to attend. Sixty-one percent of these patients foresaw less than 10 sessions.

In an analysis of the services received by minority patients in 17 community mental health facilities in the Seattle area, Sue (8) compared four ethnic groups to a Caucasian group. More than 50% of the black, Native American, and Asian-American patients dropped out after one contact with the facility, as compared to 42% of the Chicanos and 30% of the Caucasians. The mean number of sessions was 4.68 for the black patients, 3.28 for the Native Americans, 2.35 for the Asian-Americans, 5.30 for the Chicanos, and 7.96 for the Caucasians.

Acosta (9), studying treatment expectations of Mexican-American and Euro-American outpatients in an east Los Angeles clinic, found that Mexican-American patients expected therapy to last an average of 17 visits, compared to 23 for the Euro-Americans. In another study (10), he found that the reasons given for premature termination of treatment by low-income Mexican-American, black American, and Anglo-American patients were not significantly different.

Yamamoto et al. (11) reported that a difference in race between therapist and patient may hinder the psychotherapeutic process. It may even cause the patient to terminate treatment prematurely if she or he perceives the therapist to be prejudiced. These investigators measured the level of ethnocentricity of a group of therapists and found that it was inversely correlated with the frequency with which the therapists saw minority group patients for six or more visits.

It has been mentioned that therapists often lack the knowledge necessary to work effectively with minority populations and their subgroups. This, along with the presence of racism, is believed to raise prejudicial attitudes against minority groups, with the attendant provision of less intensive, unenthusiastic care (5). However, interest in understanding patients of different cultures seems to be growing, as indicated by recent research. Lopez and Hernandez (12) explored the importance that mental health professionals give to culture in their work. Thirty-nine percent of the clinicians studied rated culture as extremely important in their evaluations, and 83% took culture into consideration with most or all of their culturally different patients.

On the other hand, personal characteristics of Mexican-Americans have been held to account for their infrequent participation in intensive therapy. Karno (4) noted that the passivity and polite, inhibited silence of Mexican-Americans are poor equipment for competing for the attention of a therapist. He also described the relationship of Mexican-Americans to institutional settings as one of external compliance masking internal and hostile rejection. Heiman et al. (13) postulated that strong family loyalty and general mistrust of outsiders are major factors in the reluctance of Mexican-Americans to participate openly in psychotherapy. Yamamoto et al. (11) suggested that minority-group patients, being in a disadvantaged position, have acquired an attitude of distrust, disenchantment, and hopelessness that prepares them to leave treatment earlier.

However, in one study the perception of mental illness of a Mexican-American community was found not to be significantly different from that of a group of Anglo-Americans (14). The Mexican-Americans were more likely than the Anglo-Americans to advise a person with emotional problems to see a physician, had more trust in being helped by a psychiatrist, and were more optimistic about the curability of mental illness.

Although it has been reported that Mexican-Americans feel rejected, uncomfortable, and not understood by Anglo-American therapists (15), in a study of preferences for Mexican-American or Anglo-American therapists, both Mexican-American and Anglo-American students expressed more positive attitudes toward the Anglo-American professionals (16). Also, the two groups did not differ in their expectations of therapist behavior. In another study with Chicano community college students, Furlong et al. (17) found that the counselor's ethnic background did not affect the students' perceptions of the counselor's credibility and attractiveness.

The vast majority of studies addressing these issues reflect data collected in the 1960s and 1970s. Much has changed since then in the status of Mexican-Americans in the United States. There has been a large influx of Latin American immigrants, with much publicity and wide recognition of their growing status as a minority. Television commercials regularly portray Hispanic contexts. A presidential candidate spoke Spanish during his acceptance speech. There is a growing awareness of distinctions within the Latin American community, especially cultural ones based on country of origin. In San Antonio, Mexican-Americans have become a majority and now dominate the city council. In 1980, San Antonio became the first major American city to elect a Mexican-American mayor. But this is only the tip of the iceberg: the assistant city manager, the prelate of the archdiocese, several judges, most state legislators, and several leading newscasters and local talk show hosts are Mexican-Americans—all for the first time in the last decade. These very visible, dramatic changes reflect and result in significantly altered perceptions. They reflect growing acceptance by Anglo-Americans and increasing acculturation and political, social, and economic self-assertion by Mexican-Americans. The results are constant exposure of Anglo-Americans to Mexican-Americans and their styles and culture. An even more important result is the growing self-confidence and security among people of Hispanic background. The question is whether any of these changes will influence the attitudes of patients and therapists toward psychotherapy for Mexican-Americans.

As an institution long dedicated to community service in an area with a substantial Hispanic population, the department of psychiatry at the University of Texas Health Science Center at San Antonio conducted three separate studies of this issue on its psychotherapy service during the 1980s. This research was triggered by clinical observations of many successful Mexican-American patients on the service (as well as some unsuccessful patients of all ethnic origins), as the following brief vignettes indicate.

*Case 1.* Mr. A, a 38-year-old Mexican-American man who worked as a mid-level manager and technical analyst, sought help for depression. He comfortably engaged in exploratory psychotherapy with a male Anglo-American therapist. This therapy rapidly linked his depression to marital issues. At this point some cultural issues arose, as the patient's inclination was to "protect" his wife and only discuss his marriage with a senior male member of his extended family. At times there were feelings of shame for "embarrassing the family" by discussing such problems with an outsider. After these were worked through, the therapy moved on to Mr. A's idealization of his mother and feelings of inadequacy with respect to his father. Therapy terminated after 2 1/2 years of weekly sessions; the depression was gone, the marriage was stable and rewarding, and Mr. A was developing greater self-confidence at work.

*Case 2.* Ms. B was a 21-year-old unmarried Hispanic nursing student who had chronic feelings of emptiness, very erratic relations with men, and excessive drinking. She rapidly became dependently attached to her female Anglo-American therapist and was able to work effectively within this transference, dealing with her feelings of rage and deprivation at having had to care for her younger siblings because of her mother's depression and her father's alcoholism.

*Case 3.* Mr. C was a 42-year-old Mexican-American truck driver with a third-grade education who was referred by the police after being arrested for indecent exposure. His marriage was very traditional: he worked at two jobs, his wife did not drive or speak much English, and their relationship was marked by a rigid division of labor with a clear sense of mutual respect and responsibility. With a Latin American female therapist, Mr. C was able to verbalize his sense of abandonment resulting from his wife's heavy involvement with their first grandchild. This recalled his repeated experiences of loss as a child when his family moved piecemeal and sporadically from Mexico to the United States—first his father came for periods of work, then some older siblings immigrated, then he was placed with an aunt for a time while his mother joined her husband, and finally, he and two other children were brought to San Antonio. He successfully grieved for these losses and was able to open new lines of communication with his wife, developing greater flexibility in their relationship, with no further acting out after 2 years of therapy.

The psychotherapy service where our study took place is designed to offer psychotherapy with resident trainees on a sliding fee scale. In order to enter therapy, patients must call, fill out a preregistration form, call again to set up a screening appointment with a faculty member (all of whom are Anglo-Americans), keep the appointment, and have psychotherapy recommended. Approximately 45% of those who call are eventually assigned a therapist (almost all of whom are Anglo-Americans).

## METHOD

In the summer of 1984 a decision was made to undertake an investigation of psychotherapy with Mexican-American patients. First, the charts of all terminated cases were reviewed with a specific focus on outcome (study 1). Then, a review of the charts of all current active patients focused on longevity in psychotherapy (study 2), and finally, a prospective study was begun which followed all new patients for the next 18 months on a variety of parameters and noted when they terminated therapy (study 3). Study subjects included all current and former patients of the psychotherapy service whose charts were available.

Although chart recording had been erratic, almost all charts written since the inception of the psychotherapy service did include a notation about whether therapy was deemed completed or interrupted as well as the ethnic background of the patient. In study 1 these data were collected from all charts of closed cases (N=286) and subjected to chi-square analysis.

In study 2, data on ethnic background and total number of sessions attended were recorded for all active patients (N=124) and subjected to t tests. Active patients included some who had been seen for 3 or 4 years as well as some who had begun therapy the week before.

Studies 1 and 2 were in the form of "snapshots" to give us an idea of whether we were seeing a pattern similar to that reported in the earlier literature. Charts of closed cases are likely to have early dropouts overrepresented, and charts of active patients are likely to have long-term cases overrepresented.

In study 3, 255 consecutive new patients in 1986 who could be readily assigned to Mexican-American or Anglo-American ethnic groups were followed. Data were collected at intake on ethnic group, age, sex, years of education, monthly income, and modality of treatment recommended. The number of therapy sessions each patient attended over the following months was also recorded.

[a] With Yates' correction.

[b] N=60 for Mexican-American patients; N=226 for Anglo-American patients.

[c] N=58 for Mexican-American patients; N=197 for Anglo-American patients.

## RESULTS

The results are summarized in tables 1 and 2. The only significant differences we found were in age (Mexican-American patients were younger) and education (Mexican-American patients averaged 1 year less than Anglo-American patients, although both groups had generally gone beyond high school). Mexican-American patients did not differ from Anglo-American patients in number of sessions, likelihood of interrupting therapy, how they were handled by the screeners in terms of being offered therapy, and whether therapy was more or less likely to be short-term.

## DISCUSSION

The results of this study were essentially negative, failing to replicate earlier findings that have become accepted clinical lore. The Mexican-American patients of this study were chosen for psychotherapy as often as the Anglo-American patients, and neither duration of therapy nor dropout rates differed significantly between groups. Our failure to replicate the findings of earlier studies is important because it suggests that clinical lore and previous findings may not be as generally applicable as they once seemed.

There are a number of possible explanations for our failure to replicate previous findings. Our study was done in a different time, a different setting, and a different cultural context than most of the earlier ones. The setting—a psychotherapy service, rather than a mental health clinic, in a city that is 50% Hispanic—may well have engendered different attitudes on the part of the screeners and the residents. In addition, the 15–20 years that had elapsed since the earlier studies were a time of growing sensitivity to cross-cultural issues in psychiatry. Both of these factors are part of the changed cultural context in which our study was completed. In particular, the Anglo-American context is one of greater awareness of a significant and growing Hispanic minority that must be accepted and dealt with. Similarly, the last 20 years have been a time of increasing Hispanic pride as well as acculturation.

In the study by Sue (8), all of the ethnic groups had lower levels of income and education than the Caucasians. This could explain the differences in duration of treatment and dropout rates between Anglo-American and Mexican-American patients, which in any case were much less significant than those between the Anglo-American group and the other ethnic groups. The studies by Goin et al. (7) and Acosta (9, 10) further demonstrated that the expectations for short-term therapy and for being actively helped by a therapist were more related to low social class and, possibly, low educational level than to ethnicity. It may be that the earlier findings were never entirely accurate representations of the broad mental health needs of Mexican-Americans. Social class may have been a confounding variable.

In addition, the definition of ethnicity is not as straightforward as it might seem. Self-report, identification by Spanish surnames, and/or identification by staff members have been used in different studies. To avoid confusion in research, Lopez (18) recommended a differentiation between race and ethnic background in self-reports and identification of the countries of origin of patients, their parents, and their grandparents. In our population there were representatives of at least four different subgroups: 1) Mexican-Americans who had lived in south Texas for hundreds of years, 2) highly acculturated descendants of mostly middle-class Mexicans who had emigrated in the 1920s and 1930s to escape political and economic turmoil, 3) less acculturated more-recent immigrants and their children who were mostly uneducated and poor, and 4) Anglo-Americans with Hispanic surnames. This last group was counted as Anglo-American in our study.

Yamamoto et al. (11) demonstrated the negative effects of prejudice on treatment outcome. Although more research on the therapeutic relationship between therapists and ethnically different patients is needed, the difficulty in working with these patients cannot be denied. There will always be cultural issues that should be addressed in therapy regardless of the level of acculturation of the patient. If we add to this the differences in social class, education, and language between therapists and patients, therapy can become a complicated endeavor. Although working with more acculturated and more educated patients facilitates empathy and understanding in therapists, because of therapists' different backgrounds, training, and personal characteristics,

[b] Median=21 sessions; range=0–151.
[c] Median=27 sessions; range=0–229.
[d] N=58 for Mexican-American patients; N=197 for Anglo-American patients.
[e] Median=$725; range=$0–3,700.
[f] Median=$925; range=$0–4,000.

it is possible that some of them may still feel uncomfortable with Mexican-American patients. Some residents working at the psychotherapy service during the time of this study never saw a Mexican-American patient, whereas other residents followed the course of several Mexican-Americans at the same time. Further exploration is needed to clarify whether this reflects the method of assigning patients, the availability of patients at certain times of the year, or the residents' personal preferences. What is clear is the importance of giving residents experience with culturally different patients.

Discrimination has been one of the reasons frequently given to explain underutilization of mental health services by Mexican-American patients. The Kline study (15), describing Mexican-Americans' perception of Anglo-American therapists as cold, exploitive, and insincere, is a good example of these studies. Utilization is the most researched area with respect to the mental health of Mexican-Americans, with studies that date back three decades (18), when discrimination may have been a more intense and widespread problem. More-recent studies that encompassed two different subgroups of Mexican-Americans, low-income patients and college students, depicted Mexican-Americans as having an open and trusting attitude toward therapists and psychiatric treatment (10, 14, 16, 17). Moreover, a growing number of studies and statistical reports have found that Mexican-Americans utilize mental health services in proportion to their representation in the community (18, 19).

Whatever the cause of our failure to replicate the findings of earlier studies, it seems clear that the interaction of ethnic subgroups and the mental health field is an evolving one and that as far as psychotherapy utilization and involvement are concerned, earlier cultural distinctions may no longer be relevant.

# A Randomized Controlled Study of Psychiatric Consultation Guided by Screening in General Medical Inpatients

James L. Levenson, M.D., Robert M. Hamer, Ph.D., and Louis F. Rossiter, Ph.D.

*Objective: The purpose of the study was to test the hypothesis that psychiatric consultation would reduce health care utilization during and after medical hospitalization. Method: A randomized, double-controlled clinical trial of psychiatric consultation was conducted on the general medical inpatient services of a university hospital. After meeting inclusion criteria, 1,541 patients were screened for depression, anxiety, confusion, and pain over a period of 21 months. The 741 patients with high levels of psychopathology or pain were subdivided into baseline control subjects (N=232), contemporaneous control subjects (N=253), and an experimental consultation group (N=256). The major outcome measures were length of hospital stay and hospital costs. Secondary outcome measures were posthospital health status, rehospitalization rates, and use of outpatient medical care. Results: This study did not demonstrate an effect of experimental psychiatric consultation on hospital resource use or posthospital medical care utilization after adjustment was made for disease severity. Hospital resource use decreased in the entire sample over the 21-month duration of the study. Conclusions: The brief, efficient screen for anxiety, depression, confusion, and pain identified a group of patients who also used more hospital resources, but a single experimental psychiatric consultation did not reduce costs. The double-controlled nature of the design proved essential to avoid being misled by background changes in hospital resource use.*

(Am J Psychiatry 1992; 149:631–637)

Edward Billings began a psychiatric consultation-liaison service at the University of Colorado Hospital in 1934 and reported that over the next 5 years the service led to a reduction in hospital length of stay for medical inpatients with comorbid psychopathology from 28 to 15 days (corresponding to an estimated savings of $43 per patient, since the per diem cost was about $4.00) (1). Since then, little attention has been paid to the study of the effects of psychiatric consultation on health care utilization. Most studies have been retrospective (2–4) and therefore must be interpreted cautiously. One well-designed, prospective, randomized controlled trial demonstrated the cost effectiveness of psychiatric consultation for primary care outpatients with somatization disorder (5). There have been two very small, controlled studies of psychiatric consultation for depressed medical inpatients (6, 7), with mixed results.

Here we report the first large, randomized, controlled trial of psychiatric consultation for general medical inpatients, with health care utilization as the primary outcome studied. We demonstrated previously in our hospital setting that medical inpatients with comorbid psychopathology or pain had significantly longer hospital length of stay and greater costs (8). In this study, we hypothesized that psychiatric consultation would reduce length of stay and other resource use during the hospitalization, as well as reduce health care utilization after discharge.

## METHOD

### *Subjects*

Potential subjects were all patients consecutively admitted between July 1, 1987, and April 30, 1989, to general medical teams at a large urban academic medical center. Patients were not considered for the study if

they became unavailable because of early discharge, transfer, or death. For patients with multiple admissions during this period, at most two admissions were used, consisting of the first admission during the baseline period (July 1, 1987, to Feb. 5, 1988) and the first admission during the intervention period (Feb. 6, 1988, to April 30, 1989). Of 2,670 patients considered for the study, 1,129 were excluded. Patients were excluded if they did not speak English (N=20), were judged by the nursing staff to be too physically ill to undergo a brief interview (N=491), or were judged by the screeners to be unwilling (N=295) or unable (N=323) to give informed consent. A total of 1,541 subjects met inclusion criteria and entered the study after giving written consent. As previously reported (8), excluded (baseline) subjects were older, had longer hospital stays, greater disease severity, more procedures, and greater hospital costs and charges, which was anticipated since patients were systematically excluded if they were too ill to be interviewed or too demented to give informed consent.

### *Procedure*

*Protocol.* Patients were approached during the first 24–48 hours after admission and asked to participate in a study of the psychological effects of physical illness. After agreeing to participate, subjects were given the Medical Inpatient Screening Test (9), a composite of instruments measuring anxiety, depression, confusion, and pain. Anxiety and depression were measured with the 23 questions from the Hopkins Symptom Checklist (SCL-90-R) (10) that measure these symptoms. Cognitive dysfunction was identified with the Mini-Mental State examination (11). Pain was measured with visual analog scales. Cutoff scores and their rationale as well as other characteristics of the Medical Inpatient Screening Test have been described previously (8, 9).

Demographics, discharge diagnoses, diagnosis-related group (DRG), length of stay, hospital charges and costs, number of diagnoses, and number of procedures came from computerized hospital records and were matched with Medical Inpatient Screening Test data in our database. Costs were estimated by the hospital by means of a standard-ratio-of-cost-to-charges method based on the Medicare cost report. We used two measures of severity of illness, the DRG weight and the TOTSCALE score from the Disease Staging system of SysteMetrics (12, 13). We chose two because all current measures of disease severity have significant limitations (13). DRG weights serve as the current adjustors for Medicare in its prospective payment system. TOTSCALE incorporates DRG weights in addition to other diagnostic and procedure information to calculate a presumably more sensitive measure of overall disease severity. Demographic, disease severity, and hospital resource use data for patients in the baseline and intervention periods are displayed in table 1. Since some patients in the latter period received the experimental intervention, the two groups cannot be directly compared.

*Design.* The study was divided into two phases, a 6-month baseline period (July 1, 1987, to Feb. 5, 1988; N=455) and a 15-month intervention period (Feb. 6, 1988, to April 30, 1989; N=1,086). Patients in both periods were subdivided into those with high Medical Inpatient Screening Test scores (high levels of psychopathology or pain) and those with low test scores (low levels of psychopathology or pain). Only patients with high test scores (N=741) were subjects for this study. Patients who had high scores during the intervention period and who were randomized to receive psychiatric consultation will be referred to as the experimental group (N=256). There were two control groups, patients with high Medical Inpatient Screening Test scores from the baseline period (henceforth referred to as baseline control subjects; N=232) and patients who had high test scores from the intervention period and were randomized not to receive consultation (referred to as contemporaneous control subjects; N=253). This provided a double-comparison research design in which the experimental group could be compared to both earlier (baseline) control subjects and contemporaneous control subjects. Had we used only baseline control subjects, there would have been a risk of noncontemporaneous control bias (14) if any of the variables changed during the period of the study, a likely occurrence in health care delivery.

We chose to randomize subjects at the level of their ward team rather than by individual subjects. During the intervention period, the five general medical teams each rotated monthly between the experimental and control conditions. Thus, in any given month, three teams were in one condition, and two teams were in the other. Alternating the teams between conditions was intended to produce comparable groups, since the teams were not exactly identical in diagnostic mix. We did not randomize individual subjects, since that would have led to the same physicians caring simultaneously for experimental and control patients, creating a risk of Hawthorne and halo effects (14). We minimized such bias by rotating team condition assignment on the same schedule as the attending and resident physicians who all rotated monthly. We found no evidence of unintended changes in physician behavior caused by the study process (15).

*Experimental intervention.* All high-scoring patients on the intervention teams were assigned to receive a psychiatric consultation, which usually occurred within 24 hours. Experimental consultations were provided by six different psychiatrists over the 15 months. All six had previous experience providing consultations at the hospital. They were not part of the research team and were not informed about the hypotheses of the study. Regular (naturalistic) psychiatric consultation remained available to patients' physicians because it would have been unethical to withhold it. Nonexperimental consultations were provided by different psychiatrists as part of the regular consultation-liaison service. If the patient's physician requested a regular consultation *and* the Medical Inpatient Screening Test triggered an experimental consultation, the patient was seen by the consultant who arrived first. Twenty-one patients in the experimental group received naturalistic consultations, as did 20 contemporaneous control patients. Eight patients with low screening test scores in the intervention period also received naturalistic consultations. We analyzed the data both including and excluding patients who received naturalistic consultations from the experimental and contemporaneous control groups. A total of 158 assigned to the intervention completed experimental consultation. Seventy-seven eligible subjects in the experimental group did not receive consultation because of early discharge, transfer, or death. In our analyses, we did not exclude these 77 patients from the experimental group because to do so would have strongly biased comparisons by eliminating patients with shorter stays and would have artificially inflated length of stay in the experimental group, since there is no clear way to identify and eliminate their counterparts in the control group.

The consultations were not highly structured but followed a standard clinical format (16) that included chart review, patient interview, and contact with physicians, nurses, and family as appropriate. A standard consultation note was placed in each patient's chart including *DSM-III* diagnosis. Each consulting psychiatrist kept a log of the length and number of visits with each patient and the number and types of contacts with others performed as part of the consultation. All consultation notes were reviewed after patient discharge and were rated for concordance with a modified version of Popkin's Consultation-Liaison Outcome Evaluation System (17).

*Follow-up.* All patients in the experimental and contemporaneous control groups were targeted for survey 3 months after discharge with computer-assisted telephone interviews by survey research interviewers. Data were collected on physical functioning (activities of daily living), perceived health status, disability and work loss days, posthospital physician and drug use, financial burden, and current depression and anxiety (SCL-90-R questions). We did not attempt to assess cognitive function or pain over the telephone. Posthospital medical care measured by the interview included emergency room, physician, and clinic visits. We were able to contact 41% (N=197) of the patients, 76% (N=150) of whom completed the interview; the remainder refused (5%, N=10) or did not complete (19%, N=37) the interview. We could not reach 59% (N=281) of the patients because they had no current phone (65%, N=184), never answered (25%, N=70), or were deceased (10%, N=27). Control and intervention subjects were equally represented in those interviewed. There were no differences between those reached and those lost to follow-up on any of the demographic, Medical Inpatient Screening Test, disease severity, or hospitalization variables except for age, sex, and Mini-Mental State score at study entry. Those reached were older (mean ages=56.4 versus 47.1 years; Wilcoxon rank sum Z=1.99, $p<0.05$), were more often women (59% [N=83] versus 45% [N=156]; $\chi^2=8.22$, df=1, $p<0.004$), and had slightly higher Mini-Mental State scores (mean scores=24.8 versus 23.3; Wilcoxon rank sum Z=3.08, $p<0.002$).

While data on rehospitalization were available from the household telephone interview, we used the hospital's database instead, since it provided information for 100% of the baseline and intervention period subjects and presumably was of better validity. While the hospital database would not capture hospitalizations at other hospitals, there is no reason to suspect any difference between experimental and control subjects. We measured the number of rehospitalizations, how soon rehospitalization occurred, and the cumulative hospital days, procedures, costs, and charges that followed (but did not include) the index hospitalization until 6 months after the last subject was discharged. Thus, the period of data on rehospitalization varied with when the subject entered the study, from a minimum of 6 months to a maximum of 21 months for intervention period subjects.

### *Data Analysis*

Had the data been normally distributed, or had the data been transformable to a normal distribution, the optimal analysis would have been a two-factor, fixed-effects analysis of variance (ANOVA), using contrasts to test hypotheses. It is well known that neither length of stay nor total costs (our two primary dependent variables) are normally distributed, but transformations of them are likely to be reasonably normal (18, 19). Log transformations have in the past been shown to make such variables more normally distributed (20, 21), but we explored a subset of the family of Box-Cox transformations (which includes the log transformation). Although some of the variables were transformable to approximate normality, several were intractable. Therefore, we felt it safer to test our hypotheses using nonparametric Wilcoxon rank sum tests.

When attempting to partial out the effects of a covariate (e.g., disease severity), we used the transformed variables and added them as covariates to a fixed-effects, normal-theory ANOVA, producing an analysis of covariance (ANCOVA). Since the transformations did not always produce perfectly normally distributed variables, these results should be interpreted with caution. In addition, we checked our results by using rank ANCOVA, as proposed by Quade (22) and Conover and Iman (23, 24). While Quade (22) proposed the use of aligned ranks in rank ANCOVA, Conover and Iman proposed the use of nonaligned ranks, and we chose the latter course.

In comparing the experimental and contemporaneous control groups, we considered the possibility that results might be skewed by patients with very short or very long hospitalizations. Therefore, we also reanalyzed the data after excluding all patients with admissions of 4 days or less (34% of the sample, N=171), all with admissions of more than 30 days (5% of the sample, N=24), and both.

## RESULTS

### *Effect of Intervention on Hospital Resource Use*

There were no significant differences between baseline control subjects and experimental subjects in any demographic, screening score, DRG group, disease severity, or inpatient outcome variables (table 2). Patients assigned to receive psychiatric consultation did not differ significantly from contemporaneous control subjects on any demographic variable, screening scores, or major DRG group. Contrary to the direction of our hypothesis, the experimental group actually had longer length of stay, more procedures, and higher hospital costs and charges than the contemporaneous control subjects. However, the experimental group also had significantly more severe medical illness than the contemporaneous control subjects. This was reflected in both measures of disease severity and the number of recent hospitalizations before the index hospitalization (mean=0.99, SD=1.86, versus mean=0.59, SD=1.09; Wilcoxon rank sum Z=2.12, $p<0.03$). When severity of illness was partialed out, there were no longer any significant differences between the experimental and contemporaneous control groups in any of the inpatient utilization outcome variables. Further analyses using rank-transformed ANCOVA (22–24) also failed to show any significant differences between the experimental and contemporaneous control groups. Excluding naturalistic consultations did not change the results. Excluding patients with very short stays, very long stays, and both (as described earlier) did not reveal any differences between contemporaneous control and experimental subjects after correction for disease severity. Outcomes did not differ significantly as a function of the medical team or consulting psychiatrist.

### *Effect of Intervention on Posthospital Utilization*

For the segment of the sample who could be located and interviewed at follow-up, there were no differences between contemporaneous control and experimental subjects on activities of daily living score, emergency room visits, physician visits, number of medications, or depression and anxiety scores. Data on rehospitalization were available for the entire sample (table 3). Contemporaneous control and experimental patients did not differ significantly on the number of subsequent hospitalizations, the cumulative length of stay, cumulative number of procedures, or cumulative costs and charges.

Experimental subjects were likely to have their next hospitalization sooner, but this difference disappeared after correction for disease severity. Further analysis using rank-transformed ANCOVA (22–24) showed that a slight effect remained even after adjustment for disease severity (F=4.88, df=1, 484, $p<0.03$), but it is difficult to interpret this small remaining difference in light of the lack of effect shown on the non-rank-transformed analyses. Conover and Iman (23) advised that in this situation the distribution of the variable may be particularly troublesome, and indeed, in this case, the variable both was skewed and had outliers.

### *Consultation Characteristics*

On average, the experimental consultation (N=158) took 1.3 hours for the initial visit; 11.4% (N=18) of the subjects received 1.5 further visits totaling 0.7 hours.

[a] Wilcoxon rank sum test.

There were no significant differences between different psychiatrists in the experimental consultation process, reflected in time spent or contacts made. In experimental consultations, psychiatrists gave a *DSM-III* diagnosis to 82.0% (N=119) of the subjects (the remaining 18.0% [N=26] had no psychiatric diagnosis), made recommendations regarding drug therapy in 29.2% (N=42), and made recommendations for diagnostic procedures in 44.4% (N=64). Chart review demonstrated physician concordance with the psychiatrist in 44.1% (N=52) of the psychiatric diagnoses, 52.4% (N=22) of the drug recommendations, and 32.8% (N=21) of the diagnostic procedure recommendations.

Naturalistic consultations took slightly longer than experimental consultations (J.L. Levenson, unpublished data). While diagnoses and drug and procedure recommendations were made with similar frequency, overall physician concordance was twice as high with naturalistic consultations. The distribution of psychiatric diagnoses differed as well (table 4).

## DISCUSSION

The experimental and control groups did not differ in any of the measured outcomes during and after hospitalization after correction for differences in medical disease severity. There are a number of possible explanations for this, some of which reflect the limitations of this study. While we had demonstrated that the psychopathology and pain for which we screened were associated with greater health care costs (8), the causal relationships are far from clear. Evidence of greater utilization does not address whether comorbid psychopathology is modifiable (or even whether modifying it will reduce utilization). Organic mental disorders and substance abuse accounted for 63% of the psychiatric diagnoses in patients who received the experimental consultations; these conditions are much harder to modify with a brief intervention than most other psychiatric conditions. The prevalence of substance abuse in our sample is especially striking since we had not screened for it directly. The inclusion of pain in our screening is unlikely to be the explanation for so much substance abuse in the sample, since only 11% of the group with high scores on the Medical Inpatient Screening Test had high levels of pain. There may be specific subgroups of patients (defined by medical or psychiatric diagnoses) for whom psychiatric consultation might reduce health care utilization. The best known example is somatization disorder (5), which has a clearer causal effect on utilization than anxiety, depression, cognitive dysfunction, or pain. Either our screen did not identify such potential subgroups or they were "lost" by being submerged in the larger overall subject pool.

The results might have been different had the study been conducted in a different patient population. The majority of our patients were black and poor. Social factors such as poverty may have hampered our ability to have an effect on psychopathology or confounded the effects of psychopathology on utilization. Instability of residence and lack of telephones interfered with our ability to reach patients for follow-up after hospitalization.

Our primary hypothesis was that a psychiatric consultation would reduce length of stay. It seems likely in retrospect that it would be harder to demonstrate utilization reductions in medical inpatients than in outpatients in the current era. Cost containment and other forces have dramatically changed the length and pace of medical hospitalization. In designing this study, we based our power calculations on the ability to detect a change in length of stay of 1 day, or about 9%, because our economist (L.F.R.) viewed that as a reasonable estimate of a substantial change in length of stay. Between the time of those calculations and the beginning of our study, length of stay for general medical patients in our hospital declined about 1 day. Length of stay declined further from our 6-month baseline period to the final 6 months of the intervention period (10.1 versus 8.9 days; Wilcoxon rank sum Z=2.92, $p<0.004$). Such decreases make it more difficult for any intervention to produce further reduction. The brevity of patients' hospitalizations also weakened our intervention, as consulting psychiatrists usually did not have the opportunity to see patients more than once. It should be noted that these changes occurring in length of stay independent of the study intervention validate the importance of our double-control design and its superiority over a comparison of only experimental and noncontemporaneous (baseline) control subjects.

The brevity of the experimental consultations, usually a single visit, leaves open the possibility that more intensive consultation-liaison interventions could have measurable effects on utilization and costs. Another possible explanation of our inability to demonstrate cost benefits of psychiatric consultation is that we studied *experimental,* not naturally occurring, consultations. As noted earlier, we did not randomize naturalistic psychiatric consultation because it is regarded as part of standard care and would be unethical to withhold. There are a number of differences between natural and experimental consultations that might make the latter less effective. Natural consultations occur when physicians request them to help patients with evident psychopathology that often interferes with their medical care. Experimental consultations were triggered by a screen that identified a much larger pool of patients with a different diagnostic mix (table 4). A likely more potent limitation in experimental consultations is that patients' physicians had not *asked* for them. From clinical experience, one would suspect that physicians would pay less attention to unrequested consultations. In fact, we discovered that while experimental and naturalistic consultations were similar in length and content of the initial visit, physician concordance was much lower in experimental consultation, i.e., physicians heeded the psychiatrist's advice much less often. The ethically mandated use of an experimental consultation model that is not fully generalizable to naturalistic consultations remains a continuing difficulty for researchers in this field.

A final reason for our results regarding impact of the intervention is that we included those patients in the experimental group who did not receive the assigned consultation in our analyses comparing experimental and control groups. As explained previously, their exclusion would have artificially inflated the length of stay in the experimental group. Including them diluted any potential effect of the intervention, making it more difficult to prove our hypotheses.

In conclusion, our brief, efficient screening process identified patients with high levels of psychopathology or pain who used more hospital resources, but a simple experimental consultation intervention did not reduce costs. Whether cost benefits can be demonstrated for particular subgroups or with a different intervention requires further study. This report has examined the presence or absence of cost savings, which should not be confused with assessment of the clinical benefits of psychiatric consultation for unrecognized psychopathology. The primary purpose of psychiatric consultation is to aid primary physicians in their diagnosis and management of patients, not to save money. Finally, the value of a double-controlled design was evident because of changes over time in inpatient length of stay and costs that could have otherwise confounded our results.

# Increasing Frequency of the Diagnosis of Obsessive-Compulsive Disorder

Andrew L. Stoll, M.D., Mauricio Tohen, M.D., D.P.H.,
and Ross J. Baldessarini, M.D.

*Objective: This study attempted to document a hypothesized increase in the frequency of the diagnosis of obsessive-compulsive disorder at a large psychiatric teaching hospital and to investigate correlates of this trend. Method: The annual rates of psychiatric discharge diagnoses at the hospital from 1969 to 1990 were reviewed, and the frequency of the diagnosis of obsessive-compulsive disorder was compared with that of paranoid disorders. Correlations were also done on these diagnostic rates and the rates of reports in the literature in the same years on each of these types of disorders and their treatment. Results: The frequency of the diagnosis of obsessive-compulsive disorder, but not paranoid disorders, increased markedly during the 1980s. This increase was associated strongly and selectively with increases in publications about that disorder, particularly reports on drug and behavior therapy. Conclusions: There has been a large recent increase in the rate of diagnosis of obsessive-compulsive disorder, evidently associated with advances in the study and treatment of the disorder. The observations suggest the influence of a treatment-oriented diagnostic bias in which clinicians may more readily consider and diagnose a condition for which an innovative or effective treatment is available.*

(Am J Psychiatry 1992; 149:638–640)

It has been our impression that the diagnosis of obsessive-compulsive disorder has become more frequent recently. If there has been such a change, there is no reason to assume an increase in the incidence of the disorder. Instead, recent therapeutic advances, particularly the use of inhibitors of serotonin uptake and the use of behavior therapy, may have encouraged consideration of this diagnosis. Earlier, similar "clinician bias" was thought to account for relative increases in the diagnosis of schizophrenia in the 1950s and manic-depressive illness in the 1960s following the introduction of neuroleptics and lithium salts, respectively (1). To test the hypothesis that the diagnosis of obsessive-compulsive disorder has been rising along with more frequent research reports on the disorder, we reviewed the annual rates of discharge diagnoses of obsessive-compulsive disorder at a large university psychiatric hospital and correlated these with worldwide rates of publications on the disorder and its treatment. For comparison, we also collected similar data for paranoid disorders, as few advances in the treatment of these disorders have occurred recently (2).

## METHOD

Discharge diagnostic data were collected from the medical records department at McLean Hospital for the years 1969–1990. The proportion of patients with discharge diagnoses of obsessive-compulsive disorder out of all discharge diagnoses was calculated for each year. For comparison purposes, the proportion of patients with discharge diagnoses of paranoid disorders (which were similarly prevalent in the early 1970s) was also calculated for each year. The group of paranoid disorders included *DSM-II* acute paranoid reaction, involutional paranoid state, and other paranoid state, as well as paranoia; *DSM-III* paranoid disorder; and *DSM-III-R* delusional disorder. If more than one disorder was present, only patients with the index disorder listed first were included in this analysis.

In addition, a computer-assisted literature search using the MEDLINE database (3) was performed to identify research reports on obsessive-compulsive disorder and paranoid disorders and their treatment for the

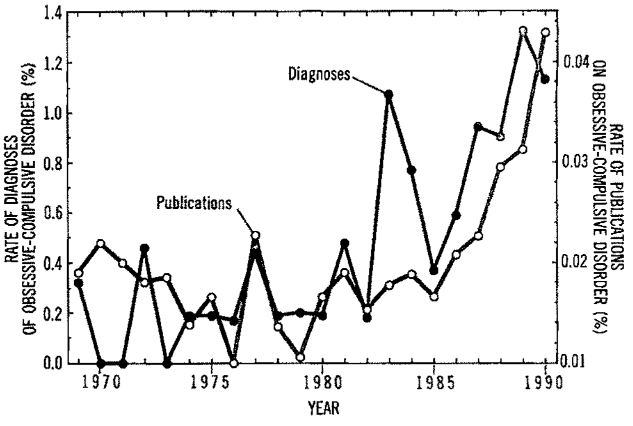
same years. Rates of publication for the disorders were expressed as percentages of the total number of publications in the database per year, to control for an overall increase in research reports of more than 70% during the last two decades. Data are presented as means and standard deviations unless otherwise stated. Rates were compared by t tests, and correlations were computed by nonparametric Spearman rank-order tests.

## RESULTS

From 1969 to 1990, the proportion of patients discharged annually from McLean Hospital with diagnoses of obsessive-compulsive disorder increased more than fourfold (figure 1), from low rates of 0.2%–0.5% in the 1970s (1969–1979 annual mean=0.196%, SD=0.161%) to more than 1.0% by 1983, with high rates sustained throughout the 1980s (1980–1990 annual mean=0.772%, SD=0.388%) (t=10.20, df=20, $p<0.0001$). Simultaneously, the average yearly proportion of MEDLINE publications on obsessive-compulsive disorder for the same periods also increased markedly (figure 1), from a mean of 0.017% (SD=0.004%) of reports per year in the 1970s to 0.023% (SD=0.008%) in the 1980s (t=2.23, df=20, $p<0.05$). Reports on the disorder rose 5.5-fold from 1979 (N=28) to 1990 (N=154). In the 1970s, approximately one-third of the publications on obsessive-compulsive disorder concerned its treatment. In the 1980s, this proportion increased to almost one-half. Correlations between increases in annual diagnosis and publication rates for obsessive-compulsive disorder were highly significant. For all publications on obsessive-compulsive disorder, $r_s=0.54$, N=22, p=0.01, and for reports on all types of treatment, $r_s=0.69$, N=22, p=0.002. Similar correlations were found for reports on pharmacological treatments ($r_s=0.64$, N=22, p=0.003) and behavioral treatments ($r_s=0.67$, N=22, p=0.002).

In contrast to the findings for obsessive-compulsive disorder, the annual frequency of diagnoses of paranoid disorders at McLean Hospital did not change significantly from 1969 to 1990 and even tended to decrease slightly (by 19%). The mean yearly rate of diagnoses of paranoid disorders from 1969 to 1979 was 0.620% (SD=0.407%), compared to 0.500% (SD=0.290%) for the period 1980–1990 (t=0.80, df=20, n.s.). The proportion of MEDLINE publications per year on paranoid disorders also declined in the 1980s, from a mean of 0.015% (SD=0.005%) in 1970–1979 to 0.010% (SD=0.003%) in 1980–1990 (t=2.84, df=20, $p<0.02$). There was no significant correlation between annual diagnostic rates and publication rates for paranoid disorders ($r_s=0.17$, N=22, n.s.).

**FIGURE 1. Annual Rate of Diagnoses of Obsessive-Compulsive Disorder Among All Diagnoses at a Psychiatric Hospital and Annual Rate of Publications on This Disorder Among All Published Medical Research Reports, 1969–1990**



## DISCUSSION

The evident recent increase in the frequency of the diagnosis of obsessive-compulsive disorder in the United States has been associated with significant advances in the study and treatment of the disorder. Obsessive-compulsive disorder is being identified at a much higher rate throughout the United States than was previously suspected (4–7). The increased attention given to this disorder and its treatment may have led to an increased clinical awareness of obsessive-compulsive disorder and greater optimism about its treatability.

During the 1980s, serotonin uptake inhibitors, including clomipramine and fluoxetine, were shown to be effective treatments for obsessive-compulsive disorder (8–10). Fluoxetine (in 1989) and clomipramine (in 1990) have been licensed for general use in the United States and are now widely prescribed (11). In addition, behavior therapy has been shown to be effective in obsessive-compulsive disorder (12, 13), and its use also appears to have become more common.

The strong association that we observed between the rise in the frequency of diagnoses of obsessive-compulsive disorder and the similar increase in journal articles concerning the disorder and its treatment is not likely due to chance alone. It is plausible that the growth of information and the availability of effective treatments for this difficult disorder (4–13) have encouraged clinicians to recognize and diagnose it. Clinicians may be more likely to consider and assign a diagnosis of obsessive-compulsive disorder to a patient when improved treatments and clinical experience with them are available. In our analysis, more than two-thirds of the patients hospitalized with obsessive-compulsive disorder in the late 1980s represented readmissions. This finding suggests that the increased rate of this diagnosis that we observed reflected recent shifts toward giving the diagnosis of obsessive-compulsive disorder to patients previously diagnosed as having other conditions and may represent an example of "diagnostic vogue bias" (14).

This hypothesis of diagnostic bias is consistent with earlier observations of a relative increase in the annual rate of diagnoses of schizophrenia after the introduction of antipsychotic drugs in the 1950s and a shift toward increased diagnosis of manic-depressive illness in the late 1960s after the introduction of lithium treatment in this country (1). Since various habit disorders, such as eating disorders, trichotillomania, kleptomania, and paraphilias, may be related to obsessive-compulsive disorder and also may respond to serotonin uptake inhibitors (15–17), one can expect a similar trend toward their increased recognition and diagnosis.

To evaluate the specificity of changes in the diagnosis of obsessive-compulsive disorder, we performed a similar analysis of annual diagnostic and publication trends for paranoid disorders. This group of disorders was chosen as a comparison syndrome because, unlike obsessive-compulsive disorder, recent advances in the diagnosis and treatment of paranoid disorders have been very limited, and the frequency of these diagnoses at McLean Hospital was similar to that of obsessive-compulsive disorder in the 1970s. Consistent with our hypothesis, there were no significant increases in the rate of diagnosis or the proportion of publications per year for paranoid disorders.

The apparent effect of *DSM-III* on the diagnostic rates of psychiatric disorders at a hospital similar to the site of our study was described recently by Loranger (18). Large shifts occurred in the frequencies of several disorders following the official introduction of *DSM-III* in 1980. For example, *DSM-III* narrowed the definition of schizophrenia and thus almost certainly contributed to decreasing the frequency of this diagnosis. Loranger did not report data for obsessive-compulsive disorder (he only examined disorders with an annual frequency greater than 1%). However, no substantial change occurred in the definition of obsessive-compulsive disorder, since *DSM-III* diagnostic criteria for the disorder were similar to the *DSM-II* criteria used in the 1970s. Moreover, we observed little change in the diagnostic frequency of obsessive-compulsive disorder until 3 years after *DSM-III* was introduced. Thus, it appears that *DSM-III* had little impact on the increased frequency of the disorder found in the late 1980s. However, *DSM-III-R* (published in 1987) substantially altered the diagnostic criteria for obsessive-compulsive disorder, permitting patients to have concurrent psychiatric disorders, such as major depression or Tourette's disorder. Although this alteration, in effect loosening the criteria, may well have contributed to very recent increases in the frequency of diagnoses of obsessive-compulsive disorder, this trend began several years before the introduction of *DSM-III-R*.

In conclusion, there has been a large recent increase in the proportion of inpatients discharged with the diagnosis of obsessive-compulsive disorder at McLean Hospital. This increase may represent a treatment-oriented "diagnostic bias" in which clinicians more readily consider and diagnose a condition for which there are innovative and effective treatments. Further shifts in diagnostic frequencies can be anticipated as more knowledge is acquired about the pathophysiology and treatment of other psychiatric disorders, independent of changes in diagnostic criteria.

# Oculomotor Performance in Obsessive-Compulsive Disorder

Allen Y. Tien, M.D., M.H.S., Godfrey D. Pearlson, M.B., B.S.,
Steven R. Machlin, M.D., Frederick W. Bylsma, Ph.D., and Rudolf Hoehn-Saric, M.D.

*Objective: Neuroimaging studies have shown abnormalities of the frontal cortex and basal ganglia in persons with obsessive-compulsive disorder. Since lesions in the frontal cortex and basal ganglia areas affect performance on goal-guided saccadic eye movements, this study investigated the relation between the diagnosis of obsessive-compulsive disorder and oculomotor performance. Method: Eleven patients with the clinical diagnosis of obsessive-compulsive disorder and 14 normal subjects were assessed with respect to their performance on both visual-guided and goal-guided oculomotor tasks. Fixation performance was also measured. Results: The group with obsessive-compulsive disorder had a very significantly greater error rate and a significantly greater rate of inaccurate saccades on the goal-guided antisaccade task, whereas they were not different from the normal group in reaction time, saccadic velocity, and accuracy on the visual-guided saccade task. The distribution of error rates for the patients with obsessive-compulsive disorder was broad, with more than one-half outside the range of the normal group. Most of the abnormal findings were among male patients. Conclusions: The results support the hypothesis of a relationship between impaired performance on goal-guided saccadic eye movement tasks and the diagnosis of obsessive-compulsive disorder, but they also suggest a gender-related subgroup within the group with obsessive-compulsive disorder.*

(Am J Psychiatry 1992; 149:641–646)

The frontal cortex and basal ganglia appear to be involved in obsessive-compulsive disorder (1). Static imaging in research on persons with obsessive-compulsive disorder has demonstrated structural abnormalities in the basal ganglia (2), and positron emission tomography (PET) and single photon emission computed tomography (SPECT) imaging studies of brain metabolism and blood flow have observed abnormalities in the orbital-frontal cortical and/or basal ganglia regions (3–6). Pharmacotherapeutic normalization of clinical symptoms of obsessive-compulsive disorder has been associated with normalization of cerebral blood flow and glucose metabolism in both the frontal cortex and the caudate nucleus (7, 8).

Brain circuits involving the frontal cortex and basal ganglia appear to be essential for executing behaviors that are based on internal representations (9). These behaviors may include certain kinds of eye movements, one major class of which is saccadic (from the French *saccade*, meaning "jerk"). Saccadic eye movements can be consciously controlled, directing the line of sight to discrete points in the visual field. Enough is known about the functional neuroanatomy of saccadic oculomotor control to allow investigators to relate saccades with differing degrees of conscious control to certain brain areas. There appear to be two major pathways, anterior and posterior, by which the cerebral cortex can generate saccades.

The anterior pathway projects from the frontal eye fields both directly to the brainstem and indirectly to the brainstem through the superior colliculus (10). This projection is also indirect through the basal ganglia and is involved in generating saccades that are directed by internal models or representations ("goal-guided" saccades) (11). Saccades to remembered targets and saccades to imagined targets are of this type and are under a high degree of conscious control. Performance of goal-guided saccades is vulnerable to lesions involving the frontal eye fields and basal ganglia (12). Lesions in the prefrontal cortex, which projects to the frontal eye fields, also impair goal-guided saccades (12). Frontal lobe lesions and degenerative disorders involving the basal ganglia result in saccadic intrusions and inappropriate reflexive saccades in response to extraneous visual stimuli (13, 14). (In a similar way, apparently "frontal" neuropsychological syndromes can be produced by

damage to basal ganglia areas connected to prefrontal areas [15]).

The posterior pathway projects from the posterior parietal cortex and neighboring regions to the superior colliculus and then to the brainstem and is involved in generating "visual-guided" and "reflexive" saccades (12). Such saccades can be considered to be under a lower degree of conscious control than goal-guided saccades. "Spontaneous" saccades do not appear to depend on the cerebral cortex at all and are presumably generated entirely by subcortical structures (16).

On the basis of reports showing frontal lobe and basal ganglia abnormalities in subjects with obsessive-compulsive disorder and the functional neuroanatomy of control of saccadic eye movements, an impairment in goal-guided (but not visual-guided) saccadic performance related to obsessive-compulsive disorder seemed likely. This article reports an experiment to test this hypothesis.

## METHOD

The psychiatric subjects were drawn from a highly selected clinical group. Eleven individuals (five male) with the *DSM-III-R* clinical diagnosis of obsessive-compulsive disorder were recruited from the anxiety disorders clinic at Johns Hopkins Hospital (all diagnoses were made by R.H-S.). Fourteen normal comparison subjects (seven male) were recruited from the hospital staff. All subjects were screened with the Structured Clinical Interview for DSM-III-R (17). Exclusion criteria were any major psychiatric disorder, substance abuse or dependence, and history of injury to the central nervous system. No subjects had schizotypal personality disorder. The mean age of the group with obsessive-compulsive disorder was 39 years (SD=7, range=27–54 years); the mean age of the normal group was 38 years (SD=10, range=22–56 years). All of the subjects with obsessive-compulsive disorder had at least a high school education, and four of the five male subjects had at least a college education. The normal subjects were similarly educated. The family histories of all subjects were negative for obsessive-compulsive disorder and tics, and no subjects reported a family history of schizophrenia.

For the patients with obsessive-compulsive disorder, the mean total score on the Yale-Brown Obsessive Compulsive Scale (18) at the time of diagnostic evaluation was 24.4 (SD=4.5, range=17–30). Their mean score was 12.4 (SD=3.2, range=5–15) on the Yale-Brown obsessions subscale and 12.2 (SD=3.1, range=6–15) on the compulsions subscale. Their mean score on the National Institute of Mental Health Global Obsessive Compulsive Scale (19) was 9.1 (SD=1.1, range=7–11). Only one patient had a history of a tic, but it was not present during oculomotor testing. At the time of oculomotor assessment, one patient was taking clomipramine, one was taking no medication, and the other nine were taking fluoxetine. All 25 subjects had clinically normal magnetic resonance imaging (MRI) brain scans.

Saccadic eye movements were assessed by means of a computerized target presentation/data acquisition system. Targets were presented on an AT-type personal computer with a VGA (640×480 pixels) graphics adapter and monitor. Saccades were recorded with infrared reflection. A chin rest and head restraint minimized head movement. Data acquisition routines sampled horizontal eye movement at 1,000 samples per second.

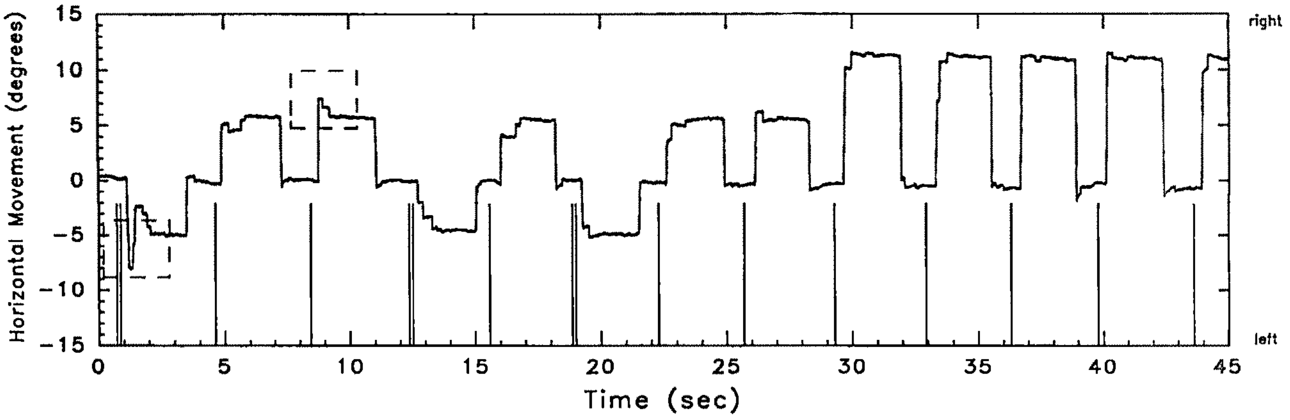
Two tasks were used to assess saccadic performance, and a fixation task was also given. Each task was recorded for 45 seconds. For each, the subjects practiced until they understood the task, in order to reduce the impact of potential generalized learning deficits. The order of tasks was as follows.

*Fixation.* The task consists of fixing the gaze on a small central target and maintaining fixation as well as possible. Square wave jerks (saccadic intrusions) were identified and counted. Square wave jerks are conjugate saccades that move the eyes away from fixation and then, after 100–300 msec, back to the fixation point. The number of blinks was also counted.

*Temporally random saccades.* This task uses spatially regular 20° displacements between left and right targets, with a random time interval ranging from 1 to 3 seconds. Reaction time, saccadic velocity (degree of eye movement per second), and gain (ratio of eye movement to target movement) were measured. The task tests performance on visual-guided saccades.

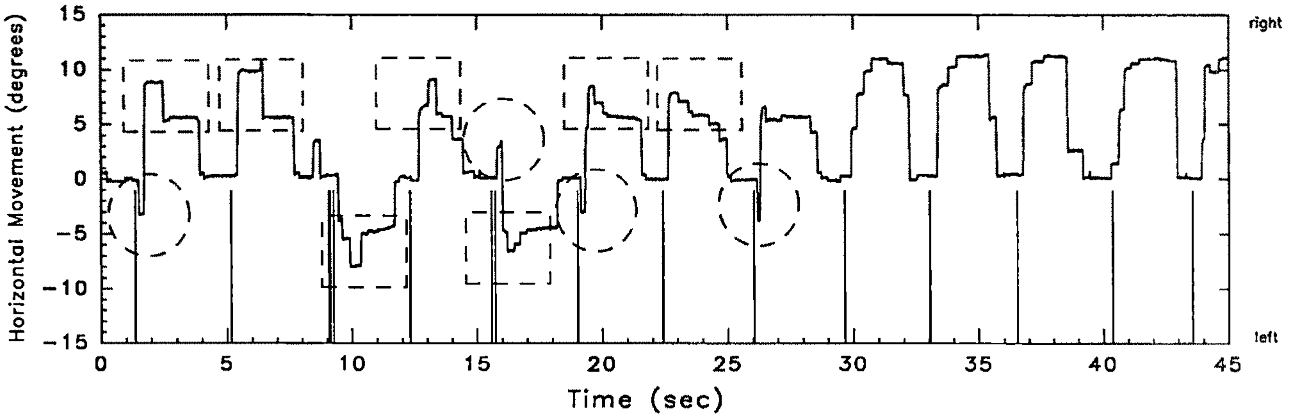
*Antisaccades.* After fixation of a central target, a peripheral target appears simultaneously with the offset of the fixation target. Subjects were instructed to make a saccade to the mirror location opposite that of the target. Subjects were allowed to practice until at least four correct trials were observed. The number of trials

FIGURE 1. Antisaccade Performance of a Normal Subject[a]



[a]Dashed squares enclose inaccurate antisaccades.

FIGURE 2. Antisaccade Performance of a Patient With Obsessive-Compulsive Disorder[a]



[a]Dashed circles enclose saccadic errors; dashed squares enclose inaccurate antisaccades.

ranged from 10 to 16, as there was a random time delay between trials. Saccades in the wrong direction were counted as errors. Saccades in the correct direction but of inaccurate amplitude—more than 20% different from the correct amplitude—were counted as inaccurate saccades. This task tests the ability to suppress a reflexive saccade in response to a suddenly appearing visual stimulus and to generate a difficult goal-guided saccade.

## RESULTS

On the fixation task there were more blinks and more square wave jerks in the group with obsessive-compulsive disorder than in the normal group (table 1), but these differences were not significantly different at the $p<0.05$ level (independent-sample t tests with separate variance) because of relatively large variance in both groups. Table 1 also shows measures of performance on the temporally random visual-guided saccade task. Mean reaction times were not significantly different between groups, and variance in reaction time also was not significantly different ($F=1.42$, $df=12, 8$, $p=0.56$). Left and right saccadic velocity were not significantly different, but there was more variance in velocity performance in the normal group (for right velocity variance, $F=8.48$, $df=12, 8$, $p=0.009$; for left velocity variance, $F=11.13$, $df=12, 8$, $p=0.004$). Visual-guided saccadic gain or accuracy was identical, within rounding error, for the two groups.

There was a significant difference between the groups in performance on the antisaccade task. Examples of antisaccade performance are shown in figure 1 and figure 2. Figure 1 shows that a normal subject made a very inaccurate saccade on the first trial but subsequently improved in accuracy, with relatively small hypometric or hypermetric inaccuracies. This subject made no errors (saccades toward the antitarget stimuli). Figure 2 shows performance by a patient with obsessive-compulsive disorder. This subject made four errors and also performed poorly in controlling the amplitude of saccades, even when successfully inhibiting reflexive glancing at the antitargets. Performance over the last five tri-

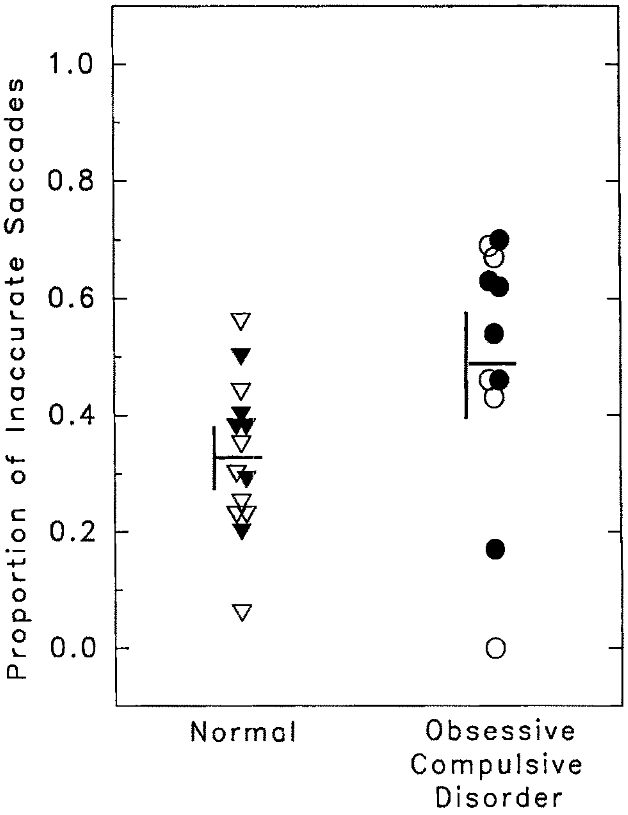
[a]Black symbols are male subjects; white symbols are female subjects. Horizontal bars are statistical means; vertical bars are 95% confidence intervals for the means.

**FIGURE 4. Antisaccade Accuracy of 14 Normal Subjects and 11 Patients With Obsessive-Compulsive Disorder**[a]



[a]Black symbols are male subjects; white symbols are female subjects. Horizontal bars are statistical means; vertical bars are 95% confidence intervals for the means.

als improved, but all subjects had demonstrated understanding and ability to do the task during practice before assessment.

On the antisaccade task, the mean proportion of errors was more than three times higher in the group with obsessive-compulsive disorder than in the comparison group (table 1). To analyze gender effects in more detail, the proportion of errors was examined as a dependent variable in a multivariable regression model using diagnosis, gender, and the interaction between diagnosis and gender. The beta for diagnosis was 1.7 (t=3.95, df=1, p=0.001), the beta for gender was 0.05 (t=0.27, df=1, p=0.79), and the beta for the interaction was –1.2 (t=–2.71, df=1, p=0.01) (model F=11.05, df=3, 21, p=0.0001). Thus, although there was a large effect for male subjects with obsessive-compulsive disorder (figure 3), there was still a gender-independent difference in performance between the group with obsessive-compulsive disorder and the normal group.

The proportion of inaccurate saccades in the antisaccade task was analyzed in the same way. The beta for diagnosis was 0.4 (t=0.73, df=1, p=0.48), the beta for gender was –0.1 (t=–0.56, df=1, p=0.58), and the beta for the interaction was –0.1 (t=–0.08, df=1, p=0.94) (model F=1.80, df=3, 21, p=0.18). Diagnosis modeled alone had a beta of 0.4 (t=2.23, df=1, p=0.04) (model F=15.23, df=1, 21, p=0.0007). Thus, there did not appear to be a gender-related difference in antisaccade accuracy, but there was a difference between diagnostic groups (figure 4).

## DISCUSSION

The results support the hypothesis of a deficit in *goal-guided* saccadic performance related to the diagnosis of obsessive-compulsive disorder. The fact that the visual-guided but not the goal-guided saccadic performance of the patients with obsessive-compulsive disorder appeared to be normal supports an inference of frontal cortical and/or basal ganglia functional abnormality underlying this performance deficit. This does not necessarily imply a structural deficit in these areas. It is possible that anxiety alone could account for poorer performance. Although the subjects were rated with the Hamilton Scale for Anxiety at the time of diagnostic interview (and there was no correlation of these ratings with oculomotor performance), a quantitative rating of anxiety at the time of oculomotor testing was not obtained, so this question cannot be answered here.

The gender difference in antisaccade error rate among the subjects with obsessive-compulsive disorder was an unexpected finding. There were no other apparent factors (including age at onset, duration of the disorder, other concurrent diagnoses, family history, and medication) that might have accounted for this difference. Another gender difference has been reported for obsessive-compulsive disorder: a trend for earlier age at onset among males (20). How these findings might be related is unclear, but the two together suggest further study of possible gender differences in obsessive-compulsive disorder.

As in research on eye movements in schizophrenia, although there were significant differences between group means, there was overlap between individuals in each group. Several factors may account for the variability in the group with obsessive-compulsive disorder. The categorical decision on the clinical diagnosis may have been in error. Although it seems unlikely that there were false negative diagnoses in the normal group, there may have been false positive diagnoses in the group with obsessive-compulsive disorder. There may be etiologic heterogeneity for developing obsessive-compulsive disorder, so that only some patients have functional brain pathology. There may be a normal distribution of oculomotor performance, so that even if relative impairment of oculomotor control is invariably associated with obsessive-compulsive disorder, absolute differences from normal are not always observed because a given individual's hypothetical baseline performance was better. In addition, clinical state at the time of testing, medication levels in blood or brain, and perhaps the nature of specific obsessions and compulsions might have effects.

Variability in the normal group could also have been due to a number of factors. For example, there is evidence that poor smooth pursuit eye movement is a manifestation of a latent trait related to schizophrenia (21). Although no subjects reported a family history of schizophrenia, this is probably not a reliable method for determining family history. Furthermore, schizophrenia spectrum conditions such as schizotypal personality disorder were not systematically assessed in the subjects' relatives. These conditions have been associated with poor smooth pursuit eye movement (22) and could possibly be associated with poor antisaccade performance.

Sampling bias might have confounded our findings. Berkson (23) suggested that when any single medical condition is apt to result in treatment with less than perfect certainty, individuals with more than one condition (including unmeasured conditions) are more likely to be in treatment than those with only one. The logic of Berkson's bias implies that individuals in treatment-based samples are more likely to reveal overlap of conditions than those in the general population who have the same conditions. Being in psychiatric treatment may be related to more general deficits in goal-guided or "executive" functioning and thus deficits in goal-guided saccadic eye movements.

## CONCLUSIONS

This is the first report of a deficit in oculomotor control among subjects with the diagnosis of obsessive-compulsive disorder. The results are consistent with evidence from other research suggesting frontal lobe and basal ganglia abnormalities in obsessive-compulsive disorder. However, replication in an independent group is needed. Although no cross-sectional associations were apparent, longitudinal study of relationships between clinical status, medication, and oculomotor performance is indicated. Study of unaffected relatives of patients with obsessive-compulsive disorder would also be of interest. If these results are replicated in a clinical sample, study of community samples will be useful to avoid the possible effects of Berkson's bias (23).

# Randomized, Double-Blind, Crossover, Placebo-Controlled Comparison of Propranolol and Betaxolol in the Treatment of Neuroleptic-Induced Akathisia

Jean-Pierre Dumon, M.D., Jacques Catteau, M.D.,
Fabrice Lanvin, M.D., and Bernard A. Dupuis, M.D., Ph.D.

*Objective: Beta-blocking agents, particularly propranolol, are considered effective in the treatment of neuroleptic-induced akathisia, but considerable controversy exists about the involved receptor subtype(s). The authors conducted a randomized, controlled trial comparing the effects of propranolol and betaxolol to determine whether central $\beta_1$-adrenoceptor blockade is sufficient to correct neuroleptic-induced akathisia. Method: The subjects were 19 patients whose neuroleptic-induced akathisia responded to 20 mg/day of propranolol and subsequently reemerged during a placebo washout period. They were randomly assigned to propranolol (20 or 40 mg/day) or betaxolol (10 or 20 mg/day) and, after another placebo period, were switched to the second β blocker. Results: There was no significant difference in the antiakathisia effects of propranolol and betaxolol. Conclusions: The lack of difference between propranolol and betaxolol suggests that $\beta_1$-adrenoceptor blockade is sufficient to improve neuroleptic-induced akathisia. The results of this explanatory study need therapeutic confirmation.*

(Am J Psychiatry 1992; 149:647–650)

Studies have demonstrated that β blockers, particularly propranolol (1–3), are effective in the treatment of neuroleptic-induced akathisia. A central site of action appears likely because several studies—unfortunately, most of them uncontrolled—have shown that hydrophilic β blockers, such as nadolol (4), atenolol (5, 6), and sotalol (7), are less effective than propranolol, which is highly lipophilic. The site of action of these drugs, however, and the involved receptor subtypes are still controversial.

Zubenko et al. (4) and Derom et al. (5) found that the $\beta_1$-receptor blockers metoprolol and atenolol are less effective than propranolol. Therefore, Zubenko et al. proposed a $\beta_2$-adrenergic mechanism of action in neuroleptic-induced akathisia. This hypothesis was supported by a study by Adler et al. (8), which showed similar efficacy of propranolol and ICI 118,551, a selective $\beta_2$ blocker. On the other hand, a study by Kim et al. (9), which used metoprolol at a dose with preserved $\beta_1$ selectivity, and our previous study using betaxolol (7) failed to demonstrate any difference in efficacy between propranolol and $\beta_1$ blockers. In an attempt to elucidate the receptor subtype(s) involved in the β blockers' effects in neuroleptic-induced akathisia, we performed a double-blind, crossover, placebo-controlled study comparing low doses of two highly lipophilic β blockers: propranolol, which is nonselective ($\beta_1$ and $\beta_2$ blocker), and betaxolol, which is highly $\beta_1$ selective.

## METHOD

We used the akathisia rating scale of Chouinard et al. (10). This includes a subjective evaluation scale rated 0 to 3 and an objective evaluation scale rated 0 to 6; only the latter was used in this study, both for selection of patients and for evaluation of drug effects. The drugs (propranolol, betaxolol, and placebo) were administrated at 8:00 p.m., and all the patients were assessed on the following day between 8:00 and 9:00 a.m., i.e., after a 12-hour interval.

Over 14 months, 68 patients with neuroleptic-induced akathisia underwent observation. The akathisia

[a] Not included in crossover study.

[b] Dropped out of study.

[c] Excluded from study because of worsening psychiatric status.

of 45 of these patients was rated as 4 or above, so these 45 were preselected for the study. None of them had any condition that was a contraindication to treatment with β blockers. All of them received 20 mg/day of propranolol.

For propranolol treatment to be considered successful, an objective akathisia score of 0 had to be maintained for at least 1 week. After a 1-week washout period with placebo, the akathisia score had to return at least to 4 and to not differ from the initial score by more than 1. These conditions were met by 19 patients.

Of these 19 patients, 18 entered the study and were randomly assigned to propranolol, 20 mg/day, or to betaxolol, 10 mg/day, for up to 10 days. In case of failure, the dose was doubled (40 and 20 mg/day, respectively). The doses of propranolol (20 and 40 mg/day) and betaxolol (10 and 20 mg/day) are considered equipotent (11).

The β blocker was then withdrawn, and the patients received placebo for 3 to 10 days, i.e., until further treatment became necessary. Then the patients received the second drug; in case of failure, the dose was doubled.

Among the 19 patients preselected for the study, 13 had akathisia scores of 4, three had scores of 5, and three had scores of 6. As required by the eligibility criteria, all of the 19 patients achieved a score of 0 with 20 mg/day of propranolol. During the washout period the score of one patient (patient 4) failed to return to its initial level, and she was then excluded from the study. During the first treatment period nine patients received propranolol and nine patients received betaxolol.

During the second placebo sequence the akathisia scores returned to their initial levels for all patients except patient 11, whose score remained zero; therefore, she was withdrawn from the study. The 17 remaining patients received the second β blocker: propranolol for nine and betaxolol for eight. Because of worsening psychiatric status, patient 14 was dropped from the study after 48 hours so his neuroleptic treatment could be changed (haloperidol, 60 mg/day, in place of pipotiazine, 40 mg/day).

We tested order, carryover, and treatment effects with the Wilcoxon rank-sum test, taking into account the design of the trial (two-period crossover clinical trial).

**TABLE 2. Group Akathisia Scores Before and After Crossover Treatment With Propranolol and Betaxolol**

| | | Akathisia Score | |
|---|---|---|---|
| Time and Condition | N | Mean | SD |
| Before study | 19 | | |
| Without drugs | — | 4.44 | 0.73 |
| Propranolol (20 mg/day) | — | 0.00 | 0.00 |

[a] 20 or 40 mg/day.
[b] 10 or 20 mg/day.

## RESULTS

It should be kept in mind that this study addressed a highly selected group of patients: 45 subjects with a score of at least 4 on the Chouinard objective akathisia rating scale were preselected, and low doses of propranolol (20 mg/day) completely ameliorated the neuroleptic-induced akathisia of 19 patients (42%).

The individual akathisia scores and background characteristics of the 19 patients are shown in table 1, and group scores appear in table 2. We found no significant difference between the antiakathisia effects of these two highly lipophilic β blockers (treatment effect: $z=0.88$, $p=0.38$; order effect: $z=0.88$, $p=0.38$; carryover effect: $z=-0.88$, $p=0.38$). Furthermore, although an increase in akathisia score of 1 was observed in some patients (patients 10, 13, 15, 16) when active drug was withdrawn, no major rebound effect was observed among our patients.

No difference in the delay before onset of action was observed: the maximal effect was observed within 3 days (propranolol: mean=2.80 days, SD=1.65; betaxolol: mean=2.34 days, SD=1.34), and in no case was there any loss of efficacy.

We had planned to subject all patients to a final placebo period, but this was considered unethical by the hospital investigational review board.

## DISCUSSION

The lack of difference between propranolol, which is a $\beta_1/\beta_2$ blocker, and betaxolol, which is a highly $\beta_1$-selective drug, suggests that $\beta_1$-adrenoceptor blockade is sufficient to improve neuroleptic-induced akathisia. This is in accordance with the results of the study by Kim et al. (9), which used low doses of metoprolol, and with our own previous study of betaxolol (7), but it contradicts the findings of Adler et al. (8), which suggested similar efficacy in $\beta_2$ blockers. Adler et al. proposed a possible "redundancy of the central beta-adrenergic receptor in the CNS."

Because of these confusing results, the possibility that these compounds could have another common property should be considered. Intrinsic sympathomimetic activity can be excluded, since propranolol and betaxolol are devoid of such activity. The membrane-stabilizing property is also unlikely, for two reasons: 1) propranolol possesses this characteristic, but it is considered of clinical relevance only at high doses, which were not attained in our study and are not usual in clinical practice, and 2) betaxolol does not have this property (12, 13).

Finally, $\beta_3$ receptors (14) appear to possess only metabolic action, chiefly in fat tissue, and conventional β blockers exert little or no effect on these receptors.

Nevertheless, from a therapeutic point of view, it is obvious that $\beta_2$ blockade is undesirable because of contraindications and its possible adverse effects (e.g., bronchospasm, vasospasm).

The results of this controlled trial confirm our previous findings and suggest that central $\beta_1$-adrenergic blockade is sufficient to correct objective neuroleptic-induced akathisia.

# Ethics Complaints Against Female Psychiatrists

Kathleen Mero Mogul, M.D.

*Objective: The purpose of this study was to assess the prevalence and nature of investigated ethics complaints against female psychiatrists and to compare them with those against male psychiatrists. Method: The author, a member of the APA Ethics Committee, reviewed informal records kept by her during a period of just under 5 years. Results: The Ethics Committee reviewed 259 complaints against men and 30 against women, constituting a prevalence rate of about 1.1% against male members and 0.4% against female members. Thirty-nine percent of the complaints against men and 60% against women were dismissed. Eighty-five sexual complaints against male psychiatrists and eight against female psychiatrists (of which two and six, respectively, were for homosexual behavior) were investigated. Also investigated were 19 complaints involving discourtesy or poor judgment against men and two against women, 21 of breach of confidentiality against men and three against women, and 23 involving financial matters against men and four against women. Conclusions: In this study of informal records, there were fewer investigated ethics complaints against female than against male psychiatrists, and more of these were dismissed after investigation. A greater proportion of the complaints of sexual exploitation made against women were for homosexual involvement. Cultural power differentials between genders may in part explain some of the data.*

(Am J Psychiatry 1992; 149:651–653)

Soon after my appointment to the APA Ethics Committee in May 1985, I was struck by the infrequency of complaints against female psychiatrists. For just under 5 years I tracked all cases that came to the Ethics Committee for review, examined the data for information about cases against women, and compared ethics investigations against women with those against men.

Particular attention was paid to cases involving "undue familiarity," that is, physical and sexual involvement of psychiatrists with patients, because they constitute the largest single category of complaints and because they have received so much recent attention in the professions, the professional literature, and the media and from legislatures and licensing bodies.

Moore reviewed the activities of the APA Ethics Committee in 1978 (1) and again in 1985 (2). He reviewed the number of complaints, the kinds of charges made, and the resolutions of the complaints but gave no information about complaints against female psychiatrists. Several books about sexual relations between therapists and their patients similarly fail to address involvement by female psychiatrists (3–5).

Gartrell et al. (6), in their report on a survey of psychiatrists regarding sexual involvement with patients, did break down the data by gender. Twenty percent (N=291) of their respondents were women. Of the responding women 3.1% acknowledged sexual involvement with patients, compared to 7.1% of the male respondents. Of all sexual contacts reported, 3.5% were between female psychiatrists and male patients and 1.4% were between female psychiatrists and female patients, while 7.6% occurred between male psychiatrists and male patients. The remaining 87.5% of cases of sexual involvement were between male psychiatrists and female patients.

## ETHICS COMMITTEE DATA

The data reported here were accumulated in just under 5 years from careful records that I kept. The data are not an official record and are nearly, but perhaps not absolutely, accurate.

For several reasons the number of cases considered in this report are not a measure of the number of complaints lodged during this period. First, district branches report to the APA Ethics Committee only those complaints which undergo a formal investigation. If allegations are judged to be trivial or not to involve

breaches of *The Principles of Medical Ethics With Annotations Especially Applicable to Psychiatry* (7), the complaints are dismissed at the local level without report to the APA Ethics Committee. Thus, there is no information available for comparing the rate or nature of those complaints against male and female psychiatrists which are dismissed after initial scrutiny. Second, as Moore (1, 2) observed, it is unclear how consistently district branches reported to the APA about investigated cases that did not result in effects on membership status. Reporting accuracy has greatly increased, especially under the standardized procedures adopted in 1989 (7). Last, at any time, a significant number of cases are under investigation at the district branch level, to be reported to the national Ethics Committee upon resolution at a future time. Thus, the figures reflect only those cases reviewed by the Ethics Committee (all cases reviewed by each member of the committee) upon their resolution at the district branch level.

The total number of cases reviewed in this period (June 1985–April 1990) was 289 or 0.002 per member per year, that is, in the same range as reported by Moore (1) for prior years. Of the 289 complaints, 259 were against male psychiatrists and 30 were against female psychiatrists. Thus, 10.4% of complaints deemed to merit investigation were against women. APA had about 35,000 members during these years, of whom about 23% were women; that is, there were 27,000 male members and 8,000 female members. (Because of the growth in membership and proportion of women, these figures may somewhat overestimate both membership and percentage of women for the years covered by the data.) The calculated prevalence of reported complaints was 0.4% against female members and 1.1% against male members for the period examined. There were investigated complaints against female psychiatrists less than half as often as there were against men, bearing out the initial impression that complaints against women are comparatively less frequent, although not nearly so infrequent as the impression from raw case figures, unrelated to membership numbers, first conveyed.

The proportion of cases dismissed after investigation, in which insufficient or no evidence of an ethics infraction was found, was greater for women than for men (60% versus 39%).

### *Complaints of Sexual Involvement*

Complaints of sexual involvement constituted the largest single category of complaints against both men and women. Eight women and 85 men were accused of having sexual or intimate physical relationships with patients; these complaints represent 27% of those against women and 33% of those against men and reveal no substantial difference in the proportion of sexual complaints by gender of psychiatrists. A considerable number of additional complaints against men (N=35–40), but not against women, seemed to arise from nonrecognition and/or mismanagement of erotic transference in which no actual sexual contact took place.

Outcomes of accusation of sexual misconduct were also similar for male and female psychiatrists. One (12.5%) of the eight cases against women and 12 (14%) of the 85 against men were dismissed because of lack of credibility of the complainant or insufficient evidence to convince the investigating body. Similarly, five of the eight accused women and 53 of the 85 accused men, constituting about 60% of each group, were either expelled or suspended from membership.

The single clearest difference between the complaints against male and female psychiatrists was in the area of homosexual involvement; only two of 85 complaints against men were for homosexual involvement, but six of eight against women were for involvement with female patients. In contrast to almost all other complaints, neither of the two complaints involving female psychiatrists engaged in sexual relations with male patients came from the patients themselves. In fact, both men defended the psychiatrists against the charge of an unethical act.

### *Other Complaints*

Breach of confidentiality was the complaint in 21 of the cases against men and in three against women. There were 23 complaints against men and four against women involving financial matters (insurance or tax fraud or billing disputes). In these two categories there appeared to be no difference in the proportion of complaints by therapist gender.

Complaints that could be called discourtesy or poor judgment in dealing with patients were made against 19 male psychiatrists but only two female psychiatrists. Eighteen (7%) of the cases against male psychiatrists and four (13%) against female psychiatrists involved complaints about forensic matters. All four forensic cases against women involved work related to child custody or child abuse, and all were dismissed upon investigation because of a finding of no unethical conduct. Eight of the 18 forensic cases against men were related to children. There was one admonishment and one suspension; the other cases were dismissed.

The remaining complaints were in a number of categories, seemed not to show a gender-related pattern, and were not tabulated. They included complaints related to managed care and other administrative practices, professional misrepresentation and false advertising, and those which could be encompassed under "incompetent practice" involving misdiagnosis, treatment mismanagement, lack of coverage, and abandonment. Some complaints remained unclear and appeared to entail suspicious, angry, or even delusional grievances.

## CONCLUSIONS AND DISCUSSION

There are many inherent problems with the data presented, and the implications must be examined with caution and modesty. Certainly no extension of conclusions to the prevalence of unethical practice by psychiatrists, nor even to the number of complaints against them, is warranted. As stated previously, there is no information about the number and nature of complaints dismissed locally without further investigation. Further, it is clear from clinical experience and various other sources, especially with regard to sexual exploitation, that a relatively small number of patients who feel cause for complaint ever lodge a complaint. Even the information regarding investigated complaints reveals that the total number of these complaints against women is low, and numbers in subcategories are so low, that comparisons have little convincing meaning.

With these caveats, it does appear from this study of informal records that there was a lower prevalence of complaints deemed to merit investigation against women than there was against men, that a greater proportion of the complaints against women were found to be groundless on investigation, and that, among sexual complaints against female psychiatrists, a greater proportion related to homosexual involvement.

Far less clearly, the figures indicate some similarities and a few differences in complaints against men and women and in the results of the investigations. The proportions of cases involving complaints of sexual involvement, breach of confidentiality, and of a financial nature appeared similar for both genders. Mismanaged erotic transference (short of physical involvement) and discourtesy-related complaints seemed more common among men, while there seemed to be relatively more complaints about forensic work against women. The similarity in percentages of sexual complaints in this study does not contradict the reports that sexual involvement with patients is less common for female than for male psychiatrists (6), since the prevalence of any complaints against women was only about half that against men.

The data lend some plausibility to power differentials as contributory to the high prevalence of male psychiatrist-female patient sexual involvement, since this is the dyad in which cultural power differences are the greatest. Perhaps female psychiatrists are less likely to initiate an exploitative relationship, especially with male patients in which the power differential is reversed. However, Gartrell et al.'s figures (6) on self-admitted sexual involvement with patients show a greater comparative percentage of sexual involvement with male patients by psychiatrists of both genders. Certainly, other explanations, instead or additionally, are possible for the lower prevalence of sexual exploitation by female psychiatrists. These could include the younger mean age of female psychiatrists, the fact that a larger proportion work in institutional settings, and the fact that, by and large, they treat an even larger proportion of female patients than do their male colleagues.

It also appears, especially taking Gartrell et al.'s data into account, that men are less likely than women to make complaints of having been victimized. In this study no men complained about sexual involvement with their female psychiatrists. In the two such cases, other parties brought the complaints against the doctors, and in the two homosexual complaints against male psychiatrists the complaints were lodged by men about exploitation during their adolescence. In our culture, it may be even more difficult for men than it is for women to acknowledge feeling exploited or victimized.

None of the previous statements is meant to imply that sexual activity with male patients by psychiatrists of either gender is less exploitative of the patient or of the treatment relationship than when female patients are involved, nor that it is less damaging to patients or less unethical.

The preceding speculations are merely an attempt to raise some ways to think about the reported data, and the meagerness of the data makes them even more conjectural. Continued collection of data, broken down by gender, appears justified.

# Effectiveness and Replicability of Modules for Teaching Social and Instrumental Skills to the Severely Mentally Ill

Charles J. Wallace, Ph.D., Robert Paul Liberman, M.D., Sally J. MacKain, Ph.D., Gayla Blackwell, R.N., M.S.W., and Thad A. Eckman, Ph.D.

*Objective: This study evaluated the effectiveness and replicability of psychoeducational modules designed to improve the social and instrumental competencies of severely mentally ill patients. Method: Staff in seven facilities used the modules to teach 108 severely mentally ill patients. Staff received 2 days of formal training followed by periodic consultation. Each module's effectiveness was measured by a test of the patients' knowledge and performance of the skills taught in that module. Staff's adherence to the instructional techniques specified in the modules was measured by directly observing them and assessing the fidelity of their behaviors to those specified in the modules. Results: The patients' skills significantly improved and were maintained during a 1-year follow-up, and staff accurately followed the modules with minimal consultation. Conclusions: These training modules are effective and replicable techniques for teaching social and instrumental skills to severely mentally ill patients. The modules can be easily disseminated to a variety of facilities and used as components in a comprehensive rehabilitation program.*

(Am J Psychiatry 1992; 149:654–658)

Although neuroleptic medication is the treatment of choice for reducing the positive symptoms of chronic schizophrenia, it does little to ameliorate the anhedonia and impoverished social and instrumental role functioning associated with the disorder's negative symptoms (1, 2). Several comprehensive model psychosocial treatment programs that complement pharmacotherapy by improving social and instrumental role functioning have resulted in reduced rates of relapse and rehospitalization (3–5). Unlike medication, however, they have not been widely adopted by the general systems of mental health care. The programs have been difficult to disseminate because of their comprehensiveness; their use of unique settings, staff, patients, and resources; and their poorly operationalized techniques (6, 7).

Less comprehensive psychosocial treatment programs focusing on improving patients' interpersonal skills have been developed. These programs have also reduced rates of relapse and rehospitalization (8–11), but they too have had little impact on the general systems of mental health care. Their treatment techniques have been poorly documented, and their narrow focus on social or family skills has not satisfied the desire for improved role performance and quality of life for patients, their significant others, and clinicians.

However, a set of psychoeducational modules have been developed with the objectives of 1) teaching patients social and instrumental competencies in key domains of community functioning and 2) being easily and accurately used by staff in general systems of mental health care. The domains include self-management of neuroleptic medication, coping with schizophrenic symptoms, grooming/personal hygiene, participating in recreational activities, and engaging in friendly conversations. These domains were chosen because competency in them has been associated with longer community tenure (12–14) and is hypothesized to be associated with less risk for symptomatic relapse according to the "stress-vulnerability" theory of schizophrenia (15).

All modules use the same highly structured and thoroughly specified instructional techniques so that staff can easily and accurately use them with a minimum of training and ongoing consultation. The techniques also compensate for patients' cognitive dysfunctions, and each module is a small, self-contained package that can be inexpensively tried and then either rejected or adopted, either alone or in combination with other modules, as the base of a comprehensive rehabilitation program (16, 17).

The purpose of the present research was to confirm that the modules fulfilled their design objectives. If they did, staff would have a set of techniques that they could use to improve the long-term outcomes of their men-

tally disordered patients by enhancing their community functioning.

## METHOD

### Modules

Each module is a self-contained curriculum that teaches from four to six competencies in a major domain of community functioning. For example, the medication management module teaches five competencies: recognizing medication's benefits, recognizing its side effects, monitoring these side effects, discussing medication with physicians and other caregivers, and recognizing the benefits of injectable medication. Each competency is divided into the specific skills that define the competency and are the focus of the training. For example, competently discussing medication with physicians and other caregivers is divided into pleasantly greeting the physician, describing the problem in detail (including its duration and severity), requesting that action be taken, clarifying and repeating the doctor's prescription, and pleasantly ending the interaction while maintaining appropriate eye contact, posture, and paralinguistic qualities during the entire exchange.

Each competency's constituent skills are taught with the same seven instructional techniques. The first three—introduction, videotape demonstration, role-playing practice—help patients learn and practice the skills in the training sessions. The fourth and fifth techniques—solving resource management problems and solving outcome problems—prepare participants to use their skills outside of the training sessions. The sixth and seventh activities—in vivo exercises and homework assignments—require that participants use the skills outside of the training session. A detailed description of the modules is given elsewhere (16).

Each module consists of a trainer's manual, participant's workbook, and demonstration videotape. The manual specifies exactly what the trainer is to say and do to teach all of the module's skills; the videotape demonstrates the skills; and the workbook provides participants with written material, forms, and exercises that help them learn the skills. The trainer instructs by reading scripts and asking questions written in the manual, by playing the videotape, and by evaluating the participants' role playing with checklists written in the manual. The trainer corrects inaccurate answers or role playing by using prompting, modeling, coaching, and reinforcement. A training session is generally conducted with four to eight patients and one trainer, and sessions are scheduled two or three times per week for 1 to 1-1/2 hours each. Approximately 13 to 20 weeks of twice-weekly sessions are needed to complete each module.

### *Facilities, Staff, and Patients*

Three modules—medication management, recreation, and grooming—were implemented in seven treatment facilities: a long-term rehabilitation program located in a state hospital that treated approximately 200 individuals; five residential care facilities that provided housing for 6, 12, 24, 50, and 60 individuals, respectively; and a day treatment program that treated approximately 35 individuals. The training was conducted by nursing staff in the inpatient program, by the owners/operators of the three smaller residential care facilities, and by recreation therapists and mental health counselors at the two larger residential care facilities and the day treatment program. The trainers' educational and clinical backgrounds ranged from completion of high school to graduation from professional master's degree programs, and from 1 month to 10 years of experience in treating severely mentally ill individuals.

Staff attended a 2-day workshop in which the rationale for each instructional activity was explained and the specific procedures were demonstrated. At the end of the workshop, staff chose the module or modules they would teach, selected the patients, and established a schedule of consultation visits by two experienced research assistants, who had also conducted the workshop.

A total of 126 severely mentally ill patients agreed to participate in training with at least one module; 108 completed the training. The 18 noncompleters were inpatients who were discharged or transferred before the end of training. All 126 had been judged to be deficient in a module's skills and able to participate in the group training sessions. Selection and recruitment were conducted by the facilities' staffs. Approximately 91% of the patients (115 of the 126 recruited and 98 of the 108 completers) had been diagnosed as having a schizophrenic or schizoaffective disorder according to *DSM-III-R* criteria, and most had been hospitalized continuously or episodically for the past several years. The average age of the 108 completers was 33 years (SD= 10), 82 were male, and 81 were Caucasian, nine were black, and 18 were Hispanic.

### *Measures*

Each module's effectiveness in producing its learning objectives was measured by a test that consisted of specific questions and role-playing situations selected from each competency area of the module. The tests were administered by a trained interviewer, who recorded the patients' answers verbatim, classified them as correct or incorrect, and calculated total scores for each competency and for the entire module.

The trainers' competency in teaching was measured by directly observing them and determining the fidelity of their behaviors to those specified in each module's manual. For example, the trainers were observed while conducting a role-playing exercise to determine if they had read the appropriate section from the manual, correctly used the checklist to evaluate each participant's role playing, correctly conducted a group review of the role playing, provided positive feedback, and suggested improvements and conducted a second role-playing exercise if needed. The ratio of performed to specified be-

[a] For the programs with relatively few patients, a one-group, pre/post study design was used.

haviors was calculated for each instructional activity, and the results were averaged across all activities to obtain a percentage for each module and facility.

The same research assistants who conducted the staff workshop also administered the tests of accuracy and effectiveness. The tests of effectiveness were administered before the instruction, immediately afterward, and, for the patients remaining at each facility, 1 year later.

In the state hospital program and the two larger residential care facilities a two-group, random-assignment, experimental research design was used; the control group patients were placed on a waiting list. The three smaller residential facilities and the day care program treated relatively few patients, and there a one-group, pre/post, nonexperimental research design was used.

### *Reliability*

Test-retest reliability for each module's measure of effectiveness was determined by calculating a Pearson r for the correlation between the two testings of the control groups at the facilities that used an experimental design. The correlations were 0.87 for the medication management module, 0.64 for the grooming module, and 0.73 for the recreation module.

Interrater reliability for each effectiveness measure was determined by calculating the intraclass correlation coefficient (ICC 2,1 [18, 19]) for the relationship between one research assistant's scoring of the participants' recorded verbatim answers and the scoring of the research assistant who initially administered and scored the test. All information identifying either the patient or the date of the testing was removed from the records of the verbatim answers. The intraclass correlations were 0.94 for the test of the medication management module (N=14), 0.97 for the test of the grooming module (N=20), and 0.95 for the test of the recreation module (N=10).

Several posttraining answers, however, were recitations of the material, which could have informed the second scorer of the date of testing. Hence, the efficacy tests were administered to 10 patients with schizophrenia who were not included in the study, and their performances were videotaped. The tapes were independently scored by the two research assistants, and the intraclass correlations between their scores were 0.92 for the medication management module, 0.97 for the grooming module, and 0.94 for the recreation module.

Interrater reliability of the accuracy measure was determined by calculating the agreement between the two research assistants' independent assessments of 17 training sessions representing all facilities and trainers. The kappa was 0.88.

## RESULTS

### *Short-Term Effectiveness*

Table 1 lists the patients' pre- and posttraining scores for each module and each facility and the percentage of the trainers' behaviors that matched those specified in the modules' manuals averaged across the observations at each facility.

The posttraining scores for the facilities that used an experimental research design were analyzed separately for each module by using a two-way (group, site) factorial analysis of covariance (ANCOVA) for the medication and grooming modules and a one-way (group) ANCOVA for the recreation module with the pretraining scores as the covariate. The results indicated significant differences between the experimental and control groups for each module (medication management: F=26.68, df=1, 22, p<0.0001; grooming: F=7.99, df=1, 24, p=0.009; recreation: F=5.51, df=1, 8, p=0.05). There was no significant difference among the sites (medication: F=0.10, df=1, 22, p=0.76; grooming: F=0.50, df=1, 24, p=0.49) and no significant Site by Group interaction (medication: F=0.44, df=1, 22, p=0.51; grooming: F=1.71, df=1, 24, p=0.20).

To further analyze the effects of training, for each module a partial correlation between the posttraining scores and group was calculated, with partialing of the pretraining scores from both variables. Site was not considered in this analysis since it was not significant either as a main effect or in interaction with group in either the medication or grooming ANCOVA. The results were partial correlations of 0.74 for the medication module, 0.46 for the grooming module, and 0.64 for the recreation module.

To analyze the replicability of each module's effects across treatment facilities, pre/post scores were analyzed with a two-way (site, pre/post) split-plot factorial analysis of variance (ANOVA), one per module. The results indicated that all sources of variance were significant for the medication module: pre/post (F=48.21, df=1, 29, p<0.0001), site (F=2.60, df=5, 29, p=0.05), and the Site by Pre/Post interaction (F=2.91, df=5, 29, p=0.03). The significant interaction was further analyzed with tests of simple main effects; the results indicated that the pre/post differences were significant for all sites except one residential care facility. The posttraining differences among the sites were further analyzed with a one-way ANCOVA using the pretraining scores as the covariate; the differences were significant (F=3.97, df=5, 28, p=0.008). Further analysis using Tukey's honestly significant difference test (corrected for unequal numbers of subjects) indicated that the posttraining scores for two residential care facilities were significantly lower than those for the other sites.

The results of the split-plot factorial ANOVA for the grooming module indicated a significant pre/post main effect (F=106.2, df=1, 21, p<0.0001) and a nonsignificant site main effect (F=1.66, df=2, 29, p=0.21) and Site by Pre/Post interaction (F=3.32, df=2, 29, p=0.06). The results of the split-plot factorial ANOVA for the recreation module indicated a significant pre/post main effect (F=53.03, df=1, 17, p<0.0001), a significant main effect of site (F=11.24, df=2, 17, p=0.0008), and a nonsignificant Site by Pre/Post interaction (F=2.85, df=2, 17, p=0.09). Further analysis using Tukey's honestly significant difference test (corrected for unequal numbers of subjects) indicated that the scores at one residential care facility were significantly higher overall than at the other sites. This was confirmed by a one-way ANCOVA of the differences among the sites using the pretraining scores as the covariate; the main effect of site was significant (F=4.48, df=2, 16, p=0.03) because the scores at one residential care facility were higher than the scores at the other two sites.

### *Long-Term Effectiveness*

The participants who remained at the facilities 1 year later and to whom the follow-up tests were administered (N=35) did not differ significantly in age, sex, ethnicity, or hospitalization from the complete set of participants. The data were analyzed with a one-way ANOVA for repeated measures, followed by a Tukey's honestly significant difference test for significant main effects. The results indicated that for all three modules there were significant improvements from pre- to posttraining that had not declined at the follow-up testing.

### *Accuracy of Instruction*

As indicated in table 1, except for the residential care facility that did not achieve a learning effect, the trainers' behaviors substantially matched those specified in the manuals.

## DISCUSSION

The results confirm that the modules fulfilled their design objectives; with only a modicum of training and ongoing consultation, staff from diverse clinical and educational backgrounds working in diverse treatment facilities accurately taught the modules and achieved significant increases in the patients' knowledge and performance of the skills targeted by the training. This study replicates and considerably extends—with a more rigorous design and more modules—the previously reported findings on the modules in a national field test of 28 mental health facilities (20). Not only did the modules achieve their effects in both studies within the constraints of typical facilities that treat severely mentally ill patients, but the confirmation of the modules' effects in this study was achieved with both nonexperimental and experimental research designs, the latter of which showed significant effects with the medication and grooming modules in two facilities.

The results with the experimental design indicated that the size of the modules' effects ranged from moderate to substantial; the percentages of shared common variance between the posttraining scores and the group variable after partialing the pretraining scores were 54.9% for the medication module, 40.8% for the recreation module, and 21.3% for the grooming module. These immediate effects were not restricted to the more functional patients; although the more dysfunctional and regressed inpatients had lower pre- and posttraining scores, their changes were not significantly different from those of the other patients. Furthermore, these effects were maintained over a 1-year follow-up, which is noteworthy given that functioning deficits tend to endure in spite of improvements in symptoms (21).

The results, however, point to the limitations of the modules. In spite of the modules' robust effects, they certainly did not produce a perfect learning outcome for every patient who participated in the training. Unfortunately, to fulfill the research objectives of this study, the training was conducted for standardized durations at all sites regardless of the patients' performance. A clinically more satisfactory approach may be to conduct the instruction for each module on a "mastery" basis, i.e, conduct training until each patient achieves 100% correct. However, given the relatively poor posttraining scores of the inpatients in particular—despite their having achieved substantial learning—mastery training might require extensive and time-consuming repetitions of a module. Perhaps this is to be expected given the chronic nature of the patients' illnesses and the many years that have elapsed since most were exposed to learning in a classroom environment.

The results from one residential facility also indicate that extensive deviations from the specified procedures can be deleterious. The facility's trainer eliminated several learning activities and changed the content and order of the remaining ones. Not surprisingly, the participants' knowledge and performance of the module's skills did not improve.

The results did not address the effects of the modules on global clinical outcomes, such as relapse and rehospitalization. Since the modules are specifically designed as encapsulated units whose content, form, and size allow each to be easily adapted to the structure of diverse treatment settings, they are not meant as a comprehensive system of care that will change global clinical outcomes. Rather, since each addresses a major domain of social and instrumental functioning, the set of them can form the cornerstone of a comprehensive system of care that encompasses the pharmacotherapy, vocational, family, case management, and individual services needed to rehabilitate persons with long-term mental illness. Controlled clinical evaluations of the set of modules, embedded in a comprehensive system of care, are currently underway (22).

The national plans for schizophrenia and services research (23, 24) include a recommendation for design of skill-building treatments that are relevant to the real world of clinical programs and produce durable improvements in functioning and independence. As Lehman (25) noted in a description of the current and contemplated changes in the political and funding arrangements for services to severely mentally ill patients, new arrangements will be successful only if they include effective treatments that are operationalized by skilled and motivated clinicians. The results of this study indicate that the modules are easily used, effective, and highly focused services that clinicians can profitably add to their armamentarium of clinical tactics.

# Changes in Chronic Nightmares After One Session of Desensitization or Rehearsal Instructions

Robert Kellner, M.D., Joseph Neidhardt, M.D.,
Barry Krakow, M.D., and Dorothy Pathak, Ph.D.

*Objective: The purpose of this study was to examine the effects of one session of instructions on the frequency of chronic nightmares and on self-rated distress. Method: Twenty-eight volunteers with chronic nightmares (mean duration=19 years) were treated with either one session of desensitization with instructions on how to practice this treatment or with one session of instructions to change the nightmare and how to rehearse the new version. The authors administered four scales of the SCL-90 and the corresponding scales of the Symptom Questionnaire. Results: At 7-month follow-up of 23 patients, there was a significant reduction in the frequency of nightmares and significant decreases in self-rated depression, anxiety, and hostility. There were no significant differences between the effects of the two types of treatment. In four patients, whose mean duration of nightmares was 23 years, the nightmares ceased. Conclusions: The results of this preliminary study suggest that the instructions given to the patients reduced the frequency of their chronic nightmares and decreased their self-rated distress.*

(Am J Psychiatry 1992; 149:659–663)

Several methods have been proposed for the treatment of chronic nightmares, including rehearsal and desensitization. Halliday (1) cited several case studies in which rehearsal was used effectively to treat nightmares. Marks (2) described a patient with chronic nightmares who was treated successfully with rehearsal after she imagined a triumphant ending of the nightmare. Bishay (3) described seven patients treated with rehearsal and an altered ending. In a previous uncontrolled study (4), we treated four patients who had chronic nightmares. The patients had one session consisting of instructions on how to rehearse the nightmare and how to imagine a different ending; in three of the patients, the nightmares abruptly ceased.

There are two published controlled studies on the treatment of nightmares, and in both the treatment consisted of desensitization (5). Cellucci and Lawrence (6) and Miller and DiPilato (7) found that the outcome of patients given five or six sessions of desensitization was significantly better than that of untreated control subjects. To our knowledge, there are no published controlled studies of rehearsal.

The present study is one of a series of experiments in the treatment of chronic nightmares. Our aims were to examine the effects of one session of instructions on how to rehearse the nightmare, to use a group setting instead of treating individuals separately, and to compare the effects of rehearsal with those of desensitization.

## METHOD

Advertisements and articles in local news media recruited adults 18 years or older who had suffered from recurrent nightmares for 6 months or longer. Sixty-two callers were interviewed by telephone to determine whether they were suitable for the study. Callers who were abusing alcohol or other drugs were excluded; the rest were invited for an intake interview to determine whether any suffered from psychosis or organic brain syndrome, which would have been grounds for exclusion. No attempts were made to contact patients who failed to attend the intake interview.

### *Subjects*

Thirty-six subjects met our criteria and agreed to participate after the nature of the study had been explained. All met *DSM-III-R* criteria for the diagnosis of dream anxiety disorder (nightmare disorder) (307.47). Seven subjects who participated in the intake interview failed to attend their treatment session for reasons such

as illness or deciding not to participate; one subject was excluded from the study because the nightmares were apparently caused by antiparkinsonian drugs. The remaining 28 subjects were assigned at random to either rehearsal (N=14) or desensitization (N=14). One patient who completed treatment in each group could not be reached for follow-up. Another patient could not be contacted at 4 months, and two could not be contacted at 7 months.

The mean age of the patients treated with desensitization was 48 years (SD=14.9); the mean age of the patients treated with rehearsal was 36 years (SD=12.5) (t=2.1, df=23, p<0.04). There were no significant differences between the groups on any of the other measures. For the 26 patients who completed treatment and were followed up the duration of the disorder ranged from 2 to 46 years (mean=20.6 [SD=14.6]). The median frequency was 2–3 nightmares a week. Except for one patient who had an average of 2–3 nightmares a month during the preceding 6 months, all others had nightmares at least once a week.

Nineteen patients were women and seven were men. Twenty-two were Caucasian and the remainder were black, Native American, or Oriental. Seventeen were married. Their socioeconomic classes were similar to those of the city's population.

One patient, a 53-year-old woman, was being treated with 200 mg/day of amitriptyline for a coexisting depression when she entered the study; her nightmares had preceded the taking of the drug by several years and did not change after she started taking the drug. None of the other patients took hypnotics or psychotropic drugs, and there was no evidence that organic factors caused the chronic nightmares.

### Procedures

The protocol was approved by the research committees of the medical school. The intake interview consisted of taking a medical and psychiatric history as well as a detailed history of the nightmares. The purpose of the study and the procedures were explained to the patients and the patients were asked to give oral and written consent. The interviewing psychiatrist rated the frequency of the nightmares and administered self-rating scales. The patients were assigned to a 1–2-month waiting list, and during this period they were asked to record and describe their nightmares in a diary.

We used the following outcome criteria: 1) a 5-point rating scale of frequency of nightmares during the past month on which 1=not at all, 2=one or two times a month, 3=once a week, 4=two or three times a week, and 5=four or more times a week, 2) a 4-point global rating scale of intensity of emotional symptoms (fear, terror, panic, etc.) during the nightmare and symptoms on awakening on which 3=severe and 0=no symptoms, 3) the same scale for the rating of bodily symptoms (heart racing, breathlessness, sweating, etc.), 4) self-rating scales of anxiety, depression, hostility, and somatic symptoms of the SCL-90 (8), and 5) the Symptom Questionnaire (9), which contains the same four scales. The last two scales are scored differently and have somewhat different psychometric properties. We administered both as a method of cross-validation of the results.

We intended initially to rely entirely on self-rating scales and on daily diaries of nightmares completed by the patients as outcome measures. Only 16 patients (eight in each group), however, kept adequate diaries after the initial visit. We decided, therefore, to use as outcome measures the rating of frequency of nightmares and self-ratings of the SCL-90 and Symptom Questionnaire. In the 16 patients the recorded frequencies of nightmares in the diaries were congruent with the 5-point-scale frequency ratings.

### Treatments

Both treatments were carried out by the same psychiatrist (J.N.). Except for two patients who could not keep their appointments for the treatment session and who were treated individually, the rest were treated in groups of two to five patients. Both treatments consisted of one session with instructions on how to practice the treatment at home.

*Desensitization with muscular relaxation.* This treatment is based on Wolpe's method of reciprocal inhibition (5). Each patient was given an instruction booklet describing a modified form of progressive relaxation with desensitization (10). The patients were told to write down their nightmares. They were also told how to practice muscular relaxation during the first week and instructed to imagine the nightmare, to relax whenever the imagined nightmare caused any tension, and to practice relaxation before falling asleep during the second and third weeks. The patients were told to practice once a week during the fourth through eighth weeks but to do so more often if the nightmares persisted.

*Rehearsal of changed nightmare.* In this treatment, the patients were told to 1) select a recent nightmare and write it down, 2) change the nightmare any way they wished, 3) write down the changed version, and 4) rehearse the changed nightmare in imagery in a relaxed state. After doing so, they repeated the same steps during the same session without the therapist's guidance. Patients were told to rehearse each changed version once a day for 3 consecutive days after each nightmare or until the nightmares went away. They were given a two-page instruction sheet on the procedures.

Patients in both treatment groups were encouraged to telephone if they encountered any problems. Three patients telephoned once and one patient telephoned twice.

### Follow-Up

After 4 months, the patients were contacted by telephone and responded to a nightmare questionnaire; the ratings of the frequency and severity of the nightmares were based on the patients' replies. The interview was conducted by the psychiatrist who carried out the initial ratings. At 7 months this procedure was repeated. Telephone calls were limited to 10 minutes. At 7 months the patients were also mailed the SCL-90 and the Symptom Questionnaire and asked to fill them in and mail them back in a self-addressed stamped envelope.

The seven patients who participated in the intake interview but did not receive treatment were contacted by telephone after 7 months. They responded to the same nightmare questionnaire as the treated patients.

### *Statistical Analysis*

Changes over time within each group and across both groups, as well as between-group comparisons of the SCL-90 and Symptom Questionnaire scale scores, were tested by using two-response repeated-measures analysis of variance (ANOVA) (11). This procedure allowed for simultaneous testing of change over time, between-group comparisons, and presence of interaction between the group and time effects. If interaction was observed, the groups were then analyzed separately by using a paired t test. For the analysis of frequency of nightmares and the severity of bodily and emotional symptoms, the same approach was used but with three-response repeated-measures ANOVA because these variables were recorded at pretreatment, at 4-month follow-up, and at 7-month follow-up. All statistical analyses were carried out by using the repeated-measures ANOVA procedure or the paired t test procedure in the SAS statistical package for personal computers (12).

## RESULTS

### *Recovered Patients*

For four patients, whose mean duration of nightmares was 23 years, the nightmares ceased completely.

A 34-year-old woman had had nightmares four or more times a week since the age of 4 years. After practicing rehearsal for 3 days the nightmares ceased. She was ecstatic; she said that this had changed her life.

A 58-year-old woman had had nightmares four or more times a week for 5.5 years. After 3 months of rehearsal the nightmares ceased. "I am getting a restful sleep, I do not remember dreaming."

A 40-year-old woman had had nightmares about 2 to 3 times a week for 13 years. The nightmares ceased after practicing desensitization for 3–4 weeks. "I have a peaceful sleep and I am no longer afraid to go to sleep."

A 68-year-old man had had nightmares about once a week for 46 years. The nightmares decreased substantially after 1 month and ceased after 3 months. He continued to practice relaxation.

### *Changes in the Two Groups*

In the 16 patients who completed daily nightmare diaries while awaiting treatment, there was no change in the frequency of nightmares before treatment. After treatment, the frequency of nightmares decreased significantly in both groups. The mean score for the frequency rating for nightmares (see Procedures section) in the rehearsal group decreased from 4.4 (SD=0.8) to 3.3 (SD=1.5) at 4 months and 2.2 (SD=1.3) at 7 months. In the desensitization group the mean frequency rating for nightmares decreased from 4.2 (SD=1.2) to 2.7 (SD=1.4) at 4 months and 2.6 (SD=1.4) at 7 months. According to the three-response repeated-measures ANOVA the change across both groups was significant at 4 months (F=16.2, df=1, 21, $p<0.0006$) and at 7 months (F=33.8, df=1, 21, $p<0.0001$). There were no significant differences between the two groups in the changes in the frequency of nightmares.

At 7 months the mean rating of the severity of emotional symptoms experienced during the nightmare and on awakening had decreased in the desensitization group from 2.7 (SD=0.5) to 1.4 (SD=1.0) (t=–4.33, df=9, $p<0.002$, paired t test). The corresponding decrease in the rehearsal group was from 2.7 (SD=0.5) to 2.3 (SD=0.9) (t=–1.5, df=9, n.s., paired t test). Decreases in bodily symptoms were not significant in either group.

Self-ratings on all scales of the SCL-90 and the Symptom Questionnaire decreased from pretreatment to the end of follow-up for both treatments. Depression, anxiety, and hostility scores decreased significantly in both groups on the SCL-90 as well as on the Symptom Questionnaire; the changes on the somatic scales were not significant. The significance levels tended to vary with the scales (table 1).

None of the treated patients reported an increase in the frequency of nightmares. Two patients (one in each group) reported a decrease in frequency but an increase in severity of the nightmares.

Of the seven subjects who participated in the intake interview but received no treatment, two experienced no change in the frequency of nightmares and two experienced nightmares more often. Three of these subjects experienced a decrease in nightmare frequency: one was recording her nightmare, one obtained psychiatric treatment as an inpatient, and one had learned a yoga-type of relaxation and practiced desensitization on her own.

## DISCUSSION

The frequency of nightmares decreased significantly 7 months after one treatment in 23 patients who had experienced nightmares for an average of more than 20 years. These patients' self-ratings of depression, anxiety, and hostility but not of somatic symptoms significantly improved. There were no significant differences between the groups who were treated with rehearsal and those who were treated with desensitization. The patients' mean self-ratings on the SCL-90 and the Symptom Questionnaire for depression, anxiety, hostility, and somatization were in the range of psychiatric outpatients before treatment and approached the means of family practice and medical patients after treatment (13–15).

**TABLE 1. Changes in the Scores of 23 Patients With Chronic Nightmares[a] on the Anxiety, Depression, Somatization, and Hostility Subscales of the SCL-90 and the Symptom Questionnaire After One Session of Desensitization or Rehearsal Instructions**

| | Desensitization Group | | | | | Rehearsal Group | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Before Treatment | | 7-Month Follow-Up | | | Before Treatment | | 7-Month Follow-Up | | | | |
| Scale | N | Mean | SD | Mean | SD | N | Mean | SD | Mean | SD | F[b] | df | p |
| Anxiety | | | | | | | | | | | | | |
| SCL-90 | 11 | 1.4 | 0.9 | 0.8 | 0.7 | 10 | 1.4 | 0.7 | 0.8 | 0.5 | 16.5 | 1, 19 | 0.001 |
| Symptom Questionnaire | 12 | 13.8 | 5.6 | 9.3 | 8.3 | 9 | 16.6 | 6.1 | 10.7 | 6.0 | 7.9 | 1, 19 | 0.01 |

| SCL-90 | 11 | 1.1 | 0.7 | 0.9 | 1.0 | 10 | 0.7 | 0.3 | 0.5 | 0.3 | 1.9 | 1, 19 | n.s. |
| Symptom Questionnaire | 11 | 8.7 | 4.2 | 7.7 | 5.6 | 10 | 9.0 | 3.8 | 7.6 | 4.7 | 0.9 | 1, 19 | n.s. |
| Hostility | | | | | | | | | | | | | |
| SCL-90 | 11 | 1.0 | 0.8 | 0.6 | 0.5 | 10 | 0.9 | 0.6 | 0.4 | 0.3 | 15.2 | 1, 19 | 0.001 |
| Symptom Questionnaire | 11 | 9.6 | 5.1 | 7.4 | 6.7 | 9 | 15.1 | 6.7 | 8.6 | 4.5 | 7.2 | 1, 18 | 0.05 |
| Total | | | | | | | | | | | | | |
| SCL-90 | 11 | 1.4 | 0.7 | 0.8 | 0.8 | 10 | 1.3 | 0.4 | 0.8 | 0.4 | 18.4 | 1, 19 | 0.001 |
| Symptom Questionnaire | 10 | 43.2 | 15.7 | 26.2 | 23.6 | 8 | 58.8 | 14.9 | 36.9 | 15.9 | 11.5 | 1, 18 | 0.005 |

[a] Fourteen subjects in each group completed the treatment. One patient in each group could not be reached for any follow-up. Another patient could not be contacted at 4 months, and two could not be contacted at 7 months. A few patients did not return the self-rating scales or returned incomplete scales. N indicates the number of complete scales.

[b] Repeated-measures ANOVA for the before-after treatment comparison across both groups. No statistically significant differences were observed between the effects of the two treatment groups. The test for interactions was not significant.

The seven patients who did not receive the treatment in the present study cannot be regarded as a random untreated control group. It is of interest, however, that none of the patients in the treated groups failed to improve to some degree but two of the seven untreated patients remained unchanged and two got worse. Of the three untreated patients who improved, one rehearsed the nightmares by recording them and two were exposed to some form of treatment.

At present we are conducting a study of a group of patients given one session of rehearsal compared with a control group of subjects who are recording their nightmares in a diary. The findings suggest that the effects of rehearsing the changed nightmare are similar to those of the present study.

Our finding of a reduction in nightmares after one session of treatment in the present study is comparable to findings of two previous controlled studies in which the patients were treated with five or six sessions of systematic desensitization. Whether more elaborate treatments will improve results is unknown; one session, however, appears to constitute adequate treatment for some patients.

An altered, favorable, or triumphant ending of the nightmare is not essential for improvement or recovery. The patients in the desensitization group improved and yet had not changed the ending of their nightmares. Both groups had rehearsal in common (one of a changed version, the other of the original nightmare), which is a form of exposure. The treatment of phobias with exposure takes several sessions and leads to gradual and intermittent improvement, but rehearsal, in a few patients, has resulted in rapid recovery from chronic nightmares without recurrences.

The interpretation of dreams has been one of the tenets of Freudian psychoanalytic theory. In our study we compared simple treatments and did not attempt to deal with the psychodynamics of the patients' nightmares. Chronic nightmares and recurring dreams of a traumatic event have been described in posttraumatic stress disorder (PTSD) in children and in adults (*DSM-III-R*, pp. 248–249). In the present study we elicited detailed histories from the patients but did not explore specifically whether psychological trauma preceded the onset of nightmares. Discussions of the psychodynamic implications and the relationship of chronic nightmares to PTSD lie beyond the scope of this report.

The reason for the decrease in the frequency of nightmares is not known. It may have been in part a spontaneous improvement with the passage of time, in part a placebo effect ("the impact of a place of healing" [16, 17]), or the effect of exposure to the nightmares in the waking state. The extent to which these factors contributed to the observed improvement is at present unknown. These results must be regarded as preliminary and require replication.

# Posttraumatic Stress Disorder Among Substance Users From the General Population

Linda B. Cottler, Ph.D., Wilson M. Compton III, M.D., Douglas Mager, B.S.,
Edward L. Spitznagel, Ph.D., and Aleksandar Janca, M.D.

*Objective: The purpose of the study was to evaluate the prevalence of posttraumatic stress disorder (PTSD) among substance users in the general population. Method: The St. Louis Epidemiologic Catchment Area study, a survey of psychiatric illness in the general population, collected data on PTSD and substance use with the Diagnostic Interview Schedule. Among the 2,663 respondents, 430 reported a traumatic event that could qualify for PTSD; however, the rate of PTSD was low, 1.35% overall. To evaluate the relationship between PTSD and substance use, respondents were hierarchically classified into one of four substance use categories ranging from polydrug use to alcohol use only. Substance users from each category as well as substance users in general were compared with persons who did not meet the substance use threshold (comparison subjects). Results: Findings indicate that cocaine/opiate users are over three times as likely as comparison subjects to report a traumatic event, report more symptoms and events, and are more likely to meet diagnostic criteria for PTSD. Physical attack, but not combat-related events, was the most prevalent event reported among cocaine/opiate users. Onset of substance use preceded onset of posttraumatic symptoms, suggesting that substance use predisposes the individual to exposure to traumatic events. When other variables—including antisocial behavior—were controlled, female gender and use of cocaine/opiates predicted PTSD. Conclusions: These analyses of the co-occurrence of substance abuse and PTSD warrant further study and suggest that PTSD is much more common among substance abusers than was previously known.*

(Am J Psychiatry 1992; 149:664–670)

Several studies have suggested a strong relationship between substance use and posttraumatic stress disorder (PTSD). For example, a report by Helzer et al. (1) from the St. Louis National Institute of Mental Health (NIMH) Epidemiologic Catchment Area (ECA) project, a multistage probability survey of psychiatric illness in the general population, reveals that men with PTSD were five times as likely as men without PTSD to have a *DSM-III* drug abuse or dependence disorder; women with PTSD were 1.4 times as likely to have drug abuse or dependence as women without PTSD. In a study of postdisaster victims, Smith et al. (2) found that 22% of subjects with PTSD had been abusing or were dependent on alcohol before the disaster. In addition, Breslau and Davis (3) found the rate of drug abuse or dependence to be 86% among Vietnam veterans with PTSD. The relationship between PTSD and substance use is of concern since psychoactive substance use may increase the risk of exposure to events outside the range of normal experience, which in turn may increase the risk for experiencing symptoms of PTSD. Moreover, little is known about risk factors for PTSD in the general population. To address these salient issues, we have expanded analyses on PTSD by using data from the St. Louis ECA sample.

The ECA sample is an especially useful sample for such an evaluation because selection of these general population subjects was not based on substance use, PTSD, or experience in the combat theater of war. Moreover, the sample includes women, who are rarely studied. The questions addressed in this evaluation included the following: 1) Are substance users at greater risk for traumatic events than are nonusers? 2) Do substance users experience certain events more often than nonusers? 3) Once exposed to an event, are substance users more likely than nonusers to meet the criteria for

PTSD? 4) Are certain substance use patterns associated with greater risk for PTSD than others? 5) Do symptom patterns among those who experienced an event vary with type of substance? 6) Does the onset of drug abuse precede the onset of symptoms attributable to a traumatic event? 7) When other risk factors are controlled, which variables best predict PTSD?

## METHOD

### *Sample*

The data for these analyses were collected in 1982 and 1983 as part of the second wave of the St. Louis NIMH ECA survey (4), a study of the lifetime prevalence and 1-year incidence of mental disorders in the general population. (Five sites nationwide were selected to participate in this study of approximately 20,000 respondents; however, since questions to assess the *DSM-III* diagnosis of PTSD were not included in the "core" psychiatric interview used at other sites, only the data from the St. Louis site are available for these analyses.) The NIMH Diagnostic Interview Schedule (DIS), a structured interview that can be administered by trained nonclinician interviewers, was used as the core psychiatric interview to obtain the information necessary to make psychiatric diagnoses (5). The DIS has been shown to have very good reliability for substance abuse disorders (6) and PTSD (3).

From the St. Louis site 3,004 household residents were interviewed in the first wave. Individuals were selected after a five-stage probability sampling that began with selection of three mental health catchment areas. These three were selected for this general population study because they approximated the demographic composition of the nation as a whole in 1980, and thus the results would allow for the generalizability of findings to other U.S. communities. After the catchment area was selected, census tracts, enumeration districts, blocks, and households were selected. An 81% overall completion rate for the first wave was achieved (7).

One year later, the same respondents were asked to participate in a follow-up interview. At that time, questions to assess *DSM-III* PTSD were added. All data for this paper came from persons who continued to participate in the second wave of the study, that is, participants in the 1-year follow-up. However, when age at onset of drug use is compared with age at first PTSD symptom, the first wave data are used because this information was not elicited again at the second wave. The sample size was 2,663, representing an 89% one-year follow-up rate.

### *Substance Abuse Questions*

Lifetime history of substance use was obtained by the DIS. As part of the DIS, respondents were given a list of the names of psychoactive medications and asked which they had used more than five times in their life without a prescription, more than prescribed, or to get high. On the basis of their self-reported drug use, respondents were classified into one of five mutually exclusive substance use groups for these analyses. Briefly, 1) cocaine/opiate users were those persons who ever used heroin, other opiates, or cocaine (whether or not they used other drugs); 2) pill/hallucinogen users were those who reported using amphetamines, barbiturates, tranquilizers, or hallucinogens regardless of manner of administration and may or may not have used marijuana and alcohol; 3) users were classified in the marijuana category if their substance use was restricted to cannabinoids, with or without alcohol; and 4) the heavy alcohol category was reserved for persons whose substance use was limited to drinking heavily once a week for at least 2 months or persons who met criteria for alcohol abuse or dependence. A residual category of nonusers consisted of all persons who did not meet the thresholds for use as previously defined and represent the comparison group. These mutually exclusive categories have provided a useful hierarchy with which to make comparisons (8). This classification of substances relies heavily on prior work which shows that marijuana is a "gateway" drug; therefore, those who limit their drug use to marijuana may have different vulnerabilities to stress. In addition, prior studies have shown that a history of heroin use is associated with other substance use (9–11). These same studies have also found that pill users form another group with different problems and consequences of drug use. The substance use classification employed in the present analyses has been previously associated with high-risk sexual behaviors (12).

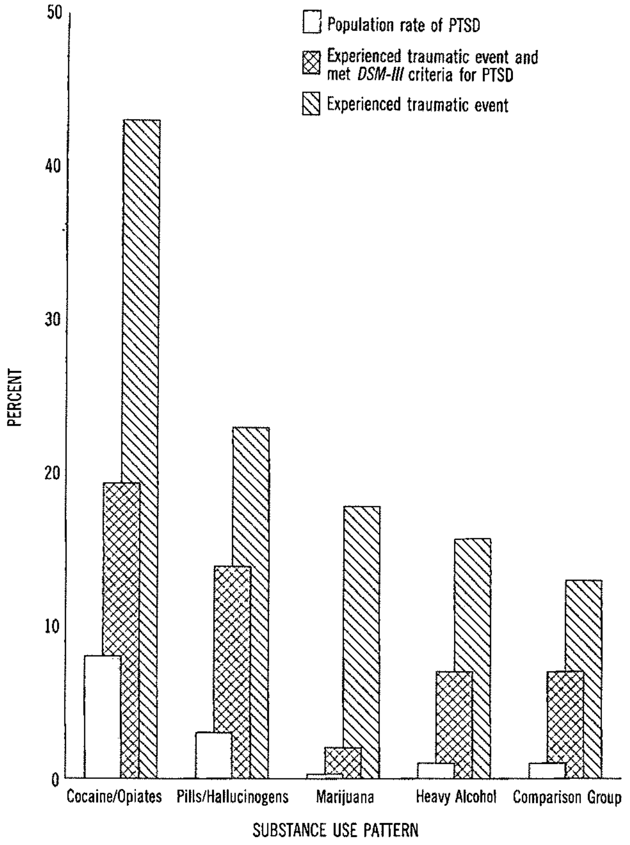
### *PTSD Questions*

The DIS was also the instrument used to assess the *DSM-III* diagnosis of PTSD. Respondents were asked whether they had ever experienced something so horrible that they had nightmares from it. If so, they were asked an open-ended question about the nature of the event. The categories of events included combat, serious accident, physical attack, natural disaster, threats, witnessing someone being killed or injured, and a category for other. The respondents were then asked whether they had jumpiness, guardedness, insomnia, trouble concentrating, social impairment, or loss of interest after that particular event or after any other event outside the normal range of human experience. Responses regarding two additional symptoms, being ashamed after such an event and avoiding situations that reminded them of the event, were also elicited. Thus, the DIS version III PTSD section focused not on event-related symptoms but on symptom-related events. Responses regarding onset of the event-induced symptom, as well as duration and recency of the symptom, were also elicited.

### *Data Analysis*

Associations found between substance use and PTSD were tested by using the chi-square statistic, with one degree of freedom, in the following instances: 1) when sub-

**FIGURE 1. Traumatic Events and PTSD Among Substance Users and Comparison Subjects[a]**



[a]St. Louis Epidemiologic Catchment Area data.

stance users as a group were contrasted with comparison subjects and 2) when each substance use group was contrasted with the comparison group. Odds ratios and their 95% confidence intervals were calculated by using the Epistat program for the personal computer. The Bonferroni correction, a more conservative test that takes into consideration the number of substance category comparisons (N=4), was also used. With the Bonferroni test, each p value is multiplied by 4 before statistical significance is assessed. Both Bonferroni-adjusted p values and unadjusted confidence intervals are given. To test the difference between means of each substance use group and the comparison group mean, the Dunnett test was performed (13). Logistic regression in personal computer SAS version 6.04 was used to evaluate risk factors for exposure to traumatic events and was used separately to evaluate vulnerability to PTSD among subjects exposed to events, while the effects of other variables were controlled.

## RESULTS

### *Demographics of the Sample*

The sample for these analyses consisted of 1,094 men and 1,569 women. At the time of the second wave, the youngest respondents were at least 19 years of age. The mean age of the sample was 43.6 years (SD=19); 38% of the sample was black, which represents an oversample of this population in St. Louis.

### *Prevalence of Substance Abuse and Posttraumatic Stress*

The data from the 2,663 respondents indicate that 144 persons (5%) reported lifetime cocaine/opiate use, 163 (6%) reported pill/hallucinogen use, 308 (12%) reported marijuana only use, and 388 (15%) reported heavy or problem drinking. The remaining 1,655 persons (62%) did not meet the defined thresholds for any substance use and were classified as comparison subjects. (Data were missing for five subjects.) Thus, 38% of the sample met the criteria for substance use.

Overall, 430 persons (16%) reported ever experiencing a symptom-related event. The lifetime prevalence of *DSM-III* PTSD in this general population sample was 1.35%.

### *Associations*

Substance users experienced more traumatic events than nonusers (odds ratio=1.83, 95% confidence interval=1.47–2.26). Moreover, there was an increasing relationship between use of the more addictive illicit drugs and reports of traumatic events. As shown in figure 1, 43% of the polydrug or cocaine/opiate users reported experiencing a qualifying PTSD event, compared with 23% of the pill/hallucinogen users, 18% of the marijuana users, 16% of the heavy alcohol users, and 13% of the comparison subjects. Cocaine/opiate users were statistically significantly more likely than comparison subjects to report a qualifying event (odds ratio=5.06, 95% confidence interval=3.48–7.37), as were pill/hallucinogen users (odds ratio=1.95, 95% confidence interval=1.29–2.94) and marijuana users (odds ratio=1.46, 95% confidence interval=1.04–2.04) but not alcoholics.

Substance users, in general, were not more likely than comparison subjects to experience certain types of stressors. However, when specific substances were evaluated, physical attack was the event most likely to be reported by cocaine/opiate users (table 1). In fact, cocaine/opiate users were over three times as likely as comparison subjects to experience a physical attack. Combat-related events were ranked among the least prevalent events reported by cocaine/opiate users and were no more likely to occur among substance abusers than nonusers, except for the heavy alcohol group. These persons were over three times as likely to have experienced combat-related events. All other stressors were as likely to occur among comparison subjects as among substance users.

Among the subjects exposed to events, cocaine/opiate users were more likely than comparison subjects to meet *DSM-III* criteria for PTSD (odds ratio=3.62, 95% confidence interval=1.46–8.94). Denominators for

rates of PTSD have previously included all persons whether or not they have been exposed to an event. This may have produced underestimates of the rates. Our analyses evaluated the rate of PTSD among persons who were at risk because they had been exposed to an event. Thus, we feel these rates are more appropriate and closer to the true prevalence rates. As shown in the middle row of figure 1, nearly one-fifth of the cocaine/opiate users exposed to events met criteria for PTSD (19%); thus, the higher exposure to events among these persons was associated with a concomitant higher rate of PTSD. The rate of PTSD among the persons experiencing an event was lowest among persons whose illicit substance use was limited to marijuana (2%). Surprisingly, the event-exposed marijuana users were less likely to meet criteria for PTSD than were comparison subjects exposed to events (odds ratio=.27, 95% confidence interval=0.02–2.10). Although not statistically different from the rate among comparison subjects, the lower rate among marijuana users is noteworthy, since the rate of exposure to events among marijuana users was not similarly lower than that of all other substance use groups.

The overall rate of PTSD among persons regardless of event exposure was higher among substance users than comparison subjects (odds ratio=2.63, 95% confidence interval=1.28–5.43). Shown in the first row of bars in figure 1 are general population rates of PTSD among persons regardless of exposure to an event. The general population lifetime prevalence rates of PTSD were 8.3% among cocaine/opiate users and 0.3% among comparison subjects. Persons whose drug use patterns included cocaine or opiates were over 10 times as likely as comparison subjects to meet criteria for PTSD (odds ratio=10.75, 95% confidence interval=4.56–25.25). Persons with a pattern of pill and/or hallucinogen use, regardless of event exposure, were almost four times as likely as comparison subjects to meet criteria for PTSD (odds ratio=3.68, 95% confidence interval=1.14–11.13).

Substance abuse patterns affect the clinical course of PTSD. Overall, the most commonly reported symptoms among persons experiencing an event, whether they met criteria for PTSD or not, were jumpiness (48%), nightmares (43%), and sleep problems (38%). Substance users as a group were no more likely than comparison subjects to report any specific symptoms. However, as shown in table 2, cocaine/opiate users were statistically more likely than comparison subjects to report guardedness, sleep problems, social impairment,

and loss of interest in things they usually cared about. Interestingly, alcoholics were less likely to report situational avoidance than were comparison subjects. After the Bonferroni correction for multiple comparisons was used, only one symptom remained significantly different: cocaine/opiate users were more likely to report social impairment than were comparison subjects.

There was no statistically significant difference between event-exposed substance users and comparison subjects in the mean number of symptoms and events reported, except for cocaine/opiate users. As shown in table 3, they reported more events and symptoms than did comparison subjects. Although users of other classes of drugs did not experience more symptoms or events, they experienced their stressor at a younger age than did comparison subjects.

Age at onset of substance use preceded the onset of event-related symptoms. Several analyses were performed to determine whether the event-related symptoms were experienced before, at the same time as, or after the involvement with substances. First, the age at first symptom from illicit drug use was plotted against the age at first posttraumatic symptom among the 192 persons who reported both illicit drug use and any PTSD symptom (figure 2). The onset of drug use and symptoms related to the stress disorder did not occur at the same time (difference in means is significant at $p<0.0005$), and, in fact, the age at first drug use predated the onset of posttraumatic symptoms. Second, the earliest age at any alcohol-related symptom was then plotted against the age at the first posttraumatic stress symptom (figure 3). Again, alcohol-related problems generally predated the onset of posttraumatic stress symptoms (difference in mean age is significant at $p<0.0001$).

After other variables were controlled, female gender and use of cocaine/opiates predicted PTSD among the subjects exposed to events. Logistic regression was used to investigate the association between certain risk factors and exposure to a PTSD event. Age, race, gender, history of antisocial personality disorder, depression, and substance use pattern were entered into a logistic regression equation model, with exposure to a stressor

**TABLE 4. Logistic Regression Predicting Exposure to Traumatic Events and PTSD**

| Pills/hallucinogens | 0.27 | 0.22 | 0.23 | 0.53 | 0.62 | 0.39 |
| Marijuana | 0.19 | 0.18 | 0.30 | –1.57 | 1.06 | 0.14 |
| Heavy alcohol | 0.15 | 0.17 | 0.40 | 0.73 | 0.65 | 0.26 |

as the dependent variable (table 4). Younger age, Caucasian race, female gender, and a history of antisocial personality disorder, depression, and cocaine/opiate use predicted exposure to an event that qualified as a PTSD stressor.

A second logistic regression was performed to predict vulnerability to PTSD among subjects exposed to events. In this evaluation, female gender and use of cocaine/opiates were the only two statistically significant risk factors. When all other variables were controlled, personality, depression, race, and age were not statistically related to PTSD. Of particular interest is the finding (although not statistically significant) that persons exposed to events whose drug use was limited to marijuana were "protected" from the development of PTSD (beta=–1.57).

## DISCUSSION

These data from St. Louis ECA general population subjects support an original hypothesis that illicit substance use increases the risk of exposure to traumatic events and to the subsequent development of PTSD. Specifically, our analyses reveal an increasing relationship between use of more addictive drugs, such as opiates or cocaine, and reports of events that lead to PTSD, as well as vulnerability to PTSD once exposed. Substance users in general were no more likely than comparison subjects to experience a certain type of stressor; however, in contrasting specific types of users with comparison subjects, we found that cocaine/opiate users were more likely than comparison subjects to experience a physical attack. This association is not surprising given the situations in which cocaine/opiate users find themselves (14). However, the low rate of combat-related events among cocaine/opiate users was surprising, since Vietnam-exposed soldiers, individuals assumed to be at high risk for PTSD (1), are also assumed to be at higher risk for heroin use. Alcoholics, on the other hand, were more likely to report combat-related events than were comparison subjects. Data on substance type and event specificity have not previously been provided on this correlation.

A preponderance of PTSD among women in the general population has been previously shown (1). However, our analyses yield a unique finding in that both women and cocaine/opiate users who were exposed to events were found to be significantly more likely to meet criteria for PTSD than were men and persons who did not include cocaine and opiates in their drug use patterns, even after other risk factors, such as age, race, antisocial personality disorder, and depression were controlled. One possible explanation for women's preponderance to develop PTSD may be their greater tendency to report symptoms in general. Cocaine/opiate users may similarly perceive themselves as sicker than nonusers, may interpret their symptoms as more severe, or may be more willing than nonusers to report symptoms and events, which could account for the difference in clinical course (15). Although antisocial personality disorder and depression were not predictive of PTSD, they were associated with exposure to an event even after other factors were controlled. In addition, the fact that younger cohorts were more likely to be exposed to an event may suggest that there is a cohort effect to posttraumatic stress events and that posttraumatic stress is more common than ever before. This certainly has been suggested by a recent general population study by Breslau et al. (16).

The finding that marijuana users were protected from PTSD, but not events, is interesting and deserves further replication. As Penk et al. (17) suggested with their evaluation of MMPI scales for PTSD, this is one of the few disorders affected by personality maturation. If individual variation plays a major role in the development of symptoms, it seems plausible that if persons are able to limit their drug abuse to marijuana, they also could cope better with stress than nonusers. This might explain the low rate of PTSD among subjects who used only marijuana.

We found nightmares, jumpiness, and sleep problems to be the most prevalent symptoms reported, which confirmed the symptom criteria requirements in *DSM-III*. Furthermore, this finding is consistent with data from Ross and colleagues, who suggest that sleep problems are fundamental for PTSD (18).

The analyses showing the onset of drug use and alcohol problems before the onset of PTSD symptoms suggest a possible premorbid vulnerability to PTSD among drug users, a finding that challenges the predicted course suggested by the *DSM-III* manuals of drug abuse complicating PTSD. This potential vulnerability is of considerable importance because it may explain the etiologic link in the association between Vietnam veterans' PTSD and subsequent drug use. Our findings of directionality deserve replication both with different assessment tools and among different populations.

The findings reported here should be interpreted in light of several weaknesses. For example, cross-sectional studies such as the ECA might potentially suffer from recall bias inherent in all studies of retrospective recall. Systematic and standardized questioning, however, minimize this bias to an extent. In addition, the findings are limited by the DIS version used. The ECA study used a methodology for assessing PTSD that was symptom related, rather than event related. However, this should not pose as great a problem as expected because this method would tend to underestimate the rates, rather than overestimate them.

The ECA has provided a unique opportunity to study substance use as a risk factor for both greater exposure to events and subsequent development of PTSD. The strength of our study derives from the fact that it is a general population, non-treatment-seeking sample that included women and nonveterans. Further, the study was not initiated with a PTSD-substance use association in mind. In addition, we feel that the reporting of prevalence rates of PTSD in subjects exposed to traumatic events comes closer to true prevalence rates than any previously reported and should be considered in future analyses on rates of PTSD.

# Posttraumatic Stress Disorder in an Urban Population of Young Adults: Risk Factors for Chronicity

Naomi Breslau, Ph.D., and Glenn C. Davis, M.D.

*Objective: Despite progress in epidemiologic research on posttraumatic stress disorder (PTSD), little is known about factors that distinguish chronic from nonchronic PTSD. In a previous report, the authors identified a set of personal predispositions associated with PTSD following traumatic events in a general population sample of young adults. The purpose of this analysis was to identify characteristics of chronic PTSD and examine whether any of the suspected risk factors for PTSD was associated specifically with chronic PTSD. Method: A random sample of 1,007 21- to 30-year-old members of a large health maintenance organization in the Detroit area was interviewed, using the National Institute of Mental Health Diagnostic Interview Schedule (DIS), revised for* DSM-III-R. *The analysis was performed on data from 394 respondents who reported traumatic events, of whom 93 met criteria for PTSD. Chronic PTSD was defined as duration of symptoms for 1 year or more. Results: Persons with chronic PTSD (N=53) had, on the average, a significantly higher total number of PTSD symptoms and higher rates of overreactivity to stimuli that symbolized the stressor and interpersonal numbing than persons with nonchronic PTSD. The rates of one or more additional anxiety or affective disorders and a variety of medical conditions were higher in persons with chronic than nonchronic PTSD. Family history of antisocial behavior and female sex were associated specifically with chronic PTSD. Conclusions: The findings suggest that chronic PTSD may be associated with specific risk factors and clinical features. Longitudinal data on the course of PTSD are needed to determine whether the distinct features and the medical and psychiatric histories of persons with chronic PTSD are complications attendant on a chronic course or coexisting disturbances that inhibit recovery.*

(Am J Psychiatry 1992; 149:671–675)

Epidemiologic studies have confirmed previous reports of persistent psychiatric morbidity in Vietnam combat veterans and have provided evidence that an important determinant of chronic posttraumatic stress disorder (PTSD) is level of combat exposure (1–5). A similar observation with respect to level of exposure was made in regard to chronic PTSD among survivors of a civilian disaster (6, 7). The definition of PTSD in *DSM-III-R* requires that the disturbance lasts for at least 1 month. However, unlike *DSM-III*, *DSM-III-R* does not specify subtypes of PTSD, classified according to duration of symptoms. Nonetheless, chronicity in PTSD continues to be an important clinical and research issue (8, 9). While there is evidence that a high level of exposure to combat and to civilian disasters may be associated with chronic PTSD, little is known about how chronic PTSD differs from nonchronic PTSD and why PTSD symptoms subside in some affected persons but persist for long periods in others.

Previously, we reported on the lifetime prevalence of PTSD and potential risk factors associated with its occurrence in a random sample of young adults selected from the membership of a large health maintenance organization (HMO) in the Detroit area (10). Of 1,007 respondents, 394 reported that they had experienced in their lifetime typical PTSD stressors and 93 met *DSM-III-R* criteria for PTSD. With the exception of rape, differences in the rate of PTSD across classes of traumatic events were relatively small. The following six factors were found to be associated with greater vulnerability to PTSD following exposure to traumatic events: female sex, prolonged childhood separation from parents, family history of anxiety, family history of antisocial behavior, preexisting anxiety or depression, and neuroticism. These results applied to the entire subset with PTSD regardless of the duration of symptoms beyond the 1-month diagnostic requirement.

**TABLE 1. Lifetime Prevalence of PTSD, by Various Duration Criteria, in Urban Young Adults**

| | Lifetime Prevalence of PTSD | | | | | |
|---|---|---|---|---|---|---|
| | Total (N=1,007) | | Men (N=386) | | Women (N=621) | |
| Duration Criterion | N | % | N | % | N | % |
| 1 month or longer | 93 | 9.2 | 23 | 6.0 | 70 | 11.3 |
| 6 months or longer | 71 | 7.1 | 18 | 4.7 | 53 | 8.5 |
| 1 year or longer | 53 | 5.3 | 9 | 2.3 | 44 | 7.1 |
| 3 years or longer | 34 | 3.4 | 5 | 1.3 | 29 | 4.7 |

In the present study we focused on chronic PTSD, defined as duration of symptoms for 1 year or longer. We examined the characteristics of chronic PTSD and inquired whether any of the personal dispositions, identified as predictors of who developed PTSD following exposure, was associated specifically with chronic PTSD. Because persistent psychiatric disturbances are associated with disabilities and greater use of health care, an analysis of factors associated with chronicity of PTSD is of great clinical importance.

## METHOD

A detailed description of the sample and the measurement instruments was provided previously (10). Briefly, a random sample of 1,200 was selected from all 21- to 30-year-old members of a 400,000-member HMO in the Detroit metropolitan area. A total of 1,007 (84%) were interviewed at their homes in 1989; 81% were white and 19% were black; 62% of the sample were women. The National Institute of Mental Health Diagnostic Interview Schedule (DIS), revised to cover *DSM-III-R* disorders, was used. The revised DIS section on PTSD opens with a question in which several typical PTSD events are mentioned, and respondents were asked whether any of these events had ever happened to them. A report of an event that did not fit the *DSM-III-R* stressor definition (e.g., illness, death in the family, divorce) was excluded from further inquiry, and the respondent was asked whether or not he or she had experienced another event of the sort described in the question. A respondent's report of a PTSD-type stressor was followed by questions about the occurrence of PTSD symptoms after the event. Information was gathered on age at exposure, the time of onset of symptoms, and their duration. In addition, the interview covered psychiatric disorders in parents and siblings, a history of prolonged childhood separation from parents, personality factors, and sociodemographic characteristics.

Chronic PTSD was defined as duration of symptoms for at least 1 year. While the concept of chronicity is widely used in clinical psychiatry, the choice of a precise quantitative definition is in part an arbitrary decision. Chronic PTSD, as a subtype, was deleted from *DSM-III-R,* probably because of lack of evidence supporting any single cutoff point. This is not unique to PTSD; there are no definitions of chronic subtypes of any psychiatric disorder in *DSM-III-R.* With respect to axis I disorders in which nontransient, or prolonged, disturbance is a defining feature (rather than a characteristic of a subtype), duration criteria vary from 6 months (generalized anxiety disorder) to 2 years (dysthymia or cyclothymia). While we could have chosen 6 months as a cutoff, following the previous rule in *DSM-III,* our purpose was to define a threshold for chronic PTSD, rather than to separate acute (or transient) from nonacute (or nontransient) reactions. There are also precedents in the research literature supporting the 1-year cutoff for chronic PTSD (11). Furthermore, in our sample of young adults, 1 year was the median of the duration distribution.

Of the 93 respondents who met criteria for PTSD, 70 were in remission during the year before the interview. Duration of PTSD was estimated for these subjects by subtracting the age at onset from the age at which the last symptom was experienced. Duration of PTSD could not be estimated for 23 persons who continued to experience symptoms during the year before the interview. However, with one exception, all persons with active cases of PTSD reported that their PTSD symptoms had appeared more than 1 year earlier and were thus classified as having chronic PTSD. The single person with an active case with symptoms lasting less than 1 year was not included in the analysis.

The strength of the association of chronic PTSD with suspected risk factors was measured by the odds ratio, calculated in tables of cross-tabulations, by using exposed persons with no PTSD as a reference. A multivariable logistic regression was used to estimate the odds ratio of each factor, adjusted for all other factors in the model. Goodness-of-fit chi-square was used to estimate the efficacy of the model (12). The sensitivity and specificity of the model for predicting chronic PTSD were calculated by using cutoff points that minimize the weighted misclassification rate.

## RESULTS

### *Lifetime Prevalence of PTSD and Chronic PTSD*

Of the 1,007 respondents, 394 had been exposed to traumatic events and 93 (9.2%) met *DSM-III-R* criteria for PTSD. More than three-quarters of those who met PTSD criteria reported symptoms lasting 6 months or more. However, in 43%, PTSD symptoms had resolved in less than 1 year, leaving 57% with symptoms that persisted for 1 year or more (table 1). Women were at greater risk for PTSD than men, even though they were not more likely than men to be exposed to traumatic events (10). Moreover, while they constituted 65% of those with PTSD of less than 1 year's duration, women constituted 83% of those with PTSD symptoms lasting 1 year or more.

The approximately 50% split between chronic and nonchronic PTSD, with the 1-year cutoff as a criterion, ap-

TABLE 2. Prevalence of Individual PTSD Symptoms in Urban Young Adults With Chronic and Nonchronic PTSD

| | Prevalence (%) | | | |
|---|---|---|---|---|
| Symptom | Chronic PTSD (N=53) | Nonchronic PTSD (N=40) | $\chi^2$ (df=1) | p |
| Recurrent recollections | 94.3 | 95.0 | 0.02 | 0.89 |
| Recurrent dreams | 79.2 | 80.0 | 0.008 | 0.93 |
| Flashbacks | 49.1 | 50.0 | 0.008 | 0.93 |
| Avoid thoughts | 86.8 | 90.0 | 0.23 | 0.64 |
| Avoid activities | 84.9 | 82.5 | 0.10 | 0.76 |
| Psychogenic amnesia | 24.5 | 27.5 | 0.11 | 0.75 |
| Psychologic reactivity to symbolic stimuli | 67.9 | 45.0 | 4.92 | 0.03 |
| Physiologic reactivity to symbolic stimuli | 64.2 | 40.0 | 5.35 | 0.02 |
| Diminished interest | 62.3 | 55.0 | 0.50 | 0.48 |
| Foreshortened future | 32.1 | 25.0 | 0.55 | 0.46 |
| Detachment from others | 90.6 | 67.5 | 7.77 | 0.005 |
| No loving or warm feelings | 62.3 | 37.5 | 5.60 | 0.02 |
| Sleep problems | 84.9 | 70.0 | 3.00 | 0.08 |
| Irritability/anger | 60.4 | 57.5 | 0.08 | 0.78 |
| Problem concentrating | 88.7 | 70.0 | 5.10 | 0.02 |
| Hypervigilance | 83.0 | 95.0 | 3.14 | 0.08 |
| Startle | 69.8 | 55.0 | 2.16 | 0.14 |

plied to nearly all types of events, including rape, a traumatic event associated in this study with an exceptionally high rate of PTSD (10). Personally experienced violence, that is, sudden injury or accident, physical assault, and rape, was not more likely to lead to chronic symptoms than were vicarious experiences, such as seeing someone seriously hurt or killed or receiving news of the violent death of or injury to a close relative or friend.

### *Symptoms of Chronic and Nonchronic PTSD*

Table 2 displays the prevalence of *DSM-III-R* criteria symptoms of PTSD in the chronic and nonchronic subsets. Because this analysis was exploratory in purpose, we did not adjust the alpha level for the greater chance of type I error because of multiple interrelated tests. A caveat regarding the interpretation of these results is in order.

Reexperiencing the trauma in intrusive thoughts, nightmares, or flashbacks was equally common in the chronic and nonchronic subsets. Similarly, symptoms of avoidance, diminished interest in previously salient activities, and foreshortened future were experienced in equal rates by persons with chronic and nonchronic PTSD. However, in two symptom domains, chronic PTSD was associated with higher rates of symptoms: overreactivity (both psychologic and physiologic) to stimuli that symbolized the traumatic event and interpersonal numbing, as manifested by detachment from others and diminished positive affect. Concentration problems were also significantly more common in persons with chronic than nonchronic PTSD. The mean number of PTSD symptoms in chronic and nonchronic PTSD was 12.8 (SD=2.6) and 11.4 (SD=2.6) (t=2.54, df=90, p=0.01).

TABLE 3. Prevalence and Sex-Adjusted Odds of Other *DSM-III-R* Disorders in Urban Young Adults With Chronic and Nonchronic PTSD

| | Prevalence (%) | | | |
|---|---|---|---|---|
| *DSM-III-R* Disorder | Chronic PTSD (N=53) | Nonchronic PTSD (N=40) | Adjusted Odds Ratio | 95% Confidence Interval |
| Any affective or anxiety disorder | 81.1 | 57.5 | 2.86 | 1.10–7.39 |
| Major depression | 39.6 | 32.5 | 1.24 | 0.50–2.99 |
| Dysthymia | 9.4 | 0.0 | | |
| Mania | 9.4 | 0.0 | | |
| Any anxiety disorder[a] | 66.0 | 47.5 | 1.87 | 0.78–4.45 |
| Alcohol abuse or dependence | 35.8 | 25.0 | 2.70 | 0.94–7.78 |
| Drug abuse or dependence | 18.9 | 25.0 | 0.78 | 0.28–2.17 |

[a] Includes panic disorder, obsessive-compulsive disorder, generalized anxiety disorder, and phobia.

### *Co-Occurrence of Other Psychiatric Disorders and Medical Conditions*

In table 3 appear the lifetime rates of affective and anxiety disorders and alcohol and illicit drug abuse or dependence in persons with chronic and nonchronic PTSD. Because the rates of these disorders vary by sex, and because chronicity of PTSD was observed to be sex-related, sex-adjusted odds ratios were used to estimate the associations of these disorders with chronic, compared to nonchronic, PTSD. With one exception, the rates of the disorders listed in table 3 were higher in persons with chronic than nonchronic PTSD. Illicit drug abuse or dependence was more common in the nonchronic group. The highest odds ratio was associated with any affective or anxiety disorder (odds ratio=2.86, 95% confidence interval=1.10–7.39). Manic episodes and dysthymia were reported only by persons with chronic PTSD, with 9.4% of the subset reporting each.

Persons with chronic and nonchronic PTSD were compared on self-reported lifetime histories of 11 medical conditions. On the average, persons with chronic PTSD had more self-reported medical conditions than persons with nonchronic PTSD, 1.9 (SD=1.6) versus 1.0 (SD=0.8), respectively (t=3.46, df=90, p<0.001). Because one condition—gynecologic complaints—applied only to women, we compared the two groups on number of medical conditions, deleting gynecologic complaints. The means were 1.5 (SD=1.5) versus 0.8 (SD=0.8), respectively (t=2.63, df=90, p=0.01). Each of the following conditions was significantly more common in the chronic than the nonchronic subset: arthritis (26% [N=14] versus 10% [N=4]), bronchitis (21% [N=11] versus 0%) migraine (43% [N=23] versus 2% [N=1]), and gynecologic complaints among women (55% [N=24] versus 31% [N=8]).

### *Risk Factors for Chronic PTSD*

We present, in table 4, the rates of chronic PTSD according to the presence or absence of five of the six

**TABLE 4. Risk Factors for Chronic (1 Year or More) PTSD in Urban Young Adults Exposed to Traumatic Events (N=354)**

| | Prevalence of Chronic PTSD (%) | | | |
|---|---|---|---|---|
| Risk Factor | Persons With Risk Factor | Persons Without Risk Factor | Odds Ratio | 95% Confidence Interval |
| Female sex | 21.8 | 5.9 | 4.43 | 2.09–9.39 |
| Early separation | 35.7 | 13.2 | 3.66 | 1.58–8.44 |
| Family history of anxiety | 26.7 | 8.1 | 4.15 | 2.24–7.70 |
| Family history of antisocial behavior | 34.7 | 10.0 | 4.79 | 2.57–8.92 |
| Preexisting anxiety or affective disorder | 34.6 | 13.4 | 3.42 | 1.43–8.14 |

suspected risk factors identified in our previous report (10). (Persons with nonchronic PTSD were deleted from these calculations.) Women were more than fourfold more likely than men to develop chronic PTSD after exposure to traumatic events. Separation from parents in childhood, family history of anxiety, and family history of antisocial behavior increased the odds for chronic PTSD, each by approximately fourfold. A history of preexisting anxiety or affective disorder at time of exposure to traumatic events was associated with a threefold increase in the likelihood of chronic PTSD. In addition, persons with chronic PTSD had, on the average, markedly higher scores on the Eysenck's Neuroticism Scale (mean=7.0, SD=2.9) than persons with no PTSD (mean=4.2, SD=3.1) (t=6.20, df=352, p<0.0001).

A multivariable logistic regression analysis was used to estimate the odds for chronic PTSD associated with each of the factors when all other factors were controlled. The results, which appear in table 5, show that each of the individual factors, independently of the others, increased significantly the risk for chronic PTSD (goodness-of-fit $\chi^2$ [Hosmer-Lemeshow]=8.41, df=8, p=0.39). The sensitivity of the model for predicting chronic PTSD was 75.5 and its specificity, 71.4%.

To evaluate whether these findings were specific to chronic PTSD, an analogous analysis was performed for nonchronic PTSD. The results (not shown) indicated that four of the factors found to increase the risk for chronic PTSD were implicated also in nonchronic PTSD: early separation from parents, family history of anxiety, preexisting anxiety or depression, and neuroticism. In contrast, family history of antisocial behavior, an important factor in chronic PTSD, was unrelated to nonchronic PTSD. In addition, women were not significantly overrepresented among persons with nonchronic PTSD. A multivariable logistic regression (not shown) revealed that only two factors, early separation from parents and family history of anxiety, were associated with significant increases in the risk for nonchronic PTSD when all other risk factors were controlled. The utility of the model for predicting nonchronic PTSD fell far below that for chronic PTSD, judging from a comparison of its sensitivity and specificity estimates to corresponding estimates for the model of chronic PTSD (goodness-of-fit $\chi^2$=13.22, df=8, p=0.11). The sensitivity of the model for predicting nonchronic PTSD was 55% and the specificity, 68.8%.

**TABLE 5. Multivariable Logistic Regression of Suspected Risk Factors for Chronic PTSD in Urban Young Adults**

| Risk Factor | Adjusted Odds Ratio | 95% Confidence Interval |
|---|---|---|
| Female sex | 2.83 | 1.23–6.49 |
| Early separation | 4.11 | 1.46–11.54 |
| Family history of anxiety | 3.28 | 1.60–6.69 |
| Family history of antisocial behavior | 3.49 | 1.70–7.15 |
| Preexisting anxiety or depression | 3.27 | 1.18–9.12 |
| Neuroticism[a] | 1.86 | 1.30–2.67 |

[a] Odds of chronic PTSD associated with an increase of one standard deviation.

## DISCUSSION

The findings of this study can be summarized as follows. 1) Of all 93 persons with PTSD in this sample of young adults, approximately one-half continued to experience symptoms for 1 year or longer. 2) When the subset with symptoms of 1 year's duration or longer was defined as having chronic PTSD, a similar reduction in the rate of chronic PTSD from the total rate of PTSD of 1 month's duration was observed across most types of events. 3) Compared to those with nonchronic PTSD, persons with chronic PTSD were more likely to experience psychologic and physiologic overreactivity to stimuli symbolic of the traumatic events, as well as interpersonal numbing. 4) Compared to nonchronic PTSD, chronic PTSD was associated with greater prevalence of any anxiety or affective disorder and a variety of medical conditions. 5) Four factors—early separation from parents, family history of anxiety, preexisting anxiety or depression, and neuroticism—were associated with greater odds for PTSD of either duration category. 6) Two factors were associated specifically with chronic PTSD: family history of antisocial behavior and female sex. 7) The set of suspected risk factors had a substantially greater utility in predicting chronic than nonchronic PTSD.

The interpretation of the results concerning suspected risk factors must take into account the cross-sectional design of the study. Prospective studies in which risk factors are measured before the onset of disease are needed to guard against the potentially biasing effects of a history of psychiatric disorder on respondents' reports about risk factors.

The lifetime prevalence of chronic PTSD among those who were exposed to typical PTSD events in this study was 13.4% (N=53 of 394), a figure close to the recent estimate of 15% of Vietnam combat veterans with chronic PTSD (1). Our definition of chronicity specified a duration that was markedly less than the 15–20-year period that had separated the Vietnam war from the time of the veterans' assessment. Although we found no evidence in this study that the nature of stressors was the primary determinant of the persistence of PTSD symptoms, the array of traumatic events experienced by the respondents in this study did not include combat or other war-related events. On two counts, combat experience can be viewed as distinctive (13). First, it consists of multiple events spread over a prolonged period. Second, the moral complexity of combat experience differs from other types of traumatic events, in that those who are exposed are simultaneously the victims, perpetrators, and witnesses of violence. These unique characteristics may be particularly relevant to the persistence of PTSD symptoms among Vietnam combat veterans.

We found that chronic PTSD was characterized by more PTSD symptoms than nonchronic PTSD, a finding consistent with the general tendency for chronicity of disorder to be associated with more pervasive or severe symptoms. The identification of disturbances associated specifically with chronic PTSD—overreactivity to stimuli that represent the trauma and interpersonal detachment—may offer some insight into the persistence of PTSD. The first disturbance represents the generalization of the arousal response beyond the concrete event, a psychologic process that can lead to self-imposed restrictions or avoidance of activities and may hinder recovery. The clinical significance of the second disturbance, that is, interpersonal numbing, stems from its association with social isolation, a factor that has long been viewed as a determinant of psychiatric disorders, especially depression (14–16).

Persons with chronic PTSD were more likely than those with nonchronic PTSD to experience in their lifetime at least one other anxiety or affective disorder. Additional analysis confirmed that the greater odds for any anxiety or affective disorder in persons with chronic versus nonchronic PTSD were independent of the effects of sex and family history of antisocial behavior, factors associated with greater risk for chronic PTSD. The higher lifetime rates of psychiatric disorders other than PTSD in persons with chronic PTSD might signal greater predisposition to psychopathologic reactions to traumatic events, a greater risk for the development of secondary disorders, or the contribution of concurrent disorders to the maintenance of PTSD symptoms.

Of the six suspected risk factors for PTSD identified in our previous report (10), four were found to be associated with nonchronic PTSD: early separation from parents, family history of anxiety, preexisting anxiety or depression, and neuroticism. Nonchronic PTSD was unrelated to family history of antisocial behavior and female sex. In contrast, chronic PTSD was associated with the entire set of factors. Thus, our findings suggest that certain personal dispositions increase the likelihood of PTSD following traumatic events, while a subset of these factors increases the risk for chronicity of PTSD symptoms. It should be noted that the two factors associated specifically with chronic PTSD, family history of antisocial behavior and female sex, have been previously linked, in an essential way, to somatization disorder and related diagnoses (17–19), a class of disorders in which chronicity is a hallmark.

# Symptom Responses of Female Vietnam Veterans to Operation Desert Storm

Jessica Wolfe, Ph.D., Pamela J. Brown, M.A., and Maria L. Bucsela, B.A.

---

*Objective: This study examined the status of symptoms of posttraumatic stress disorder (PTSD) in a cohort of women after the onset of Operation Desert Storm. Method: Seventy-six non-treatment-seeking Vietnam veterans were obtained from lists of those who recently had participated in other research projects conducted at the National Center for Post-Traumatic Stress Disorder. Before the onset of Operation Desert Storm, subjects had completed a set of psychometrically valid instruments measuring general psychological symptoms and PTSD symptoms (e.g., SCL-90-R, Mississippi Scale for Combat-Related Posttraumatic Stress Disorder). On the basis of the latter scale, subjects were divided into groups with and without PTSD symptoms. At the height of the military conflict, subjects were recontacted and asked to complete the SCL-90-R and the Veterans Update Form, a measure assessing changes in PTSD symptoms. Results: Multivariate analyses indicated that while most female Vietnam veterans experienced some intensification of stress-related symptoms during Operation Desert Storm, those who had previously reported high levels of PTSD were significantly more susceptible to greater distress. Conclusions: Results of this survey indicate that female Vietnam veterans with prior wartime exposure are an at-risk population for the intensification of stress symptoms after the recurrence of a military conflict.*

(Am J Psychiatry 1992; 149:676–679)

---

Events that resemble prior traumatizing experiences can reactivate symptoms of posttraumatic stress disorder (PTSD) (1–3). For example, some combat veterans have shown a reemergence or exacerbation of previous stress reactions when they are reexposed to combat in the course of additional military service (4). Similarly, Israeli children who have lost parents in terrorist attacks have evidenced the reemergence or exacerbation of PTSD symptoms when reexposed to war or further terrorist activities (5). In all of these instances, direct reexposure to events similar to the original precipitant resulted in significantly increased symptoms.

Other data suggest that indirect exposure or exposure to more abstract cues, for example, those symbolizing aspects of the original event, can provoke reactions in some individuals. For example, case studies of three male Vietnam veterans following their attendance at a dedication ceremony for the Vietnam Memorial showed that all three experienced increased PTSD symptoms (6). In a subsequent study of 94 male Vietnam veterans, Parsons et al. found that both those who attended and those who did not attend the Vietnam Memorial's dedication showed intensification of stress symptoms, especially anxiety, guilt, and sleep disturbance (7). The authors hypothesized that a range of factors including media accounts and community reactions to the dedication contributed to the veterans' increased sensitivity. Thus, a variety of cues related to the original event can be influential in exacerbating or retriggering symptoms.

The recent activities of Operation Desert Storm have received extensive, detailed media coverage and have generated considerable public concern. Recent anecdotal reports by clinicians have suggested that the onset of this war may have reactivated or intensified stress symptoms in some percentage of American war veterans (8). To date, there are no empirical data to substantiate this impression. The present study surveyed female Vietnam veterans by mail to examine whether PTSD symptoms recurred or intensified in a 2-week period after the start of Operation Desert Storm on Jan. 16, 1991. Participants were also surveyed on a range of

other psychological symptoms and on their use of mental health treatment services to gain additional information about the war's impact.

## METHOD

### *Subjects*

Subjects in this study included 76 female Vietnam veterans. (A cohort of 49 female World War II veterans served as a comparison group. Data on this cohort are available from Dr. Wolfe.) Their average age was 49.6 years (range=37–72). Average war-zone exposure for this group would be described as moderate on the basis of previously obtained information (J. Wolfe, J. Furey, P.J. Brown, et al., Women's War-time Exposure Scale, 1990, unpublished manuscript). "Moderate" in this context reflects intermittent exposure to dangerous or life-threatening events (e.g., incoming rocket or mortar attacks), close contact with the dead and dying, and other similar severe stressors.

All women volunteered to participate in this project without reimbursement. Participants did receive a follow-up letter thanking them for their assistance and a summary of the survey's results.

### *Procedure*

The participants were drawn from lists previously compiled by one of us (J.W.) for use in projects at the National Center for Post-Traumatic Stress Disorder, Women Veterans Program. Because female veterans are often difficult to locate, many names were assembled through the assistance of other veterans. Pre-Operation Desert Storm psychometric data—scores on the SCL-90-R (9) and a revised version of the Mississippi Scale for Combat-Related Posttraumatic Stress Disorder (10)—were available for those women who had previously participated in another research project at the national center. No participants were seeking services for PTSD from the Women Veterans Program at the time of the survey.

Participants were contacted by mail in late February–early March 1991 and were asked to complete the Veterans Update Form (J. Wolfe, 1991, unpublished manuscript) and the SCL-90-R (9). The SCL-90-R, rather than a PTSD instrument, was selected to provide more general indices of psychological distress. Subjects who did not reply were not contacted again by mail because of the limited period for inquiry.

The project had an overall return rate of 29%. The rate of return was partially affected by mailing constraints; approximately 7% of the surveys lacked correct current addresses. Telephone contact with 10% of the nonrespondents who were comparable in age, education, and war-zone exposure to respondents indicated no difference on any items of the survey questionnaire between these two groups. Furthermore, analyses of pre-Operation Desert Storm data on the SCL-90-R revealed no significant differences between nonrespondents and subjects who participated in the study.

### *Psychometric Assessment*

*Veterans Update Form.* A brief self-report measure was developed for the study to delineate change in the three *DSM-III-R* cardinal PTSD symptoms of reexperiencing, avoidance/numbing, and hyperarousal after the onset of Persian Gulf warfare involving American troops. Questions were based on a 5-point Likert-type scale; scores ranged from 0 (no change) to 4 (extremely increased) for each major symptom category. Respondents also answered several questions about their past and current use of psychological treatment as well as changes in mental health needs, with Jan. 16, 1991, used as the point of reference.

*SCL-90-R.* This widely used, 90-item, self-report measure instructs subjects to rate a series of broad-based psychological symptoms. Traditional symptom ratings of 0 (no distress) to 4 (very distressed) were employed. Scoring yields nine scaled symptom dimensions: somatization, obsessive-compulsive, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation, and psychoticism. Empirical research on this instrument has documented satisfactory reliability and validity for each of the symptom scales (9).

*Revised Mississippi Scale for Combat-Related Posttraumatic Stress Disorder.* Participants had previously completed the revised Mississippi scale, a variation of the 35-item, self-report scale designed to measure the cardinal symptoms of PTSD. Prior research has demonstrated that the scale possesses acceptable reliability and validity as well as other psychometric properties (sensitivity=0.93, specificity=0.89, overall efficiency=0.90) (10). The revised version incorporated minor semantic changes in three questions that previous pilot data indicated were inappropriately phrased for use with female veterans.

### *Statistical Analyses*

On the basis of previously available data, the Vietnam cohort was divided into groups with and without PTSD. A series of analyses of variance (ANOVAs) was used to compare group symptom reports by using current *DSM-III-R* criteria for PTSD. Chi-square analyses were carried out to assess any treatment utilization differences. Multivariate analyses of variance (MANOVAs) and analyses of covariance (ANCOVAs) were then conducted to examine changes in SCL-90-R profiles for the two Vietnam veteran groups.

## RESULTS

Previously collected data on PTSD symptoms (scores on the Mississippi scale for PTSD) before Operation Desert Storm were used to divide the Vietnam cohort

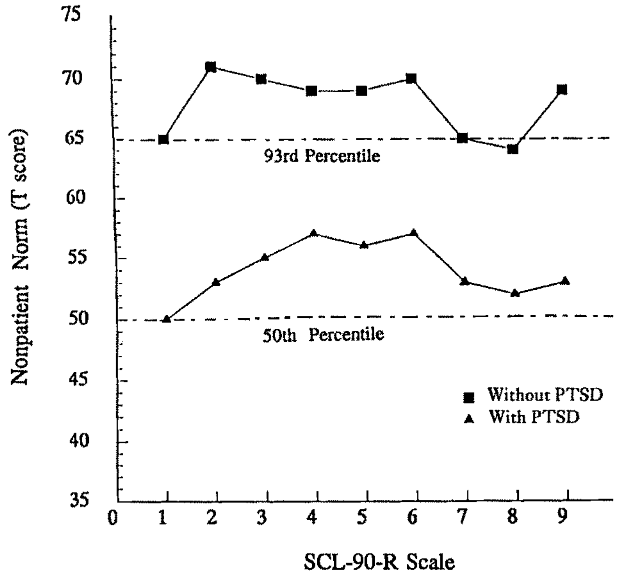
**TABLE 1. PTSD Symptom Change After the Beginning of Operation Desert Storm for Female Vietnam Veterans Without and With PTSD[a]**

| | Without PTSD[b] (N=50) | | With PTSD (N=26) | | ANOVA | | |
|---|---|---|---|---|---|---|---|
| Symptom | Mean | SD | Mean | SD | F | df | p |
| Reexperiencing | 1.2 | 1.3 | 2.4 | 1.3 | 14.35 | 1, 74 | <0.001 |
| Avoidance/numbing | 0.7 | 1.2 | 2.3 | 1.2 | 29.58 | 1, 74 | <0.0001 |
| Hyperarousal | 1.2 | 1.4 | 2.7 | 1.0 | 23.49 | 1, 74 | <0.0001 |

[a] 0=no change, 1=slightly increased, 2=somewhat increased, 3=very increased, 4=extremely increased.

[b] The t tests comparing symptom changes in this group from before to after Operation Desert Storm indicated greatest increases for symptoms of reexperiencing (t=3.34, df=49, p<0.005) and hyperarousal (t=3.27, df=49, p<0.005).

**FIGURE 1. Mean SCL-90-R Scores During Operation Desert Storm for Female Vietnam Veterans Grouped by Scores on the Mississippi Scale for Combat-Related Posttraumatic Stress Disorder**



into groups without PTSD (N=50) and with PTSD (N=26) groups. These groupings are comparable to divisions used with male Vietnam combatants to determine the PTSD diagnosis (10). Mean *DSM-III-R* PTSD symptom scores were then calculated for both Vietnam groups (table 1). One-way ANOVAs indicated that the group with PTSD had significantly greater increases than the group without PTSD across all three current PTSD ratings: reexperiencing, avoidance/numbing, and hyperarousal. In the group without PTSD, increases were greatest for symptoms of reexperiencing and hyperarousal. There were no such differences for the group with PTSD.

A MANOVA was conducted on the SCL-90-R protocols completed by women in the two groups after the start of Operation Desert Storm; univariate tests showed significant differences between the two groups on all nine dimensions (p<0.005). A series of ANCOVAs was subsequently carried out on the post-Operation Desert Storm SCL-90-R protocols, with pre-Operation Desert Storm SCL-90-R data as covariates. The group with PTSD had significantly higher levels than the group without PTSD on the following three dimensions: somatization (F=11.11, df=1, 71, p<0.005), obsessive-compulsive (F=17.59, df=1, 71, p<0.001), and hostility (F=7.55, df=1, 71, p<0.01). As can be seen in figure 1, the group with PTSD had postwar SCL-90-R T scores that averaged around the 93rd percentile.

With respect to mental health treatment status before and after the start of the war, more veterans with PTSD than veterans without PTSD reported receiving treatment at some point before Operation Desert Storm ($\chi^2$=12.80, df=1, p<0.0005.). Of those veterans not currently in treatment, more with PTSD than without it thought that they should be receiving treatment for PTSD ($\chi^2$=6.61, df=2, p<0.05).

## DISCUSSION

These results offer some of the first empirical data on veterans' responses to the recent crisis in the Middle East. Female Vietnam veterans clearly have been affected to some degree by the recent initiation of a large-scale U.S. military conflict. Because the survey was conducted close to the conclusion of the war, when a cease-fire was imminent, it is likely that these findings represent a conservative estimate of the war's impact on veterans.

Analyses of responses indicated that female Vietnam veterans with high levels of preexisting PTSD symptoms showed greater increases across symptom dimensions, which suggests that they were most vulnerable to symptom exacerbation after reexposure. This finding is consistent with reports that individuals who are unable to resolve or integrate earlier traumatic experience are at significant risk for the retriggering of stress-related symptoms when they are faced with events similar to the original stressor (11). Nonetheless, the demonstrated symptom increase across the Vietnam cohort in general suggests that a variety of veterans were at risk for reemergence of symptoms after the start of Operation Desert Storm. This broader pattern of reactivity is consonant with clinical reports from various sites within the Veterans Affairs system which indicate that two types of male veterans have recently sought increased treatment: those previously known to have problems with PTSD and those who were apparently asymptomatic before the start of the Gulf conflict (8).

The issue of more indirect forms of stressor exposure, as raised in this study, is important. As with other types of traumatic events (e.g., rape), a wide range of environmental cues appear capable of stimulating symptomatic response in previously exposed individuals. The majority of the Vietnam cohort in this study were theater veterans, many of whom felt that they knew firsthand what military personnel were undergoing in the war zone.

In the case of Operation Desert Storm, an unusually large array of cognitive and perceptual cues is likely to have added to the reactions felt among both those who had and those who had not been exposed to a war zone. Media coverage was extensive, and public and community response, while generally positive, served to heighten awareness of the war's presence and its potentially dangerous consequences. Anticipation of loss or trauma may also have played a role in veterans' reactions to the events of war. In a recent study conducted before the onset of Operation Desert Storm, anticipatory anxiety was found to contribute to a range of symptomatic responses in military wives and children of troops deployed to the Persian Gulf (12). Thus, a variety of factors influence coping and adjustment under stress.

One particular strength of this study is that it contained symptom measures obtained before the start of Operation Desert Storm, which permitted controlled comparison of changes in response to the war. Results suggested increases in levels of general psychiatric distress (e.g., somatization, hostility) that may extend beyond the specific diagnostic criteria for PTSD. Inspection of items on the obsessive-compulsive scale (elevated in the group with PTSD) indicated that many of the endorsed items reflect symptoms consonant with intensification of stress syndromes, for example, increased ruminative or intrusive thoughts. Further examination of the SCL-90-R scales in conjunction with broader diagnostic assessments will help to delineate the nature of symptom intensification after reexposure and its specificity for the PTSD diagnosis.

At the present time, there are no data on whether veterans who experienced increased symptoms secondary to the onset of Operation Desert Storm are at greater risk for subsequent psychological or health-related problems; consequently, planning of treatment resources remains uninformed. Data from this study suggest that it is important for mental health professionals to attend to factors associated with the reemergence of stress reactions and to consider the need for early clinical intervention. The importance of such intervention is supported by Laufer and others who have observed the adverse effects of recurrent war stress on subsequent functioning throughout the life span (13).

Overall, the data in this study suggest that further investigation of the response of previously exposed veterans to subsequent trauma is also worthwhile for scientific purposes. Tracking of these responses is required to determine whether these reactions are sustained and, if so, what their effect is on social and vocational functioning. In addition, future research comparing female veterans' responses to those of male veterans will shed light on whether gender is a factor in the genesis and mediation of the response to recurrent life trauma (14).

# Suicidal Ideation and Suicide Attempts Among Patients With Panic Disorder: A Survey of Two Outpatient Clinics

Steven Friedman, Ph.D., Jennifer C. Jones, Ph.D.,
Leslie Chernen, Ph.D., and David H. Barlow, Ph.D.

*Objective: Recent epidemiologic studies found that 20% of subjects with the diagnosis of panic disorder had attempted suicide. This study sought to determine the prevalence of suicidal ideation and suicide attempts among patients with panic disorder and whether the presence of comorbid borderline personality disorder influenced the prevalence of suicidal thoughts and behavior. Method: At two outpatient clinics, experienced clinicians conducted retrospective reviews of data from the intake interviews and charts of 59 patients with panic disorder and comorbid borderline personality disorder and 234 patients with panic disorder with or without axis II disorders other than borderline personality disorder. Results: Suicide attempts were reported by 2% of the patients with panic disorder, compared to 25% of the patients with both panic disorder and borderline personality disorder. In addition, 2% of the patients with panic disorder, compared to 27% of the patients with panic disorder and borderline personality disorder, reported suicidal ideation that was judged to be of clinical significance. Conclusions: The rate of suicidal ideation and suicide attempts for psychiatric outpatients with panic disorder was discrepant with the findings of the earlier studies. The increased suicide risk in this group of patients was associated with borderline personality disorder, increased substance abuse, and affective instability. While 61% of the panic disorder patients and 78% of the patients with both panic disorder and borderline personality disorder reported thinking about death, this must be distinguished from actual suicidal ideation and clinical risk of suicide.*

(Am J Psychiatry 1992; 149:680–685)

A reanalysis of data from the Epidemiologic Catchment Area (ECA) study on the prevalence of suicidal ideation and suicide attempts among persons with psychiatric disorders was recently conducted by Weissman et al. (1). They found that 20% of patients with panic disorder had made a suicide attempt. These findings are surprising, since individuals with major affective disorders, schizophrenia, and some personality disorders have been considered to be at greater risk for suicidal behavior than those with panic disorder. The findings could also be quite disconcerting to clinicians who treat patients with panic disorder. Weissman and colleagues (1, 2) concluded 1) that suicide attempts were associated with panic disorder in both its complicated and uncomplicated forms and 2) that the risks were comparable to that associated with major depression. Since these findings have far-reaching implications, further study of the prevalence of suicidal ideation and suicide attempts among patients with panic disorder is warranted.

Careful examination of the two reports by Weissman and associates (1, 2) revealed two issues that might benefit from further exploration. First, for questions addressing suicidal ideation, the clinical severity and precise nature of the ideation were not reported. Second, data on the timing of the suicide attempts were not available, and thus the attempts may not have been concurrent with or related to the disorder. The ECA study dealt with disorders that had occurred only in the past 6 months, but it recorded suicide attempts covering a lifetime. Thus, it is not clear whether the suicide attempts and suicidal ideation were related to panic disorder pathology.

The authors (1, 2) did find that female sex and coexisting alcohol and drug abuse increased the risk for suicide attempts in the group with panic disorder and the group with major depression. Patients with panic disorder and other comorbid psychiatric disorders were also more likely to be younger and to have never been mar-

ried. A patient population with these characteristics (i.e., one that is primarily female, with a diversity of psychopathology including impulse disorders such as substance abuse) suggests that a coexisting *DSM-III-R* axis II disorder—borderline personality disorder—may be involved. A large-scale study (3) reported that 85% of patients with borderline personality disorder were female, and all suffered from a host of psychiatric conditions, including major depression (68%), mania (6%), bipolar disorder (11%), panic disorder (12%), alcoholism (31%), and drug use (23%).

The experience of clinicians and researchers at the anxiety and phobia clinics at the State University of New York, Health Science Center at Brooklyn, and the State University of New York at Albany suggested that patients with panic disorder with or without agoraphobia who present for treatment do not report high rates of suicidal ideation or suicide attempts. However, no formal examination of the data had been conducted. Thus, the purpose of our investigation was to examine the prevalence of fear of death, clinically significant suicidal ideation, and suicide attempts in a group of patients with *DSM-III-R* axis I panic disorder. In addition, we sought to determine whether the presence of borderline personality disorder increased the prevalence of suicidal behavior in a group of patients with panic disorder. We hypothesized that patients with panic disorder and other comorbid pathology—such as borderline personality disorder, which often includes a high rate of alcohol and drug abuse—would show a greater risk for both suicidal ideation and suicide attempts.

## METHOD

Two groups of subjects, both diagnosed as having panic disorder, were used for this study. The first group comprised 234 patients with a principal axis I diagnosis of panic disorder, with or without an axis II personality disorder other than borderline (antisocial, histrionic, avoidant, dependent, passive-aggressive, and not otherwise specified). One hundred forty-seven patients at Albany and 87 at Brooklyn met these criteria. Since Albany is the site for a number of clinical research projects on panic disorder, patients in need of crisis-oriented services were eliminated through telephone screening. At Brooklyn there is an ongoing project involving patients who have been carefully diagnosed as suffering from both panic disorder and borderline personality disorder. Therefore, the large majority of the second group of subjects for our analysis, composed of 59 patients who met the diagnostic criteria for both panic disorder and borderline personality disorder, was obtained at the Brooklyn site (N=57 at Brooklyn and N=2 at Albany).

Data were collected by a retrospective chart review of outpatients being treated by doctoral-level staff members at each clinic. All charts of patients with panic disorder and patients with panic disorder and borderline personality disorder from 1982 to the present at Brooklyn and from 1986 to the present at Albany were reviewed. Patients had originally been interviewed by experienced, doctoral-level clinicians at both sites and by advanced graduate students at Albany with the Anxiety Disorders Interview Schedule—Revised (4), a structured interview designed to assess differentially the anxiety disorders as well as the major affective disorders and substance/alcohol abuse; a brief screen is also included to rule out psychotic disorders. All interviewers had been trained to a reliability criterion by senior clinicians before doing solo interviews. At the Albany site, approximately 50% of the patients had been interviewed by an independent clinician; only those cases in which the interviewers had agreed on a principal diagnosis of panic disorder were used. The initial interviewer at Brooklyn had specifically assessed for borderline personality disorder according to the *DSM-III-R* criteria. The patient's chart had then been reviewed and a diagnosis given independently by another senior clinician at the time of the evaluation. Only cases in which both assessors had concurred were used in this study.

A 16-item standard protocol was developed for use at both clinics. The protocol assessed such variables as age, sex, marital status, length of illness, and socioeconomic status (not all data were available for all patients). Alcohol and drug histories, medical emergency room presentations, self-destructive behavior (other than suicide attempts), affective instability, perceptions of life as chaotic and/or empty, and suicide attempts were rated as either present or absent. The severity of death fears, degree of suicidal ideation, and severity of any suicide attempts were rated on 5-point Likert-type scales. Finally, self-reported frequency of panic attacks per month was included. No distinction was made between full- and limited-symptom panic attacks. Ten percent of the charts in each clinic were reviewed by a second rater for reliability estimations on certain items (thoughts of death, severity of suicidal ideation, history of suicide attempt, and severity of suicide attempt) according to the following formula: the number in agreement divided by the sum of the number in agreement and the number in disagreement. Reliability estimates for the four items were 0.80, 0.88, 0.96, and 0.96, respectively. Therefore, data obtained by the principal chart reviewers were used for all subjects.

To examine the possibility of intersite differences, chi-square analyses and t tests were conducted on all variables. No site differences emerged on any of these variables, with the exception of the axis II disorder. Therefore, all data were collapsed across sites. As we have noted, the borderline personality disorder group was almost entirely drawn from the Brooklyn site, since the Albany site routinely referred elsewhere patients who were in need of crisis-oriented services.

## RESULTS

The mean age of the patients with panic disorder was 35.3 years (SD=11.9); the mean age of the patients with

[a] With or without *DSM-III-R* axis II disorders other than borderline personality disorder.
[b] Data were not available on all variables for all subjects.
[c] Significant difference between groups ($\chi^2$=11.31, df=1, p<0.0008).
[d] Significant difference between groups ($\chi^2$=25.10, df=4, p<0.00005).

panic disorder and borderline personality disorder was 36.2 years (SD=12.0). As depicted in table 1, the two groups of subjects differed on several variables. A higher proportion of the patients with both panic disorder and borderline personality disorder were female and had never married or were separated/divorced. In addition, this group had a longer duration of illness (mean=13.7 years, SD=10.6, versus 9.9 years, SD=9.2; t=2.70, df=277, p<0.01). They were more likely to have histories of alcohol or drug abuse and more likely to present at medical emergency rooms (table 2). No differences emerged with regard to the frequency of panic attacks. The patients with panic disorder had a mean of 7.1 panic attacks (SD=7.4) in the month preceding their evaluation, and the patients with both borderline personality disorder and panic disorder had a mean of 6.2 attacks (SD=7.1) (t=0.84, df=282, n.s.).

To examine the principal hypotheses, chi-square analyses were conducted on the four items pertaining to thoughts of death (not suicidal ideation, but rather thoughts of death during a panic attack, such as fear of dying), suicidal ideation, suicide attempt, and seriousness of attempt. These data are displayed in table 3. As expected, the subjects with comorbid panic disorder and borderline personality disorder had more frequent thoughts of death. In addition, they were more likely to have clinically significant suicidal ideation and to have attempted suicide.

Other variables that are among the specific criteria necessary for a diagnosis of borderline personality disorder were subjected to chi-square analyses. These included a history of self-destructive behavior, a perception of life as chaotic and/or empty, and affective instability. Again, the results were consistent with prior hypotheses (table 2). That is, the group with panic disorder and borderline personality disorder were more likely to have histories of self-destructive behavior (other than suicide attempts), to view life as chaotic/empty, and to be affectively unstable.

Finally, we attempted to identify potential risk factors for suicidality in these two diagnostic groups. First, all variables were entered into a stepwise multiple regression analysis with pairwise deletion of missing data and suicide attempt (presence or absence) as the dependent variable. Suicidal ideation, a history of self-destructive behavior, and the frequency of panic attacks accounted for 26%, 4%, and 1.5% of the variance, respectively (F=38.13, df=3, 239, p<0.0001).

Suicidal ideation and a history of suicide attempts are almost always closely related. Since the results of this study were no different, we attempted to identify potential risk factors for suicidal ideation without entering suicide attempts into the regression analysis. The best predictors of suicidal ideation were a perception of life as chaotic/empty, affective instability, frequency of panic attacks, female sex, and self-destructive behavior (other than suicide attempts); these variables accounted for 19%, 6%, 3%, 2%, and 2% of the variance, respectively (F=21.60, df=5, 237, p<0.0001). In the stepwise regression, although diagnosis was initially the single best predictor, as other variables were added to the equation, diagnosis was removed; i.e., the other variables accounted for both diagnosis and suicidal ideation.

Although our principal hypotheses specified comparisons between the two diagnostic groups, we were also interested in potential differences between patients who had attempted suicide and those who had not. Therefore, we specifically examined these two groups without regard to diagnostic category. The mean age of the suicide attempters (N=20) was 34.5 years (SD=10.7); that of the nonattempters (N=272) was 35.6 years (SD=12.0) (t=0.46, df=22, n.s.). The mean length of illness of the suicide attempters was 12.6 years (SD=11.3); that of the nonattempters was 10.5 years (SD=9.5) (t=0.77, df=20, n.s.). As shown in table 4, patients who had made suicide attempts were more likely than nonattempters to have histories of alcohol/drug abuse, exhibit self-destructive behavior (other than suicide attempts), view life as chaotic/empty, and be affectively unstable.

## DISCUSSION

The purpose of our investigation was to assess the prevalence of suicidal ideation and suicide attempts among patients diagnosed as having panic disorder who presented for outpatient treatment. Only 2% (N=5) of our patients with panic disorder, being treated at two different sites serving a wide range of patients from different demographic and socioeconomic backgrounds, had attempted suicide, compared to 25% of the patients with panic disorder and comorbid borderline personality disorder. In addition, only 6% of the group with panic disorder reported suicidal ideation, and when concomitant clinical risk was assessed by

trained mental health interviewers, the rate was 2%. Forty-one percent of the group with panic disorder and borderline personality disorder reported frequent suicidal ideation, with 27% considered to be at clinical risk. The low rate of suicide attempts among patients with panic disorder is consistent with that reported by Beck et al. (5). In their retrospective study of 900 outpatients in various diagnostic categories, only one patient among 151 with panic disorder reported a previous suicide attempt. In contrast, they found that 7% of the patients diagnosed as having a mood disorder reported a suicide attempt.

The results of this study and that of Beck et al. (5) differ substantially from those of Weissman and associates (1, 2). In their sample, 47% of the patients with panic disorder contemplated suicide, while 44% "felt

[a] Data were not available on all variables for all subjects.

like [they] wanted to die." However, as previously discussed, ratings were made by trained lay interviewers, without any apparent attempt to assess clinical risk. Moreover, 64% of the subjects in their sample purportedly "thought a lot about death." This can be compared to 61% of the group with panic disorder and 78% of the group with both panic disorder and borderline personality disorder in our study who had thoughts of death. The frequencies reported in our study were obtained by examining the presence and severity of fear of dying and thoughts of death during panic attacks; suicidal ideation was not included in this rating.

It must be noted that the frequency of a history of suicide attempts of patients with panic disorder in this study (2%) is still higher than the 1% found in an epidemiologic study of persons without any psychiatric disorder (1, 2). In addition, the rate of suicidal ideation that was judged to be of clinical severity in our patients with panic disorder (2%) needs to be compared to the results of the reanalysis of the ECA study (1, 2), in which it was found that 15% of persons without any psychiatric disorder "thought a lot about death" and 4% of these persons responded positively to the statement "Felt so low, thought about committing suicide."

It should also be noted that individuals with panic disorder who fear losing control occasionally have thoughts that they could die as a consequence (e.g., losing control during a panic attack and driving off a bridge). However, current clinical experience suggests that this is what patients fear and that it must be distinguished from suicidal wishes and/or intent. Thoughts of death in a sample of individuals with panic disorder is not surprising; indeed, it is expected.

There may be several additional explanations for our findings and their discrepancy with those previously reported (1, 2). First, the method of assessment and the type of interviewer differed. Chart reviews on clinical patients, as done in this study, are different from a prospective epidemiologic survey and clearly may tap different patient populations.

Sample characteristics represent a second difference in these two studies. The characteristics of individuals at risk for suicide in the ECA study (1, 2) were very similar to those of our group with panic disorder and borderline personality disorder. That is, subjects at risk in both studies were young women with histories of alcohol/drug abuse. In addition, our subjects with histories of suicide attempts also described their lives as chaotic and/or empty, exhibited other self-destructive behavior, and had a great deal of affective instability. At the Albany site, if patients over the telephone described imminent suicidal ideation and/or behavior they were referred elsewhere, thereby accounting for the small number of patients with panic disorder and borderline personality disorder at Albany.

The degree of psychopathology and the psychiatric histories of the subjects in these studies are other potentially important variables. Our subjects consisted entirely of help-seeking outpatients. Less than 5% of our subjects in both the group with panic disorder and the group with panic disorder and borderline personality disorder had histories of psychiatric hospitalization. In the ECA study, although lifetime psychiatric history was assessed, it was not reported fully. In fact, the report (1) clearly stated that both the panic disorder and panic attack groups "may have had other psychiatric disorders in the past." Unfortunately, data on the proportion of individuals with other disorders in the past and the nature of such disorders were not available. Consequently, one cannot discern whether individuals who reported suicidal ideation and/or suicide attempts had suffered previously from other serious psychopathology that might have contributed to suicidality. While not denying the clinical impairment and severity of distress that patients with panic disorder may experience, one cannot rule out the hypothesis that a history of other psychiatric disorders increased the distress level beyond tolerance, so that suicide became a viable option. In fact, in the present study, the regression analysis found that perception of life as chaotic, affective instability, frequency of panic attacks, female sex, and a history of self-destructive behavior were the best predictors of suicidal ideation. Similar findings have been noted by others (5–7). Clearly, cross-validation of our findings with another sample is warranted.

Finally, the sample of Weissman et al. (1) consisted of a random assortment of community members. Thus, subjects surveyed may have included individuals who not only were untreated for panic disorder but also were unaware of the possibility of treatment for this disorder. As a consequence, they may have been particularly demoralized and helpless, resulting in a high frequency of suicidal ideation and/or suicide attempts. As Johnson et al. (2) cogently argued, the low rate of suicidality observed in clinical samples may be due to the low base rate of suicidal behavior. Lifetime analyses may be better equipped to identify such patterns.

The experience of panic disorder is distressing and is responsible for considerable help-seeking behavior and decreased quality of life. Individuals with panic disorder experience a significantly impaired quality of life, as measured by alcohol/drug abuse, time with friends and relatives, time spent on hobbies and social activities, marital functioning, and financial dependency (6). Panic disorder is often responsible for inappropriate and expensive utilization of medical resources (7). However, the results of our investigation, though certainly not conclusive, are not consistent with previous assertions that individuals with panic disorder are at a directly greater risk for suicidal ideation, suicide attempts, or possibly suicide simply by virtue of that diagnosis. Rather, the results of this and other investigations suggest that the suicidal behavior evidenced by individuals suffering from panic disorder or panic attacks may be due to the existence of other axis I disorders and/or borderline personality disorder. In addition, panic attacks and/or panic disorder may lead to an increase in alcohol and substance abuse, emergency room visits, and a decrease in overall quality of life, which may ultimately lead to such demoralization and hopelessness that the patients are then at greater risk for suicide (8–10). Further studies are needed to determine the precise conditions under which an individual with panic disorder is at greater risk for suicide.

# Low Cerebellar Metabolism in Medicated Patients With Chronic Schizophrenia

Nora D. Volkow, M.D., Alex Levy, Ph.D., Jonathan D. Brodie, Ph.D., M.D.,
Alfred P. Wolf, Ph.D., Robert Cancro, M.D., Peter Van Gelder, Ph.D.,
and Fritz Henn, Ph.D., M.D.

*Because of the frequent association of cerebellar structural defects with schizophrenia, the authors reanalyzed the metabolic brain images of patients with chronic schizophrenia to assess if they had abnormalities in cerebellar metabolism. They used carbon-11-2-deoxyglucose and positron emission tomography to study 18 medicated patients with chronic schizophrenia and 12 normal comparison subjects. Patients with schizophrenia showed significantly lower absolute and relative metabolism in the cerebellum than normal subjects.*

(Am J Psychiatry 1992; 149:686–688)

The role of the cerebellum in the pathogenesis of schizophrenia is controversial. Cerebellar atrophy in patients with schizophrenia has been documented by computerized tomography (CT) and magnetic resonance imaging (MRI) (1–5), and post-mortem studies have revealed pathological changes in the cerebellum of patients with chronic schizophrenia (6–8). However, other investigators have failed to document cerebellar atrophy in patients with chronic schizophrenia (9–12). Measurement of regional brain glucose metabolism with positron emission tomography (PET) has been shown to be a sensitive technique to demonstrate regional brain changes associated with mental illnesses (13) and may be able to detect abnormalities that cannot be documented with either CT or MRI (14). The purpose of this study was to find out if there were cerebellar metabolic abnormalities in a group of patients with chronic schizophrenia in whom we had previously documented defects in the frontal cortex and basal ganglia (15) but whose cerebellar regions we had not analyzed.

## METHOD

Twelve normal volunteers (23–47 years of age) and 18 medicated patients who fulfilled both *DSM-III* criteria and Research Diagnostic Criteria for chronic schizophrenia (22–41 years of age) were studied. The patients were recruited from an urban psychiatric hospital; 12 were in the last phases of their hospitalization, and six were discharged within 1 week of completion of the study. The clinical and demographic characteristics of the normal subjects and the patients with schizophrenia have been described elsewhere (16). The mean age of the patients was 29 years (SD=7), and they had been using neuroleptics for a mean of 7 years (SD=5). The patients' mean scores on the Brief Psychiatric Rating Scale (BPRS) are given in table 1.

Brain glucose metabolism was assessed during baseline conditions by using PET and [1-$^{11}$C]2-deoxy-D-glucose (carbon-11-2-deoxyglucose) as described elsewhere (16). Regions for the left and right cerebellum were delineated on two contiguous planes of the individual's CT scan images. These regions were then projected onto the corresponding planes of the PET scan images. A weighted average was then obtained to com-

**TABLE 2. Absolute and Relative Metabolic Values for Left and Right Cerebellum in 12 Normal Subjects and 18 Medicated Patients With Chronic Schizophrenia[a]**

| | Cerebellar Metabolic Value | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | Absolute (μmol/100 g/min) | | | | Relative | | | |
| | Left | | Right | | Left | | Right | |
| Subjects | Mean | SD | Mean | SD | Mean | SD | Mean | SD |
| Normal subjects (N=12) | 37.9 | 5 | 37.5 | 4 | 1.00[a] | 0.07 | 1.05 | 0.06 |
| Patients with schizophrenia (N=18) | 32.8 | 4 | 32.6 | 4 | 0.99 | 0.07 | 0.99 | 0.07 |

[a]Weighted averages were obtained to compute absolute metabolic values; cerebellar values were divided by whole brain metabolism to compute relative values. Two-group repeated-measures analysis of variance showed no Group by Left-Right interaction and no left-right differences but did show significantly lower overall absolute values (F=9.7, df=1, 28, $p\leq0.005$) and relative values (F=5.3, df=1, 28, $p\leq0.05$) in patients with schizophrenia.

pute the "absolute" metabolic values of the left and right cerebellum. To normalize for differences in whole brain metabolism between subjects, we also obtained "relative" measures by dividing cerebellar values by whole brain metabolism (16). Whole brain metabolism was the average metabolic activity in the 10 central slices. Differences on the absolute and relative cerebellar metabolic values between normal subjects and patients with schizophrenia were tested with a two-group repeated-measures analysis of variance (ANOVA).

Since frontal and cerebellar metabolism have been shown to be correlated (17–19) and we had previously shown that the patients investigated in this study had low relative and absolute frontal metabolism (15), we assessed the correlation between the metabolic values for the cerebellum and the frontal cortex using Pearson correlation coefficients. We also investigated the relation between cerebellar and basal ganglia metabolism because these two structures are neuroanatomically connected (20), and we had also documented significantly higher relative metabolism of the basal ganglia in these patients (15). Relative measures were chosen for the correlation analyses because these measures are better suited to investigate regional patterns of interaction than the absolute metabolic values (16).

## RESULTS

Table 2 shows the absolute and relative metabolic values for left and right cerebellum of the normal subjects and the patients with schizophrenia. The two-group repeated-measures ANOVA showed no Group by Left-Right interaction and no left-right differences but did show an overall difference between normal subjects and patients with schizophrenia for absolute and relative cerebellar metabolism.

There were no significant correlations between the relative metabolic values of the cerebellum and those of the frontal cortex (left cerebellum r=0.19, df=29, n.s.; right cerebellum r=0.05, df=29, n.s.) or between the relative metabolic values of the cerebellum and those of the basal ganglia (left cerebellum r=0.26, df=29, n.s.; right cerebellum r=0.27, df=29, n.s.).

## DISCUSSION

This preliminary study provides evidence of lower cerebellar metabolism in medicated patients with chronic schizophrenia than in normal comparison subjects. The implication of this finding with respect to the pathophysiology of schizophrenia is unclear because these patients were taking medication at the time of the study. Lower cerebellar metabolism could relate to the effects of chronic neuroleptic treatment. Although one could argue that the absence of dopamine receptors in the cerebellum would make it insensitive to the actions of dopamine antagonists, one must consider the neuroanatomical connections between the cerebellum and the basal ganglia (20). In fact, animal studies have shown increases in cerebellar glucose metabolism after administration of dopamine agonists (21) and decreases in cerebellar metabolism after administration of dopamine antagonists (22). However, since there is evidence that patients with schizophrenia have abnormalities in dopamine brain activity, lower cerebellar metabolism could also reflect these defects.

One also needs to consider the relationship between frontal and cerebellar metabolism (17–19) in the interpretation of these findings. However, the fact that there were no significant correlations between relative metabolic activity in the cerebellum and in the frontal cortex argues against the notion that the lower cerebellar metabolism is a reflection of the abnormal frontal metabolic activity seen in these patients (16).

Similarly, there were no significant correlations between relative metabolic activity in the cerebellum and in the basal ganglia, suggesting that the cerebellar metabolic changes may be independent of the frontal and subcortical defects seen in these patients.

This study documents cerebellar metabolic abnormalities in medicated patients with chronic schizophrenia. Studies on never-medicated patients with schizophrenia are required to rule out whether the findings in this report are related to chronic use of neuroleptics or to the schizophrenic process itself.

# Weight Gain Among Schizophrenic Patients Treated With Clozapine

J. Steven Lamberti, M.D., Terrance Bellnier, R.Ph., and Steven B. Schwarzkopf, M.D.

*A retrospective chart review was used to assess weight changes in 36 chronic schizophrenic inpatients who were treated with clozapine after being treated with standard neuroleptics. The average weight gain during 6 months of clozapine treatment was 16.9 lb; 75.0% of the patients gained at least 10 lb. The results confirm previous findings of clozapine-associated weight gain.*

(Am J Psychiatry 1992; 149:689–690)

Clozapine is the first antipsychotic medication that has been proven superior to standard neuroleptics for treatment-refractory schizophrenia. Depending on how treatment resistance is defined, potential candidates for clozapine therapy in the United States may number in the hundreds of thousands. Clozapine causes fewer extrapyramidal side effects than neuroleptics but has a variety of other side effects, including weight gain. While obesity is a known health risk and has been documented as a side effect of neuroleptics (1, 2), the degree of weight gain associated with clozapine is unclear. In a review of more than 13,000 patients treated with clozapine worldwide, Lieberman et al. (3) reported weight gain in 0.73%. In a retrospective review of the medical charts of 503 inpatients, Naber and Hippius (4) noted weight gain in only three patients. However, Povlsen et al. (5) noted a frequency of 11.6% in a retrospective study of 216 inpatients treated with a mean daily dose of 317 mg for up to 12 years. Taken together, these reports have suggested that weight gain occurs infrequently during clozapine treatment.

In contrast, Leadbetter et al. (6) recently reported that 38% of their group of 21 chronically mentally ill patients gained over 10% of their body weight during clozapine treatment. Also, Cohen et al. (7) have described significant weight gain in seven schizophrenic patients treated with clozapine. Six of these patients gained an average of 24.7 lb, and the authors concluded that clozapine may be associated with the same degree of weight gain seen with typical neuroleptics.

The purpose of the present study was to examine the frequency and magnitude of weight gain in clozapine-treated chronic schizophrenic patients. This study involved a retrospective review of hospital charts for a group of patients treated with both neuroleptics and clozapine.

## METHOD

Our subjects were 36 inpatients in a state hospital who were consecutively treated with clozapine over 33 months. All patients had clinical diagnoses of chronic schizophrenia, according to *DSM-III-R* criteria, with a variety of subtypes. The mean length of the current hospitalization was 8.2 years (SD=7.6), and the mean number of previous hospitalizations was 5.8 (SD=3.1). Twenty-seven (75.0%) of the subjects were male, and the mean age of the total group was 34.8 years (SD=9.3). The patients were selected for clozapine treatment by their attending psychiatrists because they had shown little or no clinical improvement during adequate trials of at least three different neuroleptics in the previous 5 years. The mean total duration of neuroleptic treatment during the current hospitalization was 6.8 years (SD=4.8). The neuroleptic treatment received by the group during the 6 months before clozapine treatment is summarized in table 1. Neuroleptics were discontinued, and the patients' mean clozapine dose was 380 mg/day (SD=135). The transition from neuroleptics to clozapine was made without a washout period and was generally completed within 4–6 weeks.

Each patient was weighed monthly during the last 6

**TABLE 1. Standard Neuroleptics Received by 36 Chronic Schizophrenic Inpatients During 6 Months Before Clozapine Treatment**

| | | Dose (chlorpromazine equivalents/day) | | Duration (days) | |
|---|---|---|---|---|---|
| Neuroleptic[a] | N | Mean | SD | Mean | SD |
| Haloperidol | 11 | 1519.5 | 781.0 | 110.2 | 57.7 |
| Fluphenazine | 8 | 1375.0 | 860.0 | 106.6 | 65.4 |
| Thiothixene | 11 | 1083.4 | 285.2 | 114.2 | 57.9 |
| Trifluoperazine | 9 | 944.4 | 481.0 | 98.1 | 63.08 |
| Perphenazine | 1 | 100.0 | | 91.0 | |
| Loxapine | 1 | 800.0 | | 118.0 | |
| Chlorpromazine | 5 | 820.0 | 465.4 | 134.0 | 46.51 |
| Thioridazine | 4 | 558.3 | 252.4 | 90.5 | 30.5 |

[a]Patients received up to three different neuroleptics each.

months of neuroleptic treatment and the first 6 months of clozapine treatment. Clozapine treatment was initiated during fall and winter months for 15 (41.7%) of the patients, and for 21 (58.3%) it began during spring and summer months. Patients were weighed in street clothes before breakfast and had unrestricted access to food and physical activity throughout the study. An ideal weight range, including minimum and maximum ideal weights, was calculated for each patient by a registered dietitian. Weight change was assessed by comparing the patient weights before and after each 6-month treatment period. The score on the Brief Psychiatric Rating Scale (BPRS) was also determined by each patient's attending psychiatrist every 6 weeks during clozapine treatment.

## RESULTS

The group showed stable weight during the 6 months of standard neuroleptic treatment (mean weight change= –0.2 lb, SD=11.0). When clozapine treatment began, seven (19.4%) of the patients weighed less than their minimum ideal weights and 23 (63.9%) weighed more than their maximum ideal weights. As a group they weighed an average of 15.3 lb (SD=35.3) more than their maximum ideal weights. The group subsequently gained an average of 16.9 lb (SD=10.9) during the 6 months of clozapine treatment ($t=9.33$, $df=35$, $p<0.0001$, paired t test). Expressed as a percentage of maximum ideal weight, the mean weight gain for each patient during clozapine treatment was 10.6% (SD=6.8%). Of the 36 patients, 27 (75.0%) gained at least 10 lb while taking clozapine, and 15 (41.7%) gained at least 20 lb. The mean BPRS score dropped from 66 (SD=15) to 47 (SD=16) during the 6 months of clozapine treatment ($t=10.25$, $df=29$, $p<0.0001$, paired t test). We noted a tendency for this change to correlate inversely with the amount of weight gained during clozapine treatment (Spearman $r=-0.31$, $df=28$, $p<0.10$). BPRS scores were not available for six patients.

## DISCUSSION

This study demonstrates significant weight gain in a group of schizophrenic patients during clozapine treatment. Weight gain associated with standard neuroleptics has been reported to plateau after 1 to 2 years of treatment (1). Since the group in our study had been maintained on neuroleptics an average of 6.8 years, this possibility would explain our failure to find a significant weight change during the neuroleptic treatment period. The patients averaged 15.3 lb over their maximum ideal weights before receiving clozapine, suggesting that clozapine treatment exacerbated a preexisting problem in the group.

The mechanism of clozapine-associated weight gain remains uncertain. Discussing neuroleptic-associated weight gain, Brady (2) noted that the mechanism is likely to be multifactorial. Possibilities include drug effects on serotonergic, anticholinergic, and histaminic neurotransmitter systems, in addition to effects on endocrine and metabolic functions.

Published estimates of the degree of weight gain associated with neuroleptics have varied widely, making comparison with clozapine difficult. Reviewing this literature, Amidsen (1) concluded that an average weight gain of 6.6 to 11 lb is usual after 6 months of neuroleptic treatment. Ability to induce weight gain has also been reported to vary inversely with neuroleptic milligram potency (2). In a recent study directly comparing fluphenazine and clozapine, Konicki et al. (8) found significantly greater weight gain with clozapine. Considered with the results of the present study, those data suggest that clozapine could cause more weight gain than many standard neuroleptics. Since prevention may be the best strategy in managing antipsychotic-induced weight gain (2), physicians should be aware of this side effect when prescribing clozapine.

# CSF Cholecystokinin Concentrations in Patients With Panic Disorder and in Normal Comparison Subjects

**R. Bruce Lydiard, Ph.D., M.D., James C. Ballenger, M.D.,
Michele T. Laraia, R.N., M.S.N., Mark D. Fossey, M.D.,
and Margery C. Beinfeld, Ph.D.**

*Cholecystokinin concentrations in the CSF of 25 patients with panic disorder and 16 normal comparison subjects were ascertained by radioimmunoassay. The patients with panic disorder had significantly lower CSF concentrations of cholecystokinin, which may reflect increased CNS cholecystokinin receptor sensitivity, reduced numbers of receptors, or a compensatory reduction in cholecystokinin octapeptide secondary to theoretically increased central cholecystokinin tetrapeptide activity.*

(Am J Psychiatry 1992; 149:691–693)

Cholecystokinin is a neuroactive peptide that exists in various forms and exhibits a variety of peripheral and CNS actions (1, 2). Cholecystokinin octapeptide (CCK-8) is believed to be the most prevalent form of cholecystokinin in the CNS (1, 2). It appears that CCK-8 and various analogues may modulate CNS dopamine neurotransmission, and they have been studied as potential antipsychotic agents (2). Animal studies indicate a functional antagonism between CCK-8 and benzodiazepines in hippocampal cells (3), and recent studies suggest that in "anxious" rats, the numbers of CCK-8 receptors are reduced in the hippocampus (4). Measurement of CSF cholecystokinin in patients with schizophrenia, mood disorders, eating disorders, and Parkinson's disease has produced inconsistent results (2).

Interesting work by de Montigny (5) and Bradwejn et al. (6) has indicated that cholecystokinin in the tetrapeptide form (CCK-4) is a potent anxiogenic agent. In patients with panic disorder, CCK-4 appears to have potent panicogenic properties with minimal gastrointestinal effects. In a recent study (7), 10 (91%) of 11 panic disorder patients experienced panic attacks, compared to two (17%) of 12 normal control subjects, after injections of 25 μg of CCK-4.

To investigate possible abnormalities in CNS cholecystokinin in patients with anxiety disorders, we analyzed the CSF of 25 patients with panic disorder and 16 comparison subjects for cholecystokinin immunoreactivity.

## METHOD

The patients with panic disorder were five men and 20 women between the ages of 18 and 65 years (mean=35.6 years, SD=8.8) who were in good physical health and had given verbal and written consent. They were evaluated by means of the Structured Clinical Interview for DSM-III (SCID) (8) and met the *DSM-III* criteria for panic disorder or agoraphobia with panic attacks. Patients with major depression were included only if their panic disorder symptoms had preceded the onset of major depression and depression was not the principal diagnosis. Patients with melancholia were excluded, as were patients with other axis I disorders.

The normal comparison subjects (eight male and eight female; mean age=30.0 years, SD=7.7) were recruited by advertisement. They were also interviewed with the SCID and were found to be free of any axis I psychiatric diagnosis. In addition, no first-degree relative of the normal comparison subjects had a psychiatric diagnosis (according to patient history).

The patients and comparison subjects were admitted to our clinical research center the night before the CSF sampling procedure was done. All subjects had been maintained on a low-monoamine diet for the previous 4 days, had had at least 9 hours of bed rest, and had fasted overnight prior to the procedure. Lumbar CSF was obtained between 8:00 and 10:00 a.m., immediately frozen on dry ice, and stored at –70 °C until assay. Total cholecystokinin immunoreactivity was assayed by radioimmunoassay (9) in aliquots from a pool of CSF (12th–25th cc). Samples were assayed by using

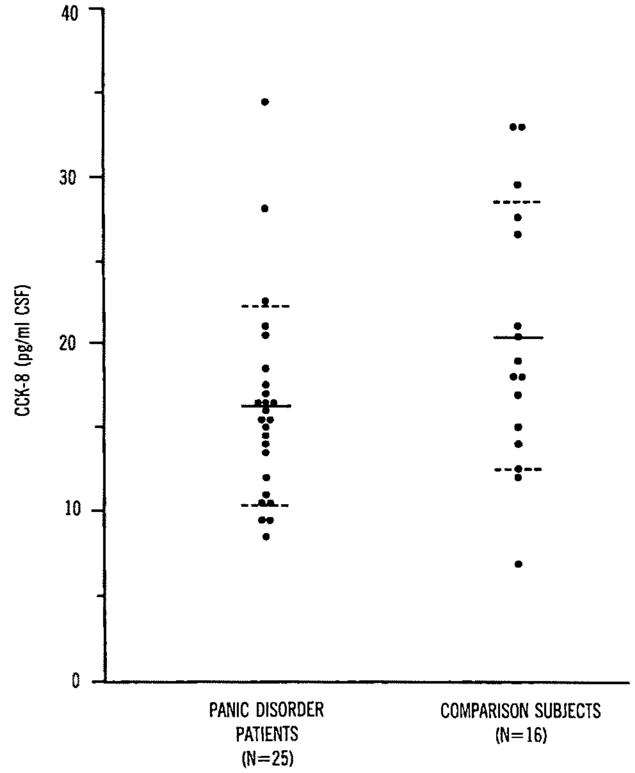
**FIGURE 1. CSF Cholecystokinin Concentrations in Patients With Panic Disorder and in Normal Comparison Subjects**[a]



[a] Solid lines are means; dashed lines are standard deviations.

200-μl aliquots in duplicate and averaging results. Results are expressed in picograms per milliliter.

## RESULTS

The group of patients with panic disorder did not differ significantly in age, height, weight, or sex from the group of normal comparison subjects. Eight of the patients with panic disorder also met the criteria for current major depression. The patients had been asked to remain medication free for 2 weeks before the procedure. Of the 25 patients, 17 had been medication free for at least 2 weeks (mean=8 weeks, range=2–28), five never took medication, and three had been medication free for 1–2 weeks (one patient had been taking diazepam, 5 mg p.r.n.; one had been taking amitriptyline, 25 mg/day; and one had been taking clorazepate, 7.5 mg/day). Five patients had taken a dose of a benzodiazepine between 2 and 7 days before the procedure (four took diazepam, 5 mg, and one took lorazepam, 1 mg).

The CCK-8 immunoreactivity of both groups is shown in figure 1. The CCK-8 concentrations in the comparison group were normally distributed. Concentrations did not differ between the men (mean=20.5 pg/ml, SD=7.3) and the women (mean=20.5 pg/ml, SD=8.5) in the normal comparison group or between the male patients (mean=15.3 pg/ml, SD=4.0) and the female patients (mean=16.5 pg/ml, SD=6.5). However, the difference between the CCK-8 levels of the comparison group (mean=20.6 pg/ml, SD=7.7) and the patient group (mean=16.2 pg/ml, SD=5.9) was analyzed with Student's t test and found to be significant (t=2.05, df=39, p<0.05). The subgroup of patients with panic disorder and major depression did not differ from the nondepressed patients with panic disorder with respect to CCK-8 concentrations.

Concentrations of CCK-8 in the CSF of the patients who had taken benzodiazepines within 1 week of the procedure (mean=16.3 pg/ml, SD=2.0) were not different from those of the rest of the patient group (mean=16.0 pg/ml, SD=6.5) (t=0.11, df=23, n.s.). CSF levels of CCK-8 in patients who had ever been treated with benzodiazepines (N=14) and those who had never taken them (N=11) were not significantly different (mean=18.7 pg/ml, SD=7.5, versus 14.2 pg/ml, SD=4.5; t=1.64, df=23, n.s.).

## DISCUSSION

To our knowledge, this is the first report of CSF cholecystokinin concentrations in patients with panic disorder. In this study, CSF cholecystokinin concentrations were significantly lower in patients with panic disorder than in normal comparison subjects, an unexpected finding. It is possible that cholecystokinin receptor sensitivity is increased in patients with panic disorder and that what we observed was a compensatory reduction in cholecystokinin activity which may occur as a secondary phenomenon. Alternatively, this finding may be a reflection of a reduced number of brain cholecystokinin receptors in these patients, with a concomitant lowering of central CCK-8 activity. In rodents, in vitro studies have shown that pretreatment of cell preparations with CCK-4 will prevent CCK-8-induced neuronal firing, suggesting that there may be some antagonistic interaction between the two forms (10). Our data may reflect indirectly an increase in CNS CCK-4 activity with a compensatory decrease in CCK-8 activity.

In the several previous reports (2), there were variable findings on CSF cholecystokinin activity in patients with various psychiatric and neurological disorders compared to normal subjects, suggesting that lowered cholecystokinin levels are not necessarily a nonspecific finding across various patient samples. Interestingly, recent evidence suggests that chronic diazepam treatment produces variable region-specific changes in cholecystokinin receptor density in rodents (11). Medication treatment history did not appear to have affected cholecystokinin measurements in our patients, although the effects of prior treatment with, or current surreptitious use of, benzodiazepines still cannot be ruled out completely. All of the patients in our study who used benzodiazepines within 1 week of testing did so to control their anxiety about coming to the hospital. None took other medication regularly during the 2 weeks before the procedure. It is likely that the four patients who took diazepam prior to hospitalization still had some residual benzodiazepine at the time of CCK-8 sampling. To the best of our knowledge, however, this did not affect our findings.

Finally, since the numbers of patients and comparison subjects were relatively small, replication of these preliminary data in a larger group is indicated. There is no known CSF concentration gradient for cholecystokinin; our use of similar pools for each sample obviates this potential technical problem. As further information regarding the distribution of cholecystokinin receptors in the human CNS becomes available, and as interaction with other monoamine and neuropeptide systems is further elucidated, additional light may be shed on the potential role of cholecystokinin in the CNS of normal subjects and patients with anxiety disorders.

# Abnormal Diurnal Variation in Circulating Natural Killer Cell Phenotypes and Cytotoxic Activity in Major Depression

**John M. Petitto, M.D., James D. Folds, Ph.D., Howard Ozer, M.D., Ph.D., Dana Quade, Ph.D., and Dwight L. Evans, M.D.**

*This investigation tested the hypothesis that depressed patients have abnormal diurnal variation of natural killer (NK) cell measures. The diurnal variation of levels of Leu-11 NK cells and NK cytotoxic activity was significantly less in 24 patients with major depression than in 24 normal comparison subjects. These findings provide evidence that aspects of immune, as well as neural and endocrine, chronobiology are abnormal in depression.*

(Am J Psychiatry 1992; 149:694–696)

Since the classic clinical investigation by Sachar et al. (1), which showed abnormal 24-hour patterns of cortisol secretion in psychotic depression, advances in the research of biological rhythms have led to new insights into the pathophysiology of affective illness. Disturbances in the circadian rhythms of several neurobiological measures—including noradrenergic activity, cortisol, melatonin, thyrotropin, temperature regulation, and the sleep-wake cycle—have been associated with major affective syndromes (2). Important components of the cellular immune system in both animals and humans also exhibit normal chronobiological patterns of activity, and considerable evidence from basic and clinical studies has established that the CNS plays a key role in modulating various aspects of immune system function (3). While the endogenous pacemakers that govern immunological rhythms are not yet understood, it has been posited that immune bioperiodicity may be entrained to rhythms of CNS origin (4).

Natural killer (NK) cells are a heterogeneous subset of large granular lymphocytes that show cytotoxicity which is not restricted by the major histocompatibility complex. These cells are believed to be involved in the natural resistance to tumor growth and microbial infection and in other important immunoregulatory functions, such as the production of lymphokines (5). Several recent clinical investigations have demonstrated that circulating NK activity (in the morning) is abnormally low in depression (6), and to date this observation has been the most reproducible abnormality in cellular immunity associated with major depression. We recently reported (7) that low circulating levels of the Leu-11 (CD16) NK cell phenotype accompany low NK activity in depressed subjects and may be one important immunological mechanism by which NK activity is impaired in depression. Basic studies provide evidence that NK activity may be regulated by neural (e.g., noradrenergic, GABA-ergic) and endocrine (e.g., corticotropin-releasing factor, ACTH, cortisol, β-endorphin) modulators, which have been implicated in the neurobiology of depression (3). Thus, several lines of evidence suggest that abnormalities in the diurnal variation in some mediators of CNS function associated with depression may lead to perturbations in the normal diurnal variation of NK cell measures. To date, however, there have been few data on such a relationship in affective disorders. To test the hypothesis that NK cell diurnal variation is abnormal in depression, we examined circulating NK cell phenotypes and NK activity in subjects with major depression and in normal comparison subjects at both 8:00 a.m. and 4:00 p.m. on the same day. These times were chosen because 8:00 a.m. and 4:00 p.m. have been shown to approximate the diurnal peak and nadir, respectively, of NK cell activity in healthy, normal individuals (on a schedule of nocturnal rest and diurnal activity) (8). To our knowledge, this is the first study to show that the diurnal variation of a measure of cellular immunity is abnormal in patients with major depression.

## METHOD

Forty-eight subjects participated in this study: 24 inpatients with major depression and 24 healthy, normal comparison subjects. All subjects provided written informed

consent. These subjects were part of a substantially larger study of depression and immune function (7) and are the subset of subjects from whom both 8:00 a.m. and 4:00 p.m. blood samples for NK determinations were obtained on the same day. As closely as possible, the comparison subjects were matched to the patients with major depression for mean age and sex distribution: mean age=30.9 years (SD=7.8) and 30.5 years (SD=8.8), respectively; percentage of men=67% and 58%. The diagnoses were assigned by a board-certified research psychiatrist (D.L.E.) on the basis of all available clinical information and data obtained with the Schedule for Affective Disorders and Schizophrenia (SADS). The comparison subjects were recruited by means of printed advertisement. The mean scores on the 17-item Hamilton Rating Scale for Depression were 16.2 (SD=8) for the subjects with major depression and 0.8 (SD=2) for the comparison subjects. The subjects were on a schedule of nocturnal rest and diurnal activity and were free of all medications with known or suspected immune effects (e.g., psychotropics—including antidepressants—anticonvulsants, antihistamines, antihypertensives, steroids, anti-inflammatory drugs, antibiotics) for at least 2 weeks before testing. The immune assays were performed blind to diagnosis, and all diagnoses were made blind to the results of the immune assays.

The NK cell phenotyping and NK activity determinations were performed with standard methods previously described (7). Briefly, Leu-7 (HNK-1) and Leu-11 (CD16) lymphocytes were identified by using Leu series monoclonal antibodies and were counted with a fluorescence-activated flow cytometer. Single-color staining was employed for the determination of the percentage of Leu-7 large granular lymphocytes (percentage of lymphocytes, $10^6$ cells/ml), and two-color staining was used in this investigation to determine the percentage of Leu-11a,c positive lymphocytes (percentage of lymphocytes, $10^6$ cells/ml); the latter are the predominant population of NK active effector cells in humans. Whereas previous chronobiological investigations of NK cell phenotype levels among normal subjects have been conducted with older, less selective monoclonal antibodies (5), this is the first investigation of which we are aware that uses the anti-Leu-11 monoclonal antibody to assess the diurnal variation of NK cell levels. NK activity determinations were performed for a subset of patients (18 depressed patients, 11 comparison subjects) with chromium-labeled, NK-sensitive K562 tumor cells as the target. The percentage of specific lysis of tumor targets at each of five effector/target cell ratios (12.5 to 200:1), the area under the concentration-response curve, and the mean NK activity (the average of the five effector/target cell ratios) were calculated for each subject.

For the individual dependent immune variables examined, a difference score was computed for each subject (4:00 p.m. value minus 8:00 a.m. value). Any potential variance in the dependent immune variables due to age or gender was controlled for in all statistical analyses. Analysis of covariance (ANCOVA), covarying for age and gender, was used to test for differences between the patients with major depression and the normal comparison subjects, and Pearson partial correlations were performed to examine the relationship between Hamilton severity rating and diurnal variation for each immune measure. For statistical analyses, immune values were log-transformed to normalize group variance. Adjusted logged values were unlogged for presentation in the text. The mean and standard deviation are reported, and two-tailed tests were used throughout. The group differences in diurnal variation of the dependent immune variables reported are computed difference scores analyzed by ANCOVA.

## RESULTS

Statistical analyses of the computed difference scores demonstrated that the subject group with major depression had significantly less diurnal variation of Leu-11 NK cell levels (+1%) than the group of normal comparison subjects (–14%) between 8:00 a.m. and 4:00 p.m. (F=3.94, df=1, 44, p=0.05). The mean level of Leu-11 cells (percentage of lymphocytes, $10^6$ cells/ml) decreased from 12.6 (SD=5.9) to 11.0 (SD=4.9) between 8:00 a.m. and 4:00 p.m. for the normal comparison subjects. For the patients with major depression the mean Leu-11 levels were 10.6 (SD=5.9) at 8:00 a.m. and 10.8 (SD=5.4) at 4:00 p.m. The diurnal variation in mean NK cytotoxic activity was also found to be significantly less for the subjects with major depression (–24%) than for the normal comparison subjects (–45%) (F=6.72, df=1, 25, p=0.02). In addition, these differences were significant for each of the five effector/target cell ratios tested—200:1 (F=5.99, df=1, 25, p=0.02), 100:1 (F=4.94, df=1, 25, p=0.04), 50:1 (F=5.71, df=1, 25, p=0.02), 25:1 (F=4.47, df=1, 25, p=0.04), and 12.5:1 (F=5.64, df=1, 25, p=0.03)—and for the NK area under the curve (F=6.67, df=1, 25, p=0.02). The mean NK activity decreased from 44 (SD=13) to 24 (SD=12) between 8:00 a.m. and 4:00 p.m. for the normal comparison subjects and from 38 (SD=13) to 29 (SD=8) for the subjects with major depression.

The levels of Leu-7 cells did not differ significantly between the subject groups (F=2.58, df=1, 43, p=0.12). Partial correlations examining the relationship between Hamilton depression score and diurnal variation in the three immune measures were not significant. There were no significant depression-related gender differences in the diurnal variation of these immune measures.

## DISCUSSION

The results reported here indicate that the diurnal variation in NK activity is abnormal in patients with the syndrome of major depression. Normal circadian variation in NK cytotoxic activity varies as a function of changes in both the level of peripheral blood NK cells and the activation state of those cells over time (8). The Leu-11 antigen marker is present on virtually all cells in the peripheral blood that are known to have functionally meaningful NK activity, and peripheral blood Leu-11 NK cell levels are positively correlated with NK activity in normal subjects (5). As expected, the normal comparison subjects in this study exhibited substantial diurnal variation in circulating Leu-11 NK cell levels that tracked the diurnal variation of NK activity. In contrast, the patients with major depression had significantly less diurnal change in NK activity and almost no variation in Leu-11 NK cell levels.

Peripheral blood NK cell phenotype levels are thought to reflect lymphocyte migration or recirculation between immune organs (e.g., spleen) and blood. In healthy subjects the response of peripheral blood NK cells to stimulatory and inhibitory immunoregulatory signals appears to differentially vary during the circadian cycle (8). Hence, our finding that there is greater diurnal variation in NK activity than in Leu-11 NK cell levels among normal subjects is in keeping with evidence in the immunological literature which suggests that the daily bioperiodicity of NK activity is a function of changes in both blood levels of NK cells and the activation state of those cells. Given the finding that diurnal variation between 8:00 a.m. and 4:00 p.m. for both Leu-11 NK cell levels and NK activity is abnormal in patients with major depression, it will be important in future studies to examine multiple time points (e.g., every 3 hours) so that time series analyses can be used to systematically assess chronobiological differences (e.g., phase differences) throughout the full circadian cycle. Moreover, determining the dynamic temporal relationship between NK measures and neuromodulators that have been suggested to play a role in NK cell regulation (e.g., corticotropin-releasing factor, cortisol, β endorphin) will be important in testing hypotheses about their role in NK cell bioperiodicity.

Diurnal variation in Leu-7 lymphocyte levels did not differ significantly between the groups in our study, possibly because the periodicities of subgroups of Leu-7 positive cells are affected differently in major depression. Unlike the lymphocytes of the Leu-11 NK cell phenotype, Leu-7 antigens are found on a variable percentage (approximately 50%) of functionally active NK cells, as well as on subsets of T lymphocytes, some of which have patterns of rhythmic variation that differ from that of NK cells.

The clinical implications of biological rhythms have been of great interest to clinical researchers in psychiatry and other areas of medicine. Experimental evidence indicates that susceptibility to microbial infection, allograft rejection, and tumor growth, as well as immunopharmacologic responses, among other clinically relevant end points, vary significantly throughout the circadian cycle (9). One clinical study (10) indicated that asymptomatic HIV-infected individuals may manifest disruptions of the normal circadian cycle of CD4 (T helper) cells and that such disruptions may predate both symptoms of HIV-spectrum disease and, in some cases, reductions in CD4 cell counts. Since HIV infection affects the CNS as well as the immune system, it is possible that abnormal CD4 circadian rhythms may be secondary to chronobiological changes in the CNS.

In conclusion, by demonstrating that the normal diurnal variations in both circulating levels of the Leu-11 NK cells and NK activity are disrupted in patients with major depression, these data provide the first evidence that measures of immunological, as well as neural and endocrine, diurnal variation are abnormal in depression. Systematic investigation of interactions between complex neural, endocrine, and immune chronobiological rhythms may lead to greater basic understanding of the biology of brain-immune interactions in depression and perhaps other neuropsychiatric syndromes.

### PSYCHOANALYSIS

**Other Times, Other Realities: Toward a Theory of Psychoanalytic Treatment,** *by Arnold H. Modell, M.D. Cambridge, Mass., Harvard University Press, 1990, 180 pp., $27.50.*

In retrospect, I find it interesting and no accident that I chose to read a book with this title while exploring aboriginal culture in the Australian outback. It was scarcely 90 years ago that white men entered and forever altered the aboriginal world. Can even the oldest aborigine be expected to remember what it was like before then, and, regardless, how could we assess that? About the same time, Freud forever altered the world for many of the rest of us, but Freud, like the rest of us, could not fully address everything he observed. Modell picks up on several of the pearls Freud uncovered but did not harvest or string together with his other ideas.

One of these unstrung pearls is the concept of *Nachträglichkeit,* which refers to the idea that memories are cyclically retranscribed over time into new cognitive and affective categories based on later life experiences. This concept produces a derivative theory that psychological development occurs in a cyclic, ongoing manner rather than in a linear, fixed fashion. Modell believes a reason this concept has not been explored in much detail previously is that Strachey mistranslated *Nachträglichkeit* as "deferred action," leading to a semantic self-fulfilling prophecy. Thus, *Nachträglichkeit* is basically a new and revolutionary concept for psychoanalysis, but it was used by Nobel Laureate (in immunology) Gerald Edelman in his 1987 book, *Neural Darwinism* (1). Edelman shifted his focus from the immune system's "memory" to the brain's memory functions. Edelman believes that memories are not simply laid down for life but are continually recategorized; retrospective attribution to past events occurs on the basis of subsequent psychic experiences. Thus, memories are reworked in a cyclic manner over time, so childhood emotional trauma or deprivation alone may not lead to later neurosis or other emotional disorders in a linear, predictable manner. Just as ontogeny does not recapitulate phylogeny, adult life is not necessarily just "new verses of the songs learned at mother's knee."

The concept of *Nachträglichkeit* is also captured in a paraphrase of Mark Twain: "When I was 15 years old, I thought my father was among the stupidest men on earth, and when I was 22, I was amazed at how much any man could learn in 7 years." Likewise, it is not possible for former analysands to fully perceive and describe how they have changed due to analysis; instead, they often think that the analyst or others have changed remarkably during the process.

Anna O. provided an anlage of this concept when she discovered that her severe hysterical symptoms could be lessened by self-treatment consisting of talking about upsetting thoughts and memories. In describing this to her physician, Josef Breuer, she coined the term "the talking cure" and the much livelier and more intriguing term "chimney sweeping." Her verbal catharsis removed the toxic accumulated residues of the emotional "fires" of her life. St. Augustine also recognized an aspect of *Nachträglichkeit* when he said there are three times: a present sense of things past, a present sense of things present, and a present sense of things future (p. 77).

Modell's central thesis in this book is that psychoanalysis works by leading to a reworking and recategorization of the patient's memories as well as by facilitating new experiences and perceptions based on the analyst's world view and on views creatively generated in the analytic setting. Based on that thesis, Modell redefines the ego as a mental structure engaged in processing or reorganizing (recontextualizing) our experiences through time. This thesis challenges a pillar of Kleinian analysis, namely, the primacy of the earliest experiences in determining later psychological life.

There are two secondary themes in the book. First, multiple levels of reality are present in the analytic setting, and those who cannot or will not learn to shift between the multiple levels of reality to understand the influences of these levels on their thoughts, feelings, and behaviors will not be able to achieve the highest level of psychoanalysis. Second, paradox is a part of mental functioning, especially of creativity; therefore, an appreciation and understanding of paradoxes will be part of the highest level of analysis. Modell's notion of "the paradox of time, that the past can alter the present and the present can alter the past" (p. 128) is implicit in Freud's ideas relating to *Nachträglichkeit.* There are other paradoxes in analysis: transference feelings are at the same time real and unreal, transference neurosis is partly a recreation of the past and at the same time a newly created illness, "transference is a major resistance to recovery and at the same time the motor that generates the cure" (p. 128), and the analyst simultaneously "represents the dangers of the past as well as the safety of the present" (p. 137).

Modell seems to blame Freud somewhat for not finding the concept of *Nachträglichkeit* as interesting and important as he has found it to be. A number of scientific advances in the past century, however, probably especially in the philosophies of science and linguistics, have made the concept more interesting and central than it may have seemed almost a century ago. In discussing Clover's 1931 paper, "The Therapeutic Effect of Inexact Interpretation," Modell implies that Clover would relentlessly pursue each fantasy in an analysis to the point of unattainable puritanical perfectionism before offering an interpretation (p. 93). I believe Clover's major intent was to suggest that we analysts listen beyond the first or second possible interpretation that occurs to us because wild analysis and shooting from the hip will otherwise increase the patient's resistance and defensiveness.

I found only two typos. On page 92, line 29, "than" should have been "then," and on page 123, a sentence reads, "I believe that in some instances the analyst's growing impatience with the analysand is ready to move to such a higher level of relatedness." I believe the phrase "indicates that the analysand" should follow "with the analysand" in the sentence.

Modell's ideas fit with my analytic experiences and are useful theoretically and therapeutically. A particular gem begins on page 119, where Modell gives a brilliantly concise integration of Kohut's concept of self-object with other psychoanalytic theories. This book should be read by psychoanalysts and psychoanalytically oriented psychotherapists, and teachers in these areas should incorporate it into the required reading for advanced psychiatry residents and psychoanalytic candidates. Like *Don Quixote,* it should be periodically reread, which further proves its central thesis.

*Philadelphia, Pa.*

**Essential Papers on Transference,** *edited by Aaron H. Esman, M.D. New York, New York University Press, 1990, 528 pp., $55.00; $25.00 (paper).*

This ninth book in the Essential Papers series is an admirable and useful addition to the list. Dr. Esman chose 29 works, arranged in nearly chronological order, beginning with papers by Ferenczi and Freud in the early years of this century and ending with more recent articles by Kernberg and Cooper. Transference, despite its universality as a phenomenon, is of special relevance to psychoanalysis from a clinical standpoint. The material for this book, not surprisingly, comes entirely from the analytic literature.

Dr. Esman offers us, in the first 13 pages, his own thoughtful and well-written review of the 29 chapters. These he organizes into three "periods:" the pioneers (1909–1936), the middle (1936–1960), and the modern (1960–1987).

Freud regarded transferences as "new editions" of fantasies and feelings reawakened in the course of the analysis and transferred onto the person of the analyst. Toward the end of the pioneer period, Strachey claimed that successful analytic therapy depended on "mutative" interpretations that were "emotionally immediate." This immediacy could come only from transference interpretations. Esman notes that "reverberations of this shot are still being heard today."

During the middle period, controversy centered around the reliance on transference interpretation. Greenacre took a conservative stand, arguing for exclusive reliance on transference work. Greenson advocated a stance that allowed for more "realistic" gratifications and for less austerity, should the clinical situation warrant them. The personal attributes of the analyst, which tended to be ignored by the early writers, were shown to have important effects, especially when dealing with more fragile patients. The papers of Bibring-Lehner and Rioch address this topic.

The authors of the modern period make clear that, in analysis of the transference, one is not necessarily recreating the patient's actual past so much as the patient's emotionally valid past as remembered and reconstructed. The papers of Schafer, Kernberg, and Cooper are especially illuminating. The "modernist" model, as Cooper calls it, posits that transference is a new experience rather than merely a reenactment of an old one.

As every editor of a volume of Essential Papers is aware, some readers will take umbrage with the selection: omissions they feel should have been included and vice versa. In my own view, Dr. Esman has chosen well in 28 of the 29 papers, a highly respectable average. I would quarrel only with the Lacan paper, which is barely about transference and surely not "essential." This quibble aside, Esman's book is an excellent addition to the series and will be of great value to psychotherapists interested in the evolution and current applications of the concept of transference—so important in their work with patients.

**Collaborative Psychoanalysis: Anxiety, Depression, Dreams, and Personality Change,** *by Walter Bonime, M.D. Cranbury, N.J., Fairleigh Dickinson University Press, 1989, 394 pp., $55.00.*

This book is an accumulation of more than 35 articles from Walter Bonime's 33 years of psychoanalytic writing. He was one of the first students in Karen Horney's American Institute for Psychoanalysis. Dr. Bonime's work has continued Horney's focus on the social and cultural aspects of the psychoanalytic process. This text is not a dry series of old papers but a rich, refreshing view of many clinical situations. It touches many differing diagnostic issues in somewhat unique ways. For example, the section on depression and paranoia reflects Dr. Bonime's view that "depression is not a passively experienced or reactive interpersonal response, but an active means of relating to people." He sees depression as one of several problems that are the result of distorted adaptive styles of relating to people and points to the similarities among narcissistic, depressive, and paranoid processes. Dr. Bonime sees a similar origin of pathology in deficiencies in childhood social interpersonal experiences, and he highlights the anger, grandiosity, and "unwillingness to enhance the lives of others" of depressed individuals as well as their tendency to manipulate others while being "allergic to coercion" themselves.

An overall focus of the book is on how a person changes his or her "sense of self" during the psychoanalytic process. Dr. Bonime addresses the stages in a change in the sense of self and how this change is both resisted and facilitated in the collaborative effort of psychoanalysis. The book shows that over the years Dr. Bonime has thoughtfully treated and skillfully written about many aspects of human mental suffering. He has examined, in his own unique way, such areas as anxiety as a barrier to treatment progress, depersonalization as reflecting evolving health, homosexuality, marital conflict, and masturbatory fantasies.

Following up on his 1962 book *The Clinical Use of Dreams* (1), which was written with his wife, Florence, Dr. Bonime has included a rich section in this text on the role and use of dreams in psychoanalysis. His "culturalist" conviction that personality evolves through and is modified by interpersonal experience is reflected in his approach to dreams. He sees the dream as a frequently useful tool to help engage patients in learning about their unconscious emotional life. These papers include ideas such as the limitations of dream work in psychoanalysis and the use of dreams in brief focused psychotherapy. This section on dreams underscores the main theme of Bonime's work, which is to promote a better understanding of the collaborative effort of analyst and patient, working together to foster growth and constructive change.

Throughout the book we see the author's view of the origin of psychopathology and his multidimensional understanding of both the source of problems and the psychoanalytic process of change. He sees the cultural encouragement of competitiveness and cynicism as an important factor in causing personality distortions, and he shows how family cooperativeness is a source of emotional health. He gives straightforward views on such sticky issues as liking and disliking our patients. Another stimulating essay in this book concerns the process of psychoanalytic writing and the attempt to communicate with colleagues. He aptly relates our problem of attempting to translate "felt experience" of real interactions into abstractions that can both condense and communicate the material. Here again I found his examples and formulations very helpful.

Psychiatrists who spend some time reading these papers by Walter Bonime will be well rewarded and will appreciate his clarity and openness. They will gain from his broad clinical experience and his unique approach to many problems that we all experience in our efforts to help people with their emotional problems.

**Psychoanalytic Terms and Concepts,** *edited by Burness E. Moore, M.D., and Bernard D. Fine, M.D. New Haven, Conn., Yale University Press, 1990, 210 pp., $35.00.*

The misuse of psychiatric and psychological nomenclature appears to be widespread (1). Psychoanalytic terms seem to be abused with particular frequency and, disturbingly, often by mental health professionals. Gabbard (2) pointed out the common overuse and misuse of the term "splitting." O'Boyle and White (3) noted the habitual use of the term "acting out," which has a precise psychoanalytic meaning, to refer to "virtually any misbehavior exhibited by children or adolescents." As a final example, I have observed many nonanalytically oriented psychiatrists and psychologists, who publicly eschew psychoanalytic thought, inappropriately use the term "countertransference" to refer to any emotional reaction therapists have toward patients.

In the light of all this, a book that offers well-written definitions and explanations of psychoanalytic terms is welcome. *Psychoanalytic Terms and Concepts* is such a volume. It contains lucid explanations of psychoanalytic terms as well as caveats about their frequent misuse, but this book is far more than a glossary. Most entries contain information on the development of the term, alternative usages, and cross-references to related terms. Additionally, the text is well referenced. Virtually every entry contains several key citations. The importance of this cannot be underestimated because even the best brief explanation of an abstract concept is necessarily limited. The inclusion of key citations enables serious scholars to obtain more detailed information.

There are also some mentions of alternative theoretical positions from research areas outside the strict psychoanalytic realm. For example, the entry on anorexia nervosa states that "various medical and sociological factors, including the widespread fear of being fat, seem to play a part in the increased incidence of cases." Thus, true to Freud's original formulations, it is recognized that hypothesized psychodynamic factors operate within broader biological and cultural contexts. To their credit, the editors have ensured that some entries note the extent to which theoretical hypotheses are supported by empirical data. Although this area could probably be improved by more extensive and frequent statements, such a change would necessitate changing an essentially well-annotated dictionary into an encyclopedia.

Finally, in this age of reference tomes costing more than $100.00, this brief but still comprehensive source is modestly priced. In short, there is much to recommend this volume to students, teachers, clinicians, and scientists.

The goals of science are generally taken to be the prediction, explanation, and control of natural phenomena. Each of these is predicated on the precise description of these phenomena through a shared language. Freud stated that "even in its caprices the usage of language remains true to some kind of reality" (4, p. 111). *Psychoanalytic Terms and Concepts* may help our use of psychoanalytic language to be a little less capricious and a little more true.

**Dimensions of Psychoanalysis,** *edited by Joseph Sandler. Madison, Conn., International Universities Press, 1990, 263 pp., $35.00.*

University College, the oldest of the colleges of the University of London, instituted a visiting Freud Memorial Chair in 1974. Holders of the 1-year professorship traditionally gave an inaugural lecture, and this volume contains those given until the chair was converted to a 5-year position in 1984. Joseph Sandler, the first long-term holder of the Freud Memorial Chair, is the editor of these 12 papers by 11 internationally recognized psychoanalytic scholars. Having also been an earlier 1-year professor, Sandler contributes two papers as well as an introduction. Most contributors are clinical analysts. The lectures include American, British, and French views. As could be expected, all of the papers are excellent.

Sandler claims that the lectures demonstrate how much and how fruitfully psychoanalysis has developed since Freud's death. He is correct, of course, and that makes this book of particular value to those psychiatrists who have not kept current with psychoanalytic ideas over the past decade and a half. I refer not only to progress within the Freudian tradition but also to the greater acceptance of clinical theory based on the contributions of Melanie Klein. This development is represented in the volume by both Hanna Segal's lecture and Sandler's own recognition of the increased interaction between the Freudian and Kleinian points of view. His position is that there is no necessary incompatibility between a psychology based on unconscious wishes and an object relations psychology.

Although the lectures cover vastly different topics, themes recur. The importance of the real world as well as the private, personal, internal world of fantasy and affect appears in work as far apart as that of John Bowlby on attachment and separation, Christopher Lasch on "The Freudian Left," and Janine Chasseguet-Smirgel on perversion. The importance of the preoedipal phases of development and the question of whether psychoanalysis is a science or an art reverberate through several papers.

Roy Schafer's chapter introduces his now well-known view that psychoanalysis needs a new language to replace Freud's metapsychology, a language based on a conception of personal existence as actions with multiple and transformable meanings. William Gillespie deals with basic Freudian ideas and does this briefly, clearly, and well. Hanna Segal uses case material to illustrate the developmental progression from split-off omnipotent fantasy to thought and the freedom that this engenders. Sandler notes that it is untenable to derive all unconscious wishes from sexual and aggressive impulses—that wishes to restore the feeling of security or self-esteem or well-being or a lost object are of equal significance. Andre Green proposes a category of tertiary thought process—beyond Freud's primary and secondary processes. He then goes on to discuss patients for whom the love of others is always uncertain but hatred is always sure—for whom fixations on hatred are much more tenacious than fixations on love.

Bowlby's chapter succinctly summarizes the source and product of his own work on attachment, separation, and loss. Christopher Lasch describes why psychoanalysis has more to say on the psychology of power than any other theory of the mind and why this appealed to elements of the political left. Karl Pribram argues that psychoanalysis would suffer a substantial loss if it abandoned its energy concept in favor of modern formation-process ideas. He reviews the experimental analysis of the neural mechanisms involved in motivation and emotion and claims that such work clearly argues for the primary transformations of energy in the behavioral economy of living systems. John Klauber's paper takes up the role of illusion in psychoanalytic treatment—by which he means the nature and value of surrender to the transference induced by psychoanalysis. Chasseguet-Smirgel presents her view that perverse temptation leads to the acceptance of pregenital desire and satisfaction as equal or superior to genital desire and satisfaction because such an objective erodes the differences between the sexes and the generations. In her view, perversion is an attempt to free oneself from a paternal universe and the law.

Albert J. Solnit's lecture deals with preparing a child for potentially traumatic experience so that remembering can contribute to development rather than impair it. Solnit's case material is particularly illuminating as well as affectively moving. Sandler's concluding chapter asks whether the concept of the child within the adult may not be a better way for the clinician to help the patient become friends with the previously unacceptable parts of himself than the concept of id.

As a collection, these papers make me a bit sad that the inaugural lectures of the Freud Memorial Chair are no longer an annual event.

## PSYCHOANALYTIC CONTROVERSY

**Melanie Klein, vol. I: First Discoveries and First System 1919–1932,** *by Jean-Michel Petot; translated by Christine Trollope. Madison, Conn., International Universities Press, 1990, 313 pp., $40.00.*

Melanie Klein represents a historically important extension of psychoanalytic thought. During her lifetime (1882–1960) she established her own school in Great Britain, which has continued to be influential there and has subsequently had a notable impact on Latin America and now elsewhere as well. When she first started developing her theories, Freud saw her work as a challenge to himself that took the form of an attack on the efforts in child analysis of his daughter Anna. As the years passed, Klein developed her ideas into what she considered a "system." She took a different approach, for example, to the psychology of women, she worked with play as a technique for treating children, and she sought to link normal development much more closely to psychotic problems than so-called classical psychoanalytic theory has ever accepted.

A fierce debate over Kleinianism raged within the British Psycho-Analytical Society toward the end of World War II. Klein and her supporters not only succeeded in not getting repudiated as "heretics" but, in the end, it was Anna Freud who felt obliged to resign from a post in the British Society in order to spend her efforts at her own child therapy clinic in Hampstead. Although the British Society remained formally united, two separate training streams were set up within it so that Anna Freud's students would not have to be involved with the concepts that Klein cherished.

*Melanie Klein, vol. I* is a curious book. Perhaps the single most notable point to comment on is that it first appeared in France in 1979. Since this text covers Klein's work only in its first phase I am reluctant to generalize about all Petot has to say, but there is enough here to be disquieting, not just about the nature of Kleinianism but about the state of publishing in the United States and the history of psychoanalysis here as well.

I cannot understand how the publisher could allow this 1979 book to appear in translation without any attempt to bring the material up-to-date. A lot of historical research has appeared over the last decade, and it seems irresponsible to allow an old text to come out without a new introduction, by the author or someone else, trying to incorporate recent research into the story as originally reconstructed in 1979.

Furthermore, Petot seems to have an inadequate amount of distance toward Klein's theories. We are told, for instance, that the child patient in an early 1921 paper of Klein's was really her youngest son. I am troubled by the fact that Petot makes no effort to come to terms with the moral propriety of Klein's having treated her son. Furthermore, it is now evident, although Petot did not know it in 1979, that Klein analyzed her two other children as well and put them into her writings as disguised clinical cases.

Even more fundamentally, I would question the correctness of describing Klein's writings as in any sense "discoveries," as proclaimed in the subtitle to this book. As far as I am concerned, Freud himself contributed a critical new way of looking at things; to call his concepts, or those of any of his followers, "discoveries" has to imply a degree of scientific standing that is belied by the very nature of the kind of unreconstructed text that *Melanie Klein, vol. I* constitutes.

Science entails change and fresh developments, as well as the possibility of confirmation. The fact that the publisher felt free to bring out a 1979 text without revising it in the light of new knowledge indicates something of the nature of the essentially religious side of what has happened to all too much psychoanalytic literature.

Those outside psychoanalysis have long bewailed the absence of genuine research in this field, and the publication of this book only confirms the worst that critics have thought Freudians have been up to. Melanie Klein herself not only lacked medical training but never attained any kind of higher education; her ideas might of course be sound nevertheless, but it is striking that she proposed that the psychoanalyst's task was to "cure" all children of their so-called psychoses, an enterprise that I myself have to regard as a menacing kind of proposed enterprise.

General readers deserve help in trying to understand Klein's work, even if they cannot swallow the idea that she succeeded in creating a theoretical structure which deserves to be analyzed and interpreted as if it were a developing holy writ. Petot's book is not reliable as history. If readers want to look at an interesting account of another early child analyst, I can highly recommend *Hermine Hug-Hellmuth: Her Life and Work* (1).

**The Freud-Klein Controversies: 1941–1945,** *edited by Pearl King and Riccardo Steiner. New York, Tavistock, 1991, 958 pp., $175.00.*

Unfortunately, the outrageous price of this book will preclude its receiving the widespread attention and readership that it deserves. The controversial problems that were introduced into psychoanalysis by Melanie Klein reached a crisis situation in the British Psycho-Analytical Society shortly after Freud's death in 1939. This produced a series of "extraordinary business meetings" and "scientific controversies" in the Society, and the book under review contains the minutes of these meetings and the papers and discussions presented in the scientific controversies, without slant or partisan remarks by the editors (who do, however, add some clearly marked and helpful "editorial comments"). As such, it represents an extremely valuable contribution to the history of ideas and the history of psychoanalysis.

Even more valuable are the descriptions of the incredibly personal narcissistic and other investments that are demonstrated here as underlying apparent "scientific disagreements" in the field. Stein (1) recently pointed out that countertransference has a hitherto unrecognized important further source, "deriving from the utilized theory of the analyst. This countertransference may occur independently of the patient's motivation and independently of the internal dynamics of the analyst." The powerful investments in various theories and the personal rancor with which they are debated are better illustrated in *The Freud-Klein Controversies* the volume under review here than in any other long volume in the field to my knowledge.

The reader should keep in mind that the background of these controversies is World War II in England, including the London "blitz" during which some analysts left the city and others intrepidly carried on what functions were possible. This was complicated by the influx of refugee psychoanalysts from Europe, including the Freuds themselves, and the inevitable chaos, competition, and confusion that such an influx as well as the horror of prolonged bombing and the deprivations of war always bring. Even more painful is the fact that the most outspoken and vitriolic attacker of Melanie Klein and the Kleinians who followed her was Melitta Schmideberg, Melanie Klein's daughter. In a way, it is to the credit of British civility that the matter became resolved without an actual fragmentation of the British Psycho-Analytical Society. King tells us,

> Overtly, controversy was mainly couched in terms of scientific differences of opinion about what was considered to be accepted psychoanalytical theory and technique, as formulated by Freud, and what view of it should be taught to students of psychoanalysis or included in public lectures by analysts representing the Society. Inevitably, these issues also masked deeper ones to do with who should decide these questions, and therefore, which individuals and groups held power in the Society. (p. 9)

Klein's work caused controversy in the Society because she treated children's play as if it were the equivalent of an adult patient's free associations and because she interpreted negative material and aggressive impulses of adult patients when they appeared "without the customary nurturing of the positive affects of the patient, without which it was widely held in the Berlin Society that psychoanalysis could not proceed" (pp. 18–19). This controversy continues today in the arguments between the followers of Kernberg and the followers of Kohut (2). The British Society debate was between the followers of Klein and the followers of Anna Freud, who held that it was important to foster a positive response from the child and that a transference could not develop in child analysis because the affects of the child were still tied to their parents. So Anna Freud's approach was more educative and explanatory than interpretive. Klein's critics also objected, as they do today, to her emphasis on fantasy to the neglect of environmental factors, her interpretation of Freud's concept of the death instinct, her early dating of the development of the superego, and her confusing concept of "internal objects." As anyone who has attempted to teach Melanie Klein's views to residents in psychiatry will attest, they are among the most difficult to accept at face value and seem to the residents as they did to Walter Schmideberg, who tells us in the book under review,

> Papers became more and more confused as the years went by. I listened to them in silence and some of them made me think that the accusation of our enemies that it is impossible to distinguish between the phantasies of the patients and those of the analyst contained more than a grain of truth. Reality seemed to disappear or become distorted. Everything was internalized and still more internalized. I sometimes thought I was following Alice through the looking glass and even seemed to hear the voice of the Mad Hatter. (p. 86)

Still, as Holland (3) has pointed out, fundamental insights can emerge from such controversial discussions, and the most important part of the book for those immersed in the clinical practice of psychotherapy or psychoanalysis contains the reports of the scientific discussions themselves. As Steiner (4) noted, there is also much to be learned from an examination of the power struggles and narcissistic investments demonstrated in the Freud-Klein controversies for those who are involved in the current power structures and hierarchies of organized psychiatry and psychoanalysis.

For the ordinary working clinician the crucial issue is to what extent the Kleinian point of view has validity and usefulness in everyday practice. Here the central part of the book (sections two, three, and four) is most valuable and requires careful study. I wish the publisher would produce selections from this central part in an inexpensive paperback because it would be a great act of kindness to students who must study this material but cannot afford $175.00 for one book.

There is no space in a review to outline in any greater detail the opposing scientific points of view that are covered in this book (Anna Freud does this beautifully on pages 417–425) as well as some of the problems described that seem to occur inevitably in the system of psychoanalytic training carried out by training analysts—problems of identification, indoctrination, and the continued relationship of training analysts and candidates after the cessation of the so-called training analysis.

These problems, of course, have been recognized elsewhere; they reached their peak of scandalous proportions in the dramatic vicissitudes of Jacques Lacan and his ever-changing schools and alliances during his meteoric career in France.

It is important to note that "unconscious phantasy" is deliberately spelled with a "ph" throughout the book in order to differentiate it from conscious "fantasy," as explained on page 242. This distinction has largely dropped out of the current literature. This is no minor issue, since one of the most caustic debates rests on the fact that Anna Freud and her colleagues could not accept the notion of "unconscious phantasy" as central to the first months of the life of the baby, especially the violently aggressive "phantasies" emphasized in Kleinian theory. The notion of "unconscious phantasy" became central in the controversies; Anna Freud's followers accused the Kleinians of an increasing mysticism based on it, and the Kleinians saw it as the key to more and more scientific discoveries and explanations of various forms of adult psychopathology. As Steiner explains here, "The notion of unconscious phantasy therefore became the theoretical rampart, the scientific paradigm, around which the Kleinians organized their defense and the weapon they used to lead their attacks" (p. 253).

The thrust of American psychiatry today seems to be away from the Kleinians in that more emphasis is placed on the actual environmental events that surrounded the child and infant than on the unconscious fantasy life that is so difficult to investigate and validate, but the matter is largely unsettled. It is extremely important to differentiate Klein's views from those of Anna Freud's traditional psychoanalysis. According to the Kleinians, "phantasy is the mental corollary, the psychic representative of instinct" (p. 277), but in the traditional view unconscious fantasies are already compromise formations in the Freudian drive/conflict/anxiety/defense/compromise sequence. Of course, for the Kleinians fantasy can also be a means of defense against anxiety, but their notion, as the fiery Glover points out (pp. 397–400), is far more basic, developmentally earlier, and all-encompassing than Freud's "hallucinatory wish fulfillment" because, for them, "phantasy expresses the specific content of the urge (or the feeling, e.g., hate, anxiety, fear, love, or sorrow) which is dominating the child's mind at the moment" (p. 277). This leads to the Kleinian claim that "fantasy is the primary content of all mental processes" (pp. 276, 334). It is hard to imagine how this could be verified.

I highly recommend this wonderful book for advanced students in the field of psychiatry, especially those who are interested in doing psychotherapy or psychoanalysis, those who are interested in rising in the power hierarchy of organized psychiatry and psychoanalysis, and those who are involved in a study of groups or group processes.

The Prisonhouse of Psychoanalysis, *by Arnold Goldberg. Hillsdale, N.J., Analytic Press, 1990, 175 pp., $26.95.*

The intriguing title of this book refers to the constraints of psychoanalysis. Goldberg appreciates that every discipline has its limitations, whether imposed by the dominant paradigm, simple ignorance, the priorities of education, publication, and funding, or, more insidiously, by pressure for conformity that usually accompanies acceptance into the select inner circle, i.e., those certified by a Ph.D. or M.D. membership in the American Psychoanalytic Association, etc. Psychoanalysis, with its dependence on N=1 research studies, the requirement of a long personal treatment in which one's personality is analyzed, and its tendency toward the deification of important contributors, may be particularly prone to all these constraints. This is not to argue that constraints are a necessary—or unnecessary—evil. They can also be a source of discipline and modesty and a stimulus for creative endeavor. Goldberg's concern is that in psychoanalysis the constraints have become subversive and the existing discipline of psychoanalysis has become a prison house as a result. The author is a widely read and highly esteemed psychoanalyst whose credentials are excellent. He speaks as both an "insider," having successfully mastered traditional analysis, and an "outsider," a leading proponent and co-creator of the self psychology of Heinz Kohut, which has been one of the major efforts in the last two decades to revise traditional psychoanalysis.

The book is far-ranging. The first chapter discusses the deterioration of psychoanalytic practice into meaningless clichés. Psychotherapists, particularly inexperienced ones, will enjoy Goldberg's discussion of such issues as abstinence, honesty, and attentiveness in therapy. Later chapters are more original. His comparison of addiction, hero worship, and the rigid codification of rules in psychoanalysis as a means of overcoming personal loneliness and providing insulation against uncertainty is interesting. The most original aspect of the book is his discussion of the role of internal representations in the mind and how they relate to treatment. Goldberg compares Freud's notion of an inner world distorted by conflict and desire, Lacan's inner world of unending unsatisfying signifiers, and Kohut's rejection of any theory of the inner world as incomplete and needing the external world to complete it. Freud and Lacan have "storehouse" theories, whereas Kohut's theory is a "connection" theory. The connection between self and object, the famous self-object theory of Kohut, is well elaborated. Goldberg attempts to define it and distinguish it from a theory of object relations and interpersonal theory.

Goldberg has a knack for discussing psychoanalytic issues within a larger context of philosophy, linguistics, literature, and science. He is at his most eloquent in proposing that the principal prison house of psychoanalysis is its imprisonment of practitioners within an incorrect theory of mind. "We are locked within a boundary wall and are so separated from each other and other ideas. We must recognize our coupling with others" (p. 128). He can also become passionately philosophical. In his chapter on the self in psychoanalysis and the importance of self-objects he writes, "The process is one of discerning the nature of those group and cultural selfobjects which encourage development, which promote a being-in-the-world that does away with the isolated individual in a sea of separate objects, and which is liberated from the prevailing sense of survival that so sadly dominates our psychoanalytic thinkers."

The book might have benefited from better editing. What seems to be petty swatting at people who have injured Dr. Goldberg's feelings does not really contribute to the more original and important discussions in the later chapters. Also there is a tone of dogmatism about the book that might stimulate strong feelings rather than thoughtful discussion in some readers. In a story that is humorous but perhaps more cynical than intended, Dr. Goldberg reports how he and a colleague listened to the presentation of a third colleague. As Dr. Goldberg formulates his objections to the presentation he realizes that the colleague sitting next to him is doing the same thing and that each knows what the other is going to say. The speaker is described as taking a "rather one-sided and biased position." Goldberg makes no comment on what the presenter and the colleague next to him would say of his own position. We never find out. They leave the discussion to go for a cup of coffee. More of an "over a cup of coffee tone" would have helped the book.

Nevertheless, I recommend this book. It should be of interest to most readers of the *Journal* who are psychodynamically and/or psychoanalytically oriented and who would like to know what one worthy critic of much of this scene has to say.

MICHAEL H. SACKS, M.D.
*New York, N.Y.*

**The Freudians: A Comparative Perspective,** *by Edith Kurzweil. New Haven, Conn., Yale University Press, 1989, 362 pp., $35.00.*

Professor Edith Kurzweil, Chair of Sociology at Rutgers University and Executive Editor of *Partisan Review,* has performed an unexpected service for American psychiatry. Her book, which can be read on many different levels, will be invaluable and essential reading for all practicing clinicians, whatever their persuasion.

For the nonanalytically informed clinician the four chapters constituting part two, Applications of Psychoanalysis, locate the contribution of psychoanalytically informed thought to psychosomatic medicine, education, the psychology of women, literature, and criticism. The chapter on the psychology of women is invaluable in indicating how far psychoanalysis has moved from its initial promulgation of sexual stereotypes as "science" to an emerging tool for the critique of stereotypes. For the psychoanalytically sophisticated clinician, part one, Psychoanalysis Before 1945, is a superb cross-cultural history of the development and reception of Freud's theory in a variety of social contexts.

I would expect that all clinicians would benefit from reading part three, Psychoanalysis Since 1945. In particular, chapter 11, "Theoretical Innovations," is simply the best summary of the current state of psychoanalytic theory and technique. For example, when explicating the contributions of Otto Kernberg, Professor Kurzweil shows how psychoanalysis has not only enriched the cultural context with which it has come into contact but also been influenced and enriched by its contact with a variety of social contexts and influences. At the same time, her summary of Kernberg's work is simply the best brief introduction I know of.

Professor Kurzweil is such a capable synthesizer that I can only hope she will continue to pay attention to and report on new developments in psychoanalysis. For example, the influence of the pioneering work of Alan Stone, Professor of Law and Psychiatry at Harvard Law School, is seminal to our understanding a wide range of pressing medical, ethical, and legal issues. At the same time, attempts at integrating psychoanalytic innovations with neurobiological models, such as Arnold Modell's, show promise of bridging the gap between biological and psychological understanding of that improbable, wonderful work we call man. Professor Kurzweil's attention to context is most welcome, as these and other pioneering efforts proceed to bear both clinical and cultural fruit.

## NEUROBIOLOGY

**Neurobiology of Stereotyped Behavior,** *edited by Steven J. Cooper and Colin T. Dourish. New York, Oxford University Press, 1990, 297 pp., $65.00.*

The broad title of this book is misleading and unfortunate. Once one gets over the disappointment over its relatively narrow focus, however, *Neurobiology of Stereotyped Behavior* is a useful update and review of neuropharmacological and behavioral understanding of stereotypy, primarily in rodents. Of the 20 contributors, half are from the United Kingdom, and almost all are basic scientists—neurochemists, pharmacologists, or experimental psychologists.

The editors provide a splendid introductory historical overview of the concept of stereotypy and the role of brain dopamine. For anyone graduating from medical school after 1960, this brings an important perspective as to the role of basic research on dopamine pathways and on psychostimulant-induced stereotypies in early formulations of schizophrenia. The recognition that dopamine is a major neurotransmitter in the normal mammalian brain, that brain amine metabolism is crucial for amphetamine-induced stereotypy, and that the location of CNS site is qualitatively important for stereotypies were seminal for an entire generation of psychiatric theories.

The greatly increased complexity of our understanding of the receptors mediating stereotypy is elaborated in a series of chapters on dopamine subtypes and stereotyped behaviors. For example, there are chapters on the role of $D_1$ receptors, the neural basis of drug-induced yawning (complex, catecholaminergic, serotonergic, and peptidergic) and the fascinating association between induction of yawning and of sexual excitation, neuropeptides and stereotypy in behavior, and stereotyped and other motor responses to 5-hydroxytryptamine (5-HT) receptor activation. All of these chapters provide lucid introductions that are useful to the experimental psychologists who may read the book as well as to the occasional clinician-researcher.

Researchers in obsessive-compulsive disorder will be particularly interested in the role of neuropeptides, particularly in grooming behaviors. The complex interplay between dopamine and ACTH-induced grooming (chapter five) as well as its role in 5-HT receptor activation is also provocative in the light of the increasingly complex psychopharmacology of compulsive rituals in obsessive-compulsive disorder.

There are also chapters on transmitters demonstrating different aspects of control of stereotyped or repetitive behaviors. These are less successful for the general reader, although the point is made that there are complex influences on the amount and type of stereotypies over and above drug dose and dopamine pathway. More general issues such as possible adaptive role of stereotypies, the question of a continuum of behavioral activation, and relevance for models of mental health are interesting, but the extensive microanalyses of behavior are not convincingly useful.

The explosion of research on compulsive ritualized behaviors makes this work of more topical relevance than it would first seem. For this reason, I recommend it to researchers in obsessive-compulsive disorder and the curious clinician occupied with mental retardation, obsessive-compulsive disorder, or any neuropsychiatric disorder with excessive repetitive behaviors.

JUDITH L. RAPOPORT, M.D.
*Bethesda, Md.*

**An Introduction to Neurotransmission in Health and Disease,** *edited by P. Riederer, N. Kopp, and J. Pearlson. New York, Oxford University Press, 1990, 394 pp., $98.00.*

This book is quite a buffet with many courses, a gluttony of neurotransmitter science with a great variety of dishes. As the internal structure reveals, it is written in the European tradition of biochemical and pharmacological presentations. The book is divided into sections such as General Phenomena Involving Neurotransmission, Neuroendocrinology, Central and Peripheral Autonomic Nervous Systems, Locomotion, and Emotion, Pain and Addiction (which includes the psychiatric disorders). The final section, Higher Cerebral Function, deals with pediatric topics, ischemia, dementia, coma, and epilepsy. There are chapters on the anatomical distributions of the monoamines and peptides, amino acids, neurological and psychiatric diseases, the biochemical changes following coma and brain ischemia (which one day will lead to rational treatment of the damage of strokes and spinal cord trauma), memory, and developmental, degenerative, and acquired diseases of the autonomic nervous system such as the Shy-Drager syndrome, as well as pediatric disorders such as sudden infant death syndrome.

The excitement of the neurosciences is that different disciplines need each other to advance the field, each nibbling away on small pieces of the many puzzles that the brain poses. Psychiatric disorders have found a place in the neurosciences and may well have been the primary stimulus for studying the brain. This book is compiled by neuropathologists, neurochemists, and neurologists, with minimal input from psychiatrists as far as I can determine. Only a decade ago neurologists were grossly uninterested in neurotransmitters and their mechanisms in the brain or in the autonomic nervous system. It seems as if with this book the neurologists are reclaiming the neurosciences. We should not forget that Freud was first of all a neurologist who made his name in aphasias, then as a pharmacologist, and finally as a psychiatrist. Interestingly, reading this book, it seems as if the mental health neuroscientists have not been the major promoters of the neurotransmitter studies from the beginning. Schizophrenia, the most mysterious of the psychiatric disorders, as well as depression, anxiety, and alcoholism, are presented as mere syndromes by nonpsychiatrists.

Unfortunately, this book is a product of its grand design. Bringing so many scientists together in an integrated text is not a small accomplishment. It is even more difficult when editors and contributors come from the United States, France, Germany, England, Belgium, Hungary, Pakistan, and Japan. Not unexpectedly, this books suffers because the interval between writing and publishing was too long. As the editors point out, being out of date is certainly a risk of the fast-moving neuroscience literature. It may explain why many of the chapters do not have references beyond 1986, except for some updates. On the other hand, there is enough information to provide beginning students or scientists who are looking to branch out into new directions an adequate basis to build on.

In its concept the book is clearly a product of the mid-1980s. Indeed, it misses such recent exciting developments as diazepam binding inhibitor; dopamine $D_3$, $D_4$, or $D_5$ receptors; G proteins; neurosteroids; membrane phospholipids; brain autopsy studies of peptides in schizophrenia; the presumed mechanisms of cocaine addiction; and ethanol interaction with the chloride channel/$\gamma$-aminobutyric acid$_A$ receptor complex, but that is unavoidable. As Pearlson states in his introductory chapter, "It is fairly easy to begin analyzing the human nervous system and its diseases but impossible to finish" (p. 7). On the other hand, there is little conjecture; the basics are there.

Pearlson also notes that "in approaching the analysis of the brain and its diseases it is necessary to be cautious of dogma and open to heterodox; indeed the probing brain needs to be as intelligent and plastic as it is capable of being. Current efforts are imperfect but a considerable degree of success has been achieved" (p. 19). The editors of this book have done a service to the field to summarize disparate neuroscience phenomena, illnesses, behaviors, and physiological functions as they relate to neurotransmitter function and make them accessible. In the preface the editors state that the book is meant to be an introduction to students of the different disciplines that make up the field of neuroscience as well as for more established scientists to see their work in a broader context, in the hope that cross-fertilization may occur. Psychiatric and neurological residents could make good use of it as well. As the editors stress, the book may lead to collaborations. I enjoyed the book, discounting an occasional typo. The diagrams emphasized by the editors, although not present in all chapters, increase its readability. In a way it may belong to the classics of neurosciences such as *Psychopharmacology: The Third Generation of Progress* (1), *The Biochemical Basis of Behavior* (2), and *The Neurobiology of Spinal Fluid* (3, 4). It appears that the editors achieved what they set out to do. I will be looking forward to a second edition or an update in a few years.

*Pittsburgh, Pa.*

**Amino Acids in Psychiatric Disease,** *edited by Mary Ann Richardson, Ph.D. Washington, D.C., American Psychiatric Press, 1990, 190 pp., $22.50.*

This volume in the Progress in Psychiatry series reviews the roles of a number of precursor amino acids in psychiatric disease. Initially, the almost total absence of discussion regarding the neurotransmitter amino acids was disconcerting for a book with this title; perhaps adding a modifier (e.g., precursor, neutral, plasma, etc.) would more accurately reflect its content. The amino acids under discussion include tyrosine, L-tryptophan, and phenylalanine (precursors or modifiers of monoamine synthesis and function), not glutamate and $\gamma$-aminobutyric acid (GABA) (neurotransmitters). Despite the limited scope of the volume relative to its title, the topics covered are of great interest as applied to a wide range of psychiatric diseases. These are topics that were formerly at the heart of psychiatric neuroscience research, given its emphasis on the monoamine neurotransmitters dopamine, norepinephrine, and serotonin.

As other neurotransmitter systems involved in mental processes have gained in importance, the "traditional" amines have moved from center stage to part of the chorus. Unfortunately, as our scientific focus changes we sometimes forget the value of former approaches in our excitement over "new" findings. This volume nicely illustrates that exciting progress is still underway in an area of psychiatric neuroscience that was in vogue, then was eclipsed, but may be poised for a stimulating renaissance based on the work of the contributors to this volume. The theme of an abnormality in amino acid membrane transport manifesting as mental illness is recurrent throughout the book—seven of the nine chapters relate to this idea in considerable detail, and the other two mention the significance of such alterations.

The chapter by the editor on plasma phenylalanine and vulnerability to tardive dyskinesia presents an intriguing hypothesis regarding predisposition to tardive dyskinesia based on abnormal metabolism of this amino acid. The theory rests on the findings of greater-than-expected rates of tardive dyskinesia in individuals suffering from phenylketonuria and the finding of significant correlations between plasma phenylalanine and tardive dyskinesia. There has been a notable lack of progress in the identification of other pharmacological risk factors for tardive dyskinesia, and this approach may yield an explanation of why this has occurred. In a similar vein, the paper by Moller demonstrates how plasma amino acid ratios may predict antidepressant efficacy better than clinical or pharmacokinetic variables.

Given the known actions of antidepressants on monoaminergic systems it is quite reasonable that much effort would go into understanding the regulation of these neurotransmitters. This topic is covered very thoroughly. If anything, the discussion of catecholamine regulation by amino acids is somewhat redundant, especially in the light of the complete omission of any discussion of, for example, the role of GABA in anxiety disorders or benzodiazepine function. What is presented here is well thought out and thorough, but I hope the next edition will include specific discussions of the neurotransmitter amino acids with their implications for psychiatry, including anxiolytic function, regulation of neurotransmission, and the possible role of excitotoxicity in neurodegenerative disorders.

*Iowa City, Iowa*

**The Clinical Relevance of Kindling,** *edited by Tom G. Bolwig and Michael R. Trimble. New York, John Wiley & Sons, 1989, 312 pp., $67.50.*

In 1967 G.V. Goddard demonstrated that repeated administration of subconvulsive electrical stimulus to different areas in the brain (especially in the olfactory-limbic system) of laboratory animals could lead to the gradual development and intensification of behavioral convulsions. This "kindling" phenomenon occurs under explicit circumstances of intracerebral, spaced, discrete, repetitive subclinical stimulation in specific brain regions in sensitive individuals. The clinical effects of kindling are long-lasting, and permanent changes (reactive gliosis, for example) in the brain of kindled animals have been reported.

Although kindling in the strictest sense cannot intentionally be demonstrated in man, many researchers have been excited by the similarities between the phenomenon and certain clinical conditions. Not surprisingly, a kindling model for epilepsy, especially temporal lobe epilepsy, has been proposed. But there are also suggestions of connections between kindling and personality disorders, panic attacks, manic-depressive illness, schizophrenia, alcohol and cocaine withdrawal, and movement disorders. This seems a fairly large expectation for the explanatory power of the kindling model. In some instances, the authors use the term "kindling-like" phenomenon, preventing the reader from a too-close connection between kindling and psychopathology. In fact, most of the contributors clearly state the lack of evidence for a kindling model in any of the clinical conditions mentioned here. Consequently, they generally call for future research to clarify the field.

We are living in a time when psychopathology badly needs brain models to lean on. Links between basic neuroscience and clinical manifestations of brain disorder are to be welcomed. This book clearly demonstrates that the kindling model stands as one of the few and most interesting of such bridges in the field of neuropsychiatry. As one of the authors puts it, "The attempts to account for different clinical syndromes . . . by a kindling-like phenomenon certainly demonstrate some heuristic value of this concept in biological psychiatry. However, a claim for construct validity definitely awaits future animal and clinical studies."

This book, the result of a symposium that gathered the main specialists in the field, covers a wide range of topics relative to kindling. Clinical relationships occupy several chapters, but reviews of basic aspects of kindling, kindling and memory and learning, chemical kindling, and kindling and antiepileptic drugs are also included. Of special interest to the clinical psychiatrist is the chapter on kindling and ECT by M. Fink, who vigorously rejects the analogy between these two kinds of electrical brain stimulation. Not only psychiatrists but also neurologists, epileptologists, and neuroscientists will find interesting and useful insights and information in this book.

*Barcelona, Spain*

## NEUROPSYCHOLOGY

**Clinical Neuropsychology and Brain Function: Research, Measurement, and Practice,** *edited by Thomas Boll and Brenda K. Bryant. Washington, D.C., American Psychological Association, 1988, 202 pp., $24.00.*

This short work is composed of lectures in neuropsychology from the American Psychological Association's 1987 annual meeting. Animal studies and human studies are covered.

Stein begins the book with a chapter that criticizes the functional localizationist paradigm. He offers an alternative, namely, that the context in which CNS trauma occurs may powerfully contribute to the severity of an injury. His own classic work has focused on the differential effects of serially staged compared with single-stage lesions. The sequelae of the former are less severe than those of the latter. This finding is of obvious clinical relevance. On the other hand, Stein's attempt to minimize the role of the hippocampal-amygdala system in memory is probably misguided, given the amount of convergent evidence from primates, penetrating head wounds, and dementia. One caveat is that Stein's chapter does not bear directly on the issue he first raises—the existence of discrete processing modules.

Thompson's lecture is conversational in tone and rich in detail. He has posited that the mossy-fiber granule-cell parallel-fiber system and the climbing fiber system are learning and teaching units in the rabbit cerebellum. He goes on to claim, with evidence to support his position, that memory trace circuits are localized. Thompson's work is internationally recognized. I only wish he had added a section on the theoretical distinction between the classical conditioning paradigms, including eye blink, thought to be "procedural," and declarative or representational memory, which might involve diencephalic and medial temporal lobe neural systems in humans.

Dennis presents a model for conceptualizing the effects of brain damage in children. In her ambitious effort to create such a framework, the actual data to support her ideas are shortchanged. After creating the framework, she presents complicated data in a clear and focused way. For instance, she shows how the systems that are involved in the development of an ability may be different from those which sustain the ability. Regarding her work on early left hemisphere injury in children, I wish she had addressed the work of Smith and Chadwick, who did not find marked language deficits after such insults in children. Dennis also presents evidence for the etiology and neuropathology of language disorders based on factor analysis and multiple regression. Despite the rarefaction of data imposed by her statistical techniques, her results and conclusions are fascinating.

The process approach advocated by Kaplan for neuropsychological assessment is beautifully presented. The chapter is full of clinical pearls and abounds with figures and illustrations that perfectly make Kaplan's points about different types of cognitive failure. In short, Kaplan attempts to quantify subtle aspects of neurobehavior that are usually deemed qualitative. She discusses in depth her modifications of such well-known tests as block design, digit symbol coding, and the Rey figure. For instance, in block design she has found that breaking the configuration of a design is often associated with right hemisphere lesions. In digit symbol coding, she includes versions that assess purely motor speed, learning, and attention in order to break down the task into its cognitive components.

Using valid and invalid cues to measure covert shifts of visual attention, Posner demonstrates how "disengage, move, and engage" operations are mediated by the parietal lobe, midbrain, and thalamus. All studies use reaction time as a measure. Posner extends his interest in automatic and effortful aspects of attention in an elegant study of the successive cortical systems involved in reading silently, reading aloud, and generating uses for words. Posner also reports on his recent studies on schizophrenia in which he detected an abnormality involving the right visual field and the left anterior brain. These results have provoked controversy because it is unclear if they reflect a lateralized "lesion" or a bilateral "lesion" superimposed on a lateralized function.

All of the authors included in this book have made seminal contributions to the study of the relation between brain and cognition. The book will be especially worthwhile to advanced graduate students in neuropsychology and residents in psychiatry and neurology. Practitioners and researchers can gain important information from the lectures as well and have their theoretical ideas on how the brain works challenged in chapters presented with style and erudition.

**Contemporary Neuropsychology and the Legacy of Luria,** *edited by Elkhonon Goldberg. Hillsdale, N.J., Lawrence Erlbaum Associates, 1990, 270 pp., $45.00.*

It would seem that it should be an easy matter to assemble a volume in honor of A.R. Luria. His interests were diverse, and his reliance on theory was explicit. Furthermore, he was able to inspire not only respect and admiration but also loyalty and affection. Contributors to the present volume either studied under his direction or believe that they apply his approach to neuropsychological analysis. In every case an interesting piece of work or thought is presented. And yet it cannot truly be said that any of these articles presents a continuity of Luria's approach, let alone the activity of a "school" inspired by him. This is because although Luria's clinical insights were often inspired, they were not based on the detailed experimental analysis and consideration of alternative explanations that are currently considered necessary in the science of neuropsychology.

Beyond advocating a process-oriented approach to case analysis, which many did before him, Luria has not initiated any new direction in neuropsychology. Three fine essays (by Goldberg, Cole, and Sachs) deal with Luria as a "cultural psychologist." Interesting as this perspective is, none of the empirical contributions to this book adopted it. The major theoretical statements—by Brown, Vaughn, and Goldberg—do not derive from Luria. It is revealing that no contributions take sides in any controversy in which Luria might have been involved. The two approaches that were dominant during his lifetime, the psychometric group comparison and the rigid connectionism, outlived him. If they are now in retreat it is because of advances in neurophysiology and cognitive science, many of which Luria foresaw but did not assist.

Luria's relative isolation in Moscow explains much of this. His legacy of insights and of the quality of character remains alive and well. The excellent book under review is witness to this fact.

MARCEL KINSBOURNE, M.D.

**Neuromethods, vol. 17: Neuropsychology,** *edited by Alan A. Boulton, G. Baker, and Merrill Hiscock. Clifton, N.J., Humana Press, 1990, 400 pp., $79.50.*

Neuropsychology is at the crossroads of the behavioral sciences (psychology and linguistics) and the neurosciences (neurology, neuroanatomy, neurophysiology, neurochemistry) and like them has experienced an exponential growth in the last few decades. New methods and technologies have revolutionized this field and provide, for the first time in history, the possibility of taking a look inside the "black box."

Some spectacular and revealing experiments (e.g., with the split-brain patient), together with the impact of the powerful and sophisticated brain-imaging technologies, may give a distorted sense of simplicity about the human mind, especially to the lay public (remember all the pop psychology about hemispheric capacities). Moreover, these experiments and technologies might lead to the naive belief that looking at fancy positron emission tomography (PET) scans will straightforwardly reveal the mysteries of the brain when nothing could be less true. This book is especially useful in pointing out the cautious attitude and the extreme rigorousness needed to deal with such powerful tools. Rigorousness is also needed in the experimental designs and interpretation of results.

The first three chapters review historical developments as well as recent contributions to neuropsychology from neurology, psychiatry, anatomy, physiology, psychology, and linguistics. The next two chapters focus on new brain imaging techniques (CT, magnetic resonance imaging, and PET). The authors give technical information about these techniques and stress methodological issues in order to avoid several common pitfalls. The following chapters address the description of techniques related to the surgical treatment of epilepsy: intercarotid sodium amobarbital, electrical stimulation of the cortex, and the testing of the commissurotomy patient. Eran and Dahlia Zaidel and Joseph Bogen provide comprehensive coverage of the methods and basic issues for examining the split-brain patient.

The differential competence of the left and right hemispheres in different—non-split-brain—populations is summarized in the next chapter by John Bradshaw, who writes a masterly account of the experimental modalities (visual, auditory, tactile) and the complex methodology related to them. Neuropsychological assessment is also reviewed, and both theoretical and practical critical insights are given about "fixed" (e.g., Halstead-Reitan) and "flexible" (e.g., Luria-Christensen) test batteries. The last chapter deals with developmental neuropsychological assessment. The authors propose a systemic approach and dedicate most of the chapter to the exposure of a rationale for the neuropsychological analysis of the child.

This book is not an exhaustive review of the field, and the editors clearly say so in the preface. However, the addition of two more chapters, one on neurophysiological methods and one on neuropharmacological manipulations, would have practically completed the scope of human neuropsychological research.

In conclusion, the effort of the editors in gathering such relevant and appropriate contributions is welcome. The book will be interesting and useful for the clinical psychologist and, obviously, for the neuropsychologist, psychobiologist, and psychophysiologist. What about the psychiatrist? Certainly, there are few references about schizophrenia, depression, or anxiety in this work. Beyond the interest in clinical cases of interface between neuropsychology and psychiatry, the psychiatrist will find in the neuropsychological methods and theories a large and heuristic ground for rethinking and reexamining the classical psychopathological conditions. So I do believe that this can be a revealing and profitable book for many psychiatrists.

## Nicotine Cessation, Mania, and Depression

SIR: I would like to report two cases of severe mood disorder following nicotine cessation. It is well known that medical conditions sometimes cause mania and depression. A recent case report (1) suggested that nicotine cessation may have caused a manic episode, but renal failure may have been a confounding factor.

At the urgings of her husband, a 37-year-old woman abruptly stopped a 20-year, one and a half pack per day smoking pattern. One week later, she gradually developed increased energy with inability to sleep. She made phone calls in the middle of the night, felt euphoria ("better than on my wedding day") mixed with terrible sadness. Her sex drive increased and thoughts raced. Inappropriate talkativeness at work, grandiosity, crying spells, and paranoid delusions led supervisors to refer her to our clinic 3 weeks after symptom onset. She had a history of alcohol dependence but had been sober for the past 6 years. There was no prior affective illness. She took no medications. Medical evaluation, including thyroid function tests, drug screen, chemistries, blood count, antinuclear antibodies, neurologic examination, and brain CT scan, was normal except for slightly enlarged lateral ventricles on the CT scan. She remained abstinent from alcohol. Over the course of 1 month she responded to haloperidol and lithium. She resumed normal functioning on a regimen of lithium.

A 48-year-old man without prior mood disorder stopped a 30-year, two pack per day smoking pattern over 3 weeks, and 2 weeks later became profoundly depressed. He lost interest in his family and work, ruminated constantly about suicide, and lost his usual sense of humor. He consistently suffered insomnia with prominent early waking. He was not abusing alcohol or illegal drugs. He took no medications. After 1 month of suffering these symptoms, he sought medical care. Medical evaluation, including CBC, chemistries, neurologic examination, thyroid function tests, chest X-ray, and drug screen, was unremarkable. He was treated with fluoxetine, and within 1 month his depression resolved.

Nicotine cessation among heavy smokers leads to a characteristic withdrawal syndrome. This withdrawal manifests itself in EEG changes (2), possibly suggesting changes in a neuroadaptational state induced by nicotine. Moreover, smoking seems prevalent among patients with a history of major depression, and these patients during nicotine abstinence commonly suffer depressed mood and failure to quit smoking (3). Perhaps this is similar to the dysphoria suffered during withdrawal from other stimulants.

In these cases, major depression and dysphoric mania followed briefly after nicotine cessation. It is difficult to know if this represented causation or an epiphenomenon. Nicotine cessation may be a clinical parameter to investigate among patients with mood disorder.

## Fluoxetine, Suicidal Ideation, and Aggressive Behavior

SIR: Recently there has been much discussion regarding the possibility that suicidal ideation (1, 2) or aggressive behavior (3) may be associated with fluoxetine pharmacotherapy. I wish to report the case of a patient whose response to learning of fluoxetine's potential dangers was dramatic.

Ms. A was a 62-year-old woman with a 5-year history of recurrent depressive episodes. At least one of these episodes was of psychotic proportions. There was no history of suicide attempts nor was there history of aggressive behavior. There was also no history of obsessions, compulsions, or agoraphobia. The patient had a history of incomplete response to various types of pharmacotherapy for depression but had done well for 10 months while taking fluoxetine, 20 mg/day. One month prior to the hospitalization described here, the patient saw two daytime audience participation television programs in close proximity to each other devoted to the dangers of fluoxetine. Although she had been satisfied with her response to fluoxetine before viewing the programs, she concluded, "There must be something to it." In particular she was concerned that she would "go berserk" and violently attack her grandchildren. Based on this conviction, she discontinued medication abruptly after viewing the second program. During the month after stopping medication, she stayed at home and limited her opportunities for contact with her grandchildren so she would not harm them. She stopped watching television due to a fear that she might see more programs discussing the dangers of fluoxetine and be stimulated to perform violent acts or, perhaps, self-destructive acts. She eventually limited her activity to the point of becoming bedridden out of a fear of her potential for violence. At this point, her children persuaded her to accept an evaluation at a psychiatric emergency room.

She presented with complaints of depressed mood, poor energy, initial insomnia, poor appetite, and poor mental concentration. She denied hallucinations. She recognized that her fears had become unrealistic and had led to great impairment in her functioning. She agreed to hospitalization and to resume fluoxetine treatment at her children's request due to her history of good response to this medication compared with other types of pharmacotherapy. Over a 3-week period there was complete resolution of her symptoms of depression. At discharge she was euthymic and confident about her treatment. She agreed to avoid making unilateral treatment decisions in the future.

There have been reports of other patients suffering rapid deterioration after discontinuing fluoxetine in response to television programs depicting fluoxetine's hazards (3). I do not know of any reports of patients so quickly developing this patient's degree of social isolation due to a fear of becoming aggressive. By history, it was clear that this patient experienced a severe depressive relapse during the month after abruptly stopping medication. Furthermore, the depression contributed to her growing conviction that she was a person capable of doing great harm. Physicians prescribing fluoxetine would do well to solicit regularly any concerns patients may have regarding this highly publicized medication.

## Penile Anesthesia and Fluoxetine

SIR: I read with great interest the letter by John R. Neill, M.D., (1). I have had a similar case in which a patient complained of penile anesthesia associated with low-dose fluoxetine.

Mr. A was a 47-year-old man with a past history of ethanol abuse and depression who presented to me with a general state of anhedonia, loss of energy, difficulty sleeping, and problems with concentration and attention. At this point, Mr. A denied difficulties with erection, ejaculation, penile anesthesia, or sexual pleasure during intercourse. Other than a loss of libido associated with his depression, Mr. A denied specific sexual difficulties. Mental status examination revealed a male whose mood was apprehensive and indifferent with a flat and depressed affect. His past medical history was remarkable only in that he had a cardiac pacemaker implant because of conduction difficulties. For this reason, he was started on a regimen of fluoxetine.

The patient responded well to 20 mg/day of fluoxetine. After 4 weeks, during a routine medication check, he reported penile anesthesia associated with sexual intercourse. This particular side effect did not seem to be ego dystonic to the patient, so he chose to continue at the prescribed dosage. After approximately 3 months of treatment with fluoxetine at 20 mg/day, Mr. A developed ejaculatory difficulties. The dose was decreased to 20 mg every other day, after which the ejaculatory problems dissipated, but the penile anesthesia continued. Approximately 4 weeks after this, there was a recurrence of Mr. A's depressive symptoms, and once again, after consultation with the patient, the fluoxetine dose was increased to 20 mg/day. At this point treatment with cyproheptadine was considered, but the patient elected not to try this medication, as he felt the ongoing depression was a greater problem than his fluoxetine-associated penile anesthesia.

My review of the available literature and discussion with the manufacturer of fluoxetine showed no previous reports of penile anesthesia associated with its use. The report by Dr. Neill, taken in light of my patient's report, suggests a spectrum of side effects of sexual dysfunction associated with the use of fluoxetine, from penile anesthesia to anorgasmia.

## Capgras' Syndrome and the Mignon Delusion

SIR: Recent years have witnessed a resurgence of interest in delusional misidentification syndromes, especially Capgras' syndrome. Over the years since Capgras and Reboul-Lachaux (1) first described this uncommon delusion, many different psychodynamic, as well as organic, and most recently cognitive (2), theories have been set up to explain it.

Here we report the interesting case of a chronic schizophrenic patient, the natural history of whose delusions might shed some light on the dynamics underlying some cases of Capgras' syndrome.

Mr. A, a 19-year-old man suffering from chronic schizophrenia in an acute exacerbation, was brought to our outpatient clinic by his family and was subsequently admitted. His illness had run a deteriorating course in the years since its onset, with two previous admissions.

On admission he was depressed and agitated with prominent persecutory and grandiose delusions. His delusions on the previous admission had included the false belief of being the offspring of other parents of a higher station (Mignon delusion), and the belief that he had been kidnapped and sold to his present parents at the age of 5. In the present admission he demonstrated a bizarre form of the Capgras' delusion, maintaining that his "adoptive" family had been replaced by a group of "foreign doctors." He asserted that these impostors, whose mission was both to look after and spy on him, looked exactly like the original persons. He also complained of being changed physically by his persecutors, so that his true origins might not be detected. Other symptoms in his mental status examination included déjà vu experiences merging into delusional memories and the delusion of being controlled by external forces.

Successive drug trials with trifluoperazine, 30 mg/day; haloperidol, 30 mg/day; and thiothixene, 30 mg/day, failed to remove his delusions but ameliorated his depression and agitation.

Organic pathology is implicated in many cases of the Capgras' syndrome. However, our patient was free of such pathology. Results of the physical and neurological examinations were normal, as were his blood biochemistry, a CT scan, an EEG, and the Bender-Gestalt test.

The sequence of the development of this patient's delusions, running parallel to the gradually deteriorating course of his illness, suggested that his Capgras' delusion might have been a more emphatic, as well as a more bizarre, form of denial of relationships than is the case with the Mignon delusion. Thus, in this case, the Capgras' delusion might be regarded as a more "psychotically" elaborated form of the same theme as that of the Mignon delusion.

### Kerosene Abuse By Inhalation and Ingestion

Sir: Chronic solvent abuse is associated with high morbidity and mortality (1) and hence warrants special attention. From India, the only published report is by Mahal and Nair (2), which describes dependence on petrol. We wish to report here an unusual case of kerosene abuse by inhalation and ingestion seen in New Delhi.

Ms. A, a 17-year-old student, presented with an 8-month history of kerosene use. Swallowing half a teaspoonful the first time, she enjoyed the tingling sensation in the mouth and the heady feeling. Subsequently she started inhaling it also. Inhalation from a large container would occur almost daily for up to 60 minutes, and ingestion alone would occur once in about 15 days.

The effects experienced were anxiety, nausea, and euphoria lasting for approximately 15, 30, and 90 minutes, respectively. Effects described were feeling intoxicated, "high," and powerful, of thoughts flowing fast, and occasionally, feeling fearful. Time appeared to move fast and her body felt lighter. There was a subjective sense of "confusion," mild headache, and a buzzing sound in the ear, lasting up to 6 hours. All these effects were shortlasting and temporally related to kerosene use. Occasionally she would feel drowsy and go off to sleep. There was no history of cognitive deficits, disorientation, or any symptoms to suggest toxic psychosis. There was no sustained mood change, grandiosity, or any other symptom suggestive of mania beyond the point of intoxication. During a period of abstinence she experienced anxiety, irritability, nausea, and abdominal pain lasting for about 5 days. Craving continued to be present even after 3 weeks of withdrawal.

Ms. A's blood chemistry, liver function test, chest X-ray, ECG, and EEG were within normal limits. Urinary porphyrins, basophilic stipling in blood, and occult blood in stool were absent. The only abnormal finding in our investigation was a hemoglobin level of 9.4 g/dl which was probably due to a nutritional cause. This is common in India, especially among women. A diagnosis of inhalant abuse (kerosene) according to *DSM-III-R*, axis I, and disorder resulting from the use of volatile solvents (harmful use, mild) according to *ICD-10* (1989 draft) was made.

The patient, though fulfilling the criteria for inhalant/solvent abuse, differed from the typical cases described in published reports in many ways. Kerosene is an unusual substance to be abused by a woman, especially with the mode of abuse being ingestion and inhalation. The literature describes male preponderance (3, 4), group activity (3), and inhalation as the preferred mode. Evidence of conduct disorder, antisocial personality traits, family disruption, and use of other psychoactive substance use was absent.

Drug abuse/dependence has shown a considerable increase in India in recent years (5). However, cases of solvent abuse are rarely encountered, possibly because most epidemiologic studies do not include questions for eliciting solvent abuse nor routine inquiry of clinical patients about drug abuse. These factors could be partially responsible for the scarcity of reported cases of solvent abuse. In view of the increasing prevalence of this problem in other countries and serious morbidity and mortality in adolescents abusing solvents, this area needs special attention in the future.

### Treatment of Pathological Gambling With Clomipramine

Sir: Pathological gambling is a common psychiatric disorder (1) with considerable morbidity and mortality (2). Nevertheless, for the most part it is a neglected disorder, with few controlled studies of its causes or treatment. Given the high rates of comorbid substance abuse, depression, and suicide, pathological gambling is a major public health problem (1, 2). Current treatments for pathological gambling include cognitive-behavioral approaches (3), self-help groups (4), and inpatient or rehabilitation programs (5). However, many patients remain refractory to treatment (3–5), and more effective treatments are needed.

While pathological gambling is currently classified as a disorder of impulse control, many patients and support groups consider it to be a compulsive disorder. Pathological gambling has also been considered to be related to obsessive-compulsive disorder. The following case describes the double-blind, placebo-controlled treatment (10 weeks for each phase) of a pathological gambler with clomipramine, a partially selective serotonin reuptake blocker marketed for the treatment of obsessive-compulsive disorder.

Ms. A was a 31-year-old woman with a 12-year history of pathological gambling. She also had a history of discrete social phobia (fear of public speaking) and mild obsessive-compulsive personality features (including perfectionism and hoarding) which did not meet *DSM-III-R* criteria for obsessive-compulsive personality disorder. The pathological gambling behavior consisted primarily of playing cards, numbers, bingo, and slot machines and occurred 2–3 times per week. Consequences of gambling included losses of up to $600 per day, loss of her apartment due to financial ruin, and loss of several jobs because she had been up all night gambling. Previous treatments included participation in Gamblers Anonymous for 3–4 years, which resulted in abstinence from gambling for the first year and a half. Other treatments included outpatient psychotherapy for 1 year, which was considered helpful, but did not result in discontinuation of gambling. Prior to current treatment, she had been gambling consistently for 6 1/2 years.

Treatment included a double-blind, placebo-controlled trial of clomipramine. At week 10 of the placebo trial, the clinician's global improvement change score was 3 (minimally improved), and the patient self-report was 25% improved. Gambling continued during this phase. Clomipramine was initiated at a dose of 25 mg/day and increased by 25 mg every 3 days to 150 mg/day. Due to the development of irritability, the dose was decreased to 125 mg/day. At week 10 of the clomipramine trial, the clinician's global improvement change score was 1 (very much improved), and the patient self-report was 90% improved. The gambling behavior discontinued by week 3 and remained in remission throughout the duration of the trial. Except for a brief relapse at week 17, the gambling remained in complete remission for an additional 28 weeks of open clomipramine treatment (175 mg/day).

This case is reported to demonstrate the possible efficacy of clomipramine in the treatment of pathological gambling. Further placebo-controlled, double-blind trials of clomipramine in large patient samples are needed to confirm the efficacy of this approach in the treatment of this major public health problem.

## Sinus Bradycardia Related to the Use of Benztropine Mesylate

Sir: We present a case of a paradoxical effect of benztropine mesylate manifested by sinus bradycardia in a patient with normal cardiac function. To the best of our knowledge this is the first such report.

Mr. A was a 50-year-old man hospitalized for severe depression with psychotic features. He had a history of bipolar affective disorder with frequent (2–3 times/year) hospitalizations since age 20. The patient received lithium, antipsychotics, antidepressants, and antiparkinsonian drugs over the course of years. His medical history was unremarkable except for hypercholesterolemia. On admission his heart rate was 108 bpm and his blood pressure was 149/100 mm Hg. The findings on physical and laboratory evaluations were normal. The patient was started on a regimen of lithium carbonate, 600 mg/day; haloperidol, 10 mg/day; bupropion, 75 mg/day; and benztropine mesylate, 2 mg/day. Because of the severity of the suicidal ideation and agitation, haloperidol was increased to 15 mg/day, and the benztropine dose was increased to 3 mg/day.

The next day bradycardia was detected with a pulse rate of 50 bpm. The blood pressure was 106/60 mm Hg. The ECG showed sinus bradycardia. The same day bupropion was discontinued. The bradycardia continued and became more pronounced the next day, when the heart rate dropped to 40 bpm and blood pressure to 90/70 mm Hg. An acute myocardial infarction was ruled out, and therefore an adverse drug reaction was suspected. Haloperidol was decreased to 10 mg/day and benztropine to 2 mg/day, while the lithium dose remained the same. The bradycardia persisted as evidenced by Holter monitor, with a minimum rate of 33 bpm and an average of 43 bpm. At this time benztropine was discontinued, as it was a possible cause of bradycardia, while haloperidol and lithium doses remained the same. In subsequent heart rate monitoring, a return to normal values was observed, with the heart rate stabilizing between 60 bpm and 84 bpm over the next 48 hours.

Our case report indicates the possibility of a paradoxical effect of benztropine on heart rate. Bradycardia in response to atropine (1) and trihexyphenidyl (2) was described previously. It has been suggested that the decrease in heart rate could have been produced through a blockade of $M_1$ receptors on postganglionic parasympathetic neurons, which differed from the effects of postsynaptic $M_2$ receptor blockade on the end organ (myocardium) (1, 3). In the case presented here, the unusual reaction to the commonly prescribed drug may have been due to the patient's altered receptor sensitivity as a result of his long-term exposure to anticholinergic drugs or to a drug combination.

## Acute Depressive Symptoms After Mefloquine Treatment

SIR: Mefloquine, a 4-quinolinemethanol derivative, is an effective drug for the prophylaxis and treatment of multiresistant plasmodium and falciparum malaria. Reversible adverse neurological reactions are well known. They include cognitive disturbances with memory impairment, confusion, and seizures (1, 2). Recently, acute psychotic symptoms such as delusions and visual hallucinations were reported by Stuiver et al. (3) and "confusion with depression" was reported by Bjorkman (4). It is estimated that 40% of patients under mefloquine treatment experience psychosis (3). Considering the increasing risks of contracting multiresistant malaria due to greater resistance of the illness to treatment and more frequent overseas travel, psychiatrists must be aware of depressive states as an adverse effect of mefloquine. To the best of our knowledge, these are the first reported cases of acute depressive symptoms after mefloquine treatment of patients without previous psychiatric history or known recent stressful events.

> Ms. A, a 33-year-old woman, was spending her holidays in Thailand. After her third weekly prophylactic dose of mefloquine, 250 mg, depressive symptoms occurred, starting with insomnia. Seventy-two hours after the beginning of the sleep disorders, she became sad and wept easily. The symptoms, including motor retardation and apathy, were constant for 5 days. She recovered spontaneously.
>
> Mr. B, a 24-year-old man on vacation in Mali, was receiving prophylactic chloroquine, 100 mg/day. He had a fever. Fearing acute malaria, he was treated with a first curative dose of mefloquine, 750 mg. The first symptoms then occurred, including insomnia, anorexia, and loss of weight (6 kg). Although no evidence of malaria had been found, a second dose of 750 mg of mefloquine was given. In the next few days he suffered panic attacks and cognitive disturbances and contemplated suicide. Because of the high risk of suicide, he was admitted to a psychiatric ward. He received an antidepressant (clomipramine, 100 mg/day for 40 days) and returned to normal in 10 days.

In both cases, following a cumulative dose of mefloquine, 750 mg, the first symptom was insomnia. Depressive symptoms were of short duration in spite of the long half-life of mefloquine (13 to 26 days) and characterized by favorable evolution and lack of residual disorders. No delusions or hallucinations were observed.

Although, of course, psychiatric vulnerability cannot be excluded, two pharmacologic hypotheses are worth discussion. 1) As with other chloroquino-derivative antimalarial drugs, direct urological toxicity can be suspected. But plasma levels of mefloquine acsertained in patient B showed a value of 260 ng/ml in the therapeutic range (10–1000 ng/ml). 2) Indirect toxicity is also a possibility. The main metabolite of mefloquine, quinoline 4 carboxylic acid, does not cross the blood-brain barrier, but other metabolites could be involved. Further studies investigating the pharmacologic process of depressive symptoms with mefloquine treatment are necessary.

## Trazodone Induction of Migraine Headache Through mCPP

SIR: We would like to report a case in which a patient suffered severe migraine headache symptoms after being treated with trazodone.

> Mr. A, a 35-year-old man with a 7-month history of lower back pain was referred to the first author's clinic for evaluation and treatment of depressive symptoms. The patient had a diagnosis of chronic myofascial pain syndrome, and on examination, he met *DSM-III-R* criteria for major depression. He had no history of previous chronic pain.
>
> The patient was started on a regimen of doxepin; however, in the second week of treatment, he developed anticholinergic side effects. These disappeared after doxepin was stopped, and 1 week later he started taking trazodone. The initial dose was 50 mg h.s., which was increased to 100 mg h.s. after week 1 and to 200 mg h.s. after week 2. On day 3 of the 200 mg dose, the patient developed severe nausea, vomiting, and right central scotomata. These symptoms were followed by a severe, throbbing, right frontotemporal headache (unlike any the patient had previously experienced), accompanied by severe photophobia and right facial numbness. Mr. A was taken to a local emergency room for evaluation where CT scans, with and without contrast, were negative. A consulting neurologist diagnosed classic migraine, new onset. Trazodone treatment was stopped, and after 1 week the patient was started on desipramine, with resolution of his depression within 1 month. At 3- and 6-month follow-ups, the patient reported no recurrence of headaches, with the exception of one 30-minute episode of frontal headache which was responsive to acetaminophen.
>
> When Mr. A was seen following his headache episode, additional history indicated that his aunt and sister suffered from headaches which were responsive to sublingual ergotamine. Also, the patient reported that as a child, he frequently experienced "car sickness," a finding which is common among migraine patients. These data suggest a genetic predisposition toward migraine, which may have been stimulated by trazodone.

Trazodone's major active metabolite is m-chlorophenylpiperazine (mCPP), which is a potent nonselective serotonin receptor agonist (1). Serotonin releasing factor has been found to be present during acute migraine attacks, and serum serotonin has been shown to be increased during such attacks (2). Cerebral vessels (whose constriction and dilation are involved in migraine mechanisms) are highly innervated by serotonin fibers from the raphe nucleus (3), and this is the likely basis of the antimigraine effectiveness of serotonin antagonists such as methysergide. Also, sumatriptan, a presynaptic serotonin $5\text{-HT}_{1D}$ autoreceptor selective agonist, has powerful antimigraine effects, apparently through its ability to enhance serotonin reuptake and thus inhibit net serotonin transmission (4). More directly relevant to this case report is prior evidence that mCPP itself can induce migraine symptoms in humans (5).

Although headache (type unspecified) is reported as a side effect of trazodone in the *Physicians' Desk Reference*, this is, to our knowledge, the first report linking this agent to vascular headache. Trazodone, through its metabolite mCPP, may potentially induce migraine symptoms in genetically susceptible patients. A detailed family history of migraine headaches, as well as a personal history and related symptom history, should be obtained from candidates for trazodone treatment.

## Laterality of Torsion in Tardive Dystonia

SIR: The study of the laterality of drug-induced movement disorders may have significant implications for the underlying neurobiology of schizophrenia and the mechanism of action of neuroleptic drugs. Studies of tardive dyskinesia in schizophrenic patients have reported a predominance of involuntary movements to the right in two studies, to the left in one, and equally to the right and left in one (1). Studies of neuroleptic-induced parkinsonism suggest a tendency for the left striatum to be hypersensitive to dopaminergic blockade, resulting in a greater degree of right-sided parkinsonism (2). Two single case reports of tardive dystonia in schizophrenia (3, 4) reported a right-sided rotation.

We have examined six patients with tardive dystonia in our clinic who had an axial dystonia with a rotational component and found a greater tendency for a right-sided rotation. All were right-handed. Five had a schizophrenic disorder. Two patients had rotation of the head to the right, one with the additional involvement of the right arm. With the third patient, although there was bilateral involvement, the movement of the head was predominantly to the right. The fourth patient had bilateral turning of the head, flexion of the trunk to the right, and involvement of the left arm. The fifth patient had head rotation to the left and involvement of the right arm. The sixth patient, who suffered from a bipolar affective disorder, had bilateral involvement of neck muscles with left-sided involvement more than the right, producing a greater tendency to rotate to the right. Three of these patients had orolingual dyskinesias which were bilaterally symmetrical on clinical inspection.

Evidence from animal studies suggests that the direction of rotation may reflect an asymmetry of striatal dopamine function. Some evidence for increased asymmetry in striatal dopamine receptors in schizophrenic subjects, as compared to normal control subjects, exists from post-mortem studies, with a reported greater density on the right (5). Whether this was caused by previous neuroleptic medication or the disease process itself remains uncertain. The evidence for the prominence of neuroleptic-induced parkinsonian symptoms on the right side (2) argues for relative hypodopaminergic activity in the left striatum. The right-sided prominence of tardive dyskinesia and the greater likelihood of rotation to the right in tardive dystonia are more difficult to interpret in the absence of a clear understanding of the pathophysiology of these disorders and considering the controversy that still exists regarding the cerebral representation of neck rotation. Our cases, therefore, lend further support to the asymmetry of neuroleptic-induced side effects but do not help settle the following questions: Are these asymmetries the result of the asymmetric action of neuroleptics on a neurochemically symmetric brain, or vice versa? Or are they indeed a combination of two asymmetries? Are the side effects asymmetric only in schizophrenia? Answers to these questions can only be obtained by investigating larger groups of patients suffering from different psychiatric disorders with in vivo functional imaging and detailed post-mortem neurochemical assessments.

## Oxytocin and Vasopressin in Obsessive-Compulsive Disorder

SIR: A growing body of literature suggests that oxytocin and vasopressin have a significant effect on behavior, mood, and memory. More recently, it has been reported that oxytocin administration ameliorates obsessive-compulsive disorder symptoms (1, 2) and that CSF concentrations of the two peptides are altered in the disorder (3, 4). We hypothesized that these alterations might be etiologically related to obsessive-compulsive disorder.

In order to evaluate the effects of brief peripheral administration of oxytocin and vasopressin on obsessive-compulsive disorder symptoms, three patients with the disorder (two male, one female) were administered, in blinded, random order, intranasal oxytocin (Syntocinon; two sprays deliver approximately 8 IU), intranasal vasopressin (80 IU of desmopressin), and normal saline. A second dose of each substance was given after 90 minutes. Patients were rated for changes in mood, memory, and obsessive-compulsive disorder symptoms at 5–30-minute intervals (chosen to correspond with periods of peak drug activity) for a total of 3 hours. Standardized visual analog scales were used to rate mood, general anxiety, global functioning, and degree of obsessionality and compulsivity (5), and digit span tests were administered to assess memory.

There were no discernible effects of vasopressin or oxytocin on any of the physician or patient ratings of obsessive-compulsive disorder symptoms, mood, or anxiety; nor was digit span appreciably affected by the drugs. One patient spontaneously reported feeling irritable and nervous within 2–3 minutes of vasopressin administration, and this discomfort persisted for over 90 minutes; however, she had similar (albeit milder) complaints following a subsequent normal saline challenge. Another patient, who had not noted any effects of normal saline or vasopressin, felt that oxytocin decreased his compulsions and stated, "I didn't check or count my steps when I left the bathroom just now— that's the first time in as long as I can remember." This was not reflected in his self-ratings, however, and when oxytocin administration was repeated in his home environment, it had no appreciable effect.

Although the methodology and sample size of this pilot investigation were severely limiting, the results suggested that obsessive-compulsive disorder symptoms were not responsive to brief oxytocin or vasopressin administration. The question of whether or not long-term administration of either of these peptides will be effective for obsessive-compulsive disorder and whether abnormalities of these neurohormones play a role in the onset of the disorder remain unanswered. Additional, controlled studies utilizing biological measures of pharmacologic activity, a range of drug dosages, and longer treatment periods may be indicated to ascertain whether or not abnormalities of oxytocin and vasopressin are directly related to obsessive-compulsive disorder.

## Acute Pancreatitis Associated With Clozapine Use

SIR: The atypical antipsychotic agent clozapine has a unique profile of side effects, which are likely to appear soon after treatment is begun and can limit its use (1). Many of the drug's complications are gastrointestinal, and clozapine has been observed to induce transient elevations of serum bilirubin and amylase (2). A patient of ours developed acute pancreatitis shortly after starting treatment with clozapine. We postulate that acute pancreatitis may be associated with clozapine use.

Mr. A, a 40-year-old man with moderate mental retardation and bipolar disorder refractory to neuroleptics, carbamazepine, and lithium carbonate, was started on a regimen of clozapine in the hope of treating his psychotic symptoms and progressive tardive dystonia.

His other antipsychotics were tapered and discontinued and clozapine was initiated at a dose of 25 mg/day. The dose was increased as permitted by postural heart rate and blood pressure changes. By the eighth day, he was receiving 150 mg/day. On the ninth day his temperature was 101.3 °F, his abdomen was mildly distended, and bowel sounds were hyperactive. Rectal examination revealed retained feces. Transient defervescence and overall improvement followed the application of enemas and laxatives. Laboratory results were within normal limits, and clozapine was continued. On the twelfth day the patient's condition again deteriorated. After three episodes of biliary emesis, his rectal temperature was 101.7 °F, and his abdomen was diffusely distended, typanitic, and tender. The rectal vault was again impacted with feces.

Abdominal X-rays showed a large amount of colonic stool and scattered air-fluid levels. Laboratory results included a normal amylase level and a WBC count of 8800/mm$^3$, with 29% bands; and the patient was treated for fecal retention. Clozapine was discontinued, however, and 36 hours after the patient's last dose, a serum lipase level of 4380 U/ml first suggested the diagnosis of pancreatitis. Amylase and lipase levels progressively rose to peak values of 343 U/ml and 5178 U/ml, respectively. CT scan of the abdomen confirmed pancreatic inflammation and edema.

Both CT scan and abdominal ultrasound demonstrated a normal pancreatobiliary tree and no evidence of gallstones. Despite a complete workup, no cause could be found for the pancreatitis. Mr. A's clinical condition rapidly returned to normal after the discontinuation of clozapine.

The patient in this case suffered an attack of acute pancreatitis during the second week of treatment with clozapine. This could have been purely coincidental, but clozapine was clearly suspect.

Clozapine is known to act on the salivary glands to produce sialorrhea through poorly understood mechanisms (3). The salivary glands and the pancreas share a common vulnerability to toxic agents (e.g., alcohol), to metabolic derangement (e.g., hyperchylomicronemia), or to immunologic attack (e.g., mumps) (4). It can be speculated that clozapine has exocrine and probably toxic effects on both salivary and pancreatic tissue. This hypothesis awaits confirmation from other clinical cases or laboratory studies associating pancreatitis with the drug.

## Battered Woman Syndrome

SIR: Since the 1970s, increasing attention and study has focused on the phenomenon known as the "battered woman syndrome." Over the last 15 years, a growing body of literature has accumulated on this topic, leading to a general acceptance in the mental health community of the legitimacy of this syndrome. As our knowledge in this area has grown, the courts have begun to recognize the battered woman syndrome as a defense, in part or whole, to charges of murder and related offenses when a woman slays her assailant after having been previously brutalized by him. Mental health professionals have provided invaluable assistance to courts by explaining the otherwise perplexing phenomena seen in battered women, such as why they do not leave their abuser and why they may subjectively believe their lives to be in danger even when their assailant is asleep. Many jurisdictions now allow expert testimony to determine whether the woman was suffering from the battered woman syndrome, which may negate the specific intent required for the offense charged, mitigate the sentence of the convicted defendant, or completely exonerate the woman for acting in self-defense based upon her honestly held, subjective belief that her life was in danger.

Although this letter is not intended to criticize the legitimacy or the importance of recognizing the battered woman syndrome, I evaluated a woman charged with the murder of her husband, who allegedly had severely abused her, in a jurisdiction in which proof of the battered woman syndrome would have led to a complete defense and a finding of not guilty. I determined that the woman was malingering. A review of the literature resulted in finding absolutely no review articles, research, or case reports documenting malingering in the battered woman syndrome.

I based the diagnosis of malingering on numerous inconsistencies involving the crime scene, statements to the police, demeanor inside and outside the clinical interviews, past psychiatric history, past alcohol and drug history, sexual history, and personal history. Reliance solely on information provided by the defendant would have led to the erroneous conclusion that she suffered from the battered woman syndrome.

The clinical information on the extent of the battered woman syndrome and its devastating consequences is vitally important to the criminal justice system in assessing culpability. However, since the general public has been exposed to this syndrome and many jurisdictions allow testimony that may mitigate or absolve defendants of criminal responsibility, the clinician and forensic examiner must consider the possibility that the battered woman syndrome may be feigned. Essential to any thorough forensic evaluation is the collection of data from sources other than the defendant. Although no other cases of malingering in relation to the battered woman syndrome appear in the psychiatric literature, I strongly suggest that at least a small percentage of such allegations in criminal proceedings may be false. Only with the reporting of such cases can the prevalence of malingering in the battered woman syndrome be known.

### Diagnostic Agreement

SIR: It is surprising, perhaps astonishing, that so few studies of diagnostic agreement on *DSM-III* (or *DSM-III-R*) have been reported. Among the few, there are the *DSM-III* field trials reported in 1980 (*DSM-III-R*, pp. 493–496) and an axis II study reported from Australia in 1982 (1).

A true test of diagnostic agreement must meet at least four criteria: 1) The diagnosticians must be clinically qualified to use *DSM-III*, 2) they must not have ordinarily worked together (thus learning each other's "diagnostic habits"), 3) the cases must be selected on some nondiagnostic basis, and 4) the same information must be made available to each diagnostician.

The *DSM-III* study, substantial though it was, failed to control for diagnosticians being familiar with each other's diagnostic predispositions. This is understandable, but even so one must have some assurance that diagnostic agreements are geographically transplantable.

Most studies have shown acceptable diagnostic agreement on broad categories (e.g., schizophrenia and organic mental disorder). An adequate assessment of agreement on finer diagnostic categories is indicated.

### Correction Rate of Severe Hyponatremia and Central Pontine Myelinolysis

SIR: Our report (1) of a polydipsic schizophrenic patient who survived an episode of severe hyponatremia with status epilepticus induced by hydrochlorothiazide drew responses from Pritesh J. Shah, M.D., and William M. Greenberg, M.D. (2), as well as from Hans Rittmannsberger, M.D. (3), warning of the dangers of central pontine myelinolysis when the correction of hyponatremia is made too rapidly.

Central pontine myelinolysis is the selective loss of myelin involving the center of the basal pons and other extrapontine areas of the brain where gray and white matter intermix. It accompanies many chronic debilitating diseases and is most often seen in malnourished alcoholics. Symptoms of the fulminant state include dysarthria, impaired swallowing, pseudobulbar signs, quadriparesis, and quadriplegia.

The too-rapid correction of hyponatremia has been implicated in a number of cases of central pontine myelinolysis, but the picture is anything but clear. Major ambiguities include whether the severity and/or chronicity of hyponatremia prior to correction contribute to demyelinization and what constitutes a safe correction rate for different degrees of hyponatremia. Hyponatremia is defined as a serum sodium level below 135 meq/liter and is most often mild (serum sodium level above 120 meq/liter) and asymptomatic. Severe hyponatremia (serum sodium level below 120 meq/liter) may lead to severe neurological damage or death.

Our patient was admitted to the intensive care unit unresponsive and in status epilepticus, with a serum sodium level of 108 meq/liter. Treatment with intravenous phenytoin sodium and diazepam did not break the seizure, which resolved only after administration of a short course of 3% saline; this was stopped once the serum sodium level rose to 126 meq/liter (mild hyponatremia). As is common with psychogenic polydipsic patients during fluid restriction, a large free water diuresis developed and continued until the serum sodium level spontaneously reached 135 meq/liter, 8 hours after admission (average rate of bimodal correction=3.4 meq/liter per hour). This rapid diuresis and change in serum sodium may have been potentiated by phenytoin sodium, which is known to inhibit release of ADH from the pituitary.

Two years after this eposode, our patient shows no sign of neurologic damage. A recent review (4) of 13 psychogenic polydipsic patients with hyponatremic seizures showed that 12 of the patients had serum sodium levels corrected "rapidly" to 120–130 meq/liter within 12 hours. In no case was there clinical or radiologic evidence of neurologic sequelae after 6 years of follow-up.

Critically summarizing the literature on the correction rate of hyponatremia, Ayus et al. (5) conclude:

> Severe symptomatic hyponatremia (serum sodium level below 120 meq/liter) is often a life-threatening emergency that can result in permanent neurologic damage or death if left untreated. Early recognition and rapid correction to mildly hyponatremic levels by administration of hypertonic saline are important in order to reduce the potential mortality and morbidity. If the serum sodium level is more than 105 meq/liter, it can be corrected to a value of 125 to 130 meq/liter. Care should be taken to avoid acute correction to normonatremia or hypernatremia.

It is the too-rapid correction of severe hyponatremia to normal or above normal levels (3% saline was stopped at 126 meq/liter in our patient) that appears to hold the greatest risk of central pontine myelinolysis.

## On Organic Unity Theory

Sir: There has been a recent resurgence of interest among psychiatrists, particularly in the Unitied States, Great Britain, and Germany, in exploring philosophical issues, e.g., the mind-body problem and our notions of psychopathology. One focus has been the reexamination of the biopsychosocial model, as articulated by George Engel (1–3). Aviel Goodman, M.D., in championing "mental-physical identity" as an elaboration of Engel's model, has presented a thoughtful, sophisticated enhancement (4). As welcome as his discussion is, I nonetheless have two critical comments.

Many "identity" and "correspondence" theories of the mind-body problem have been insufficiently characterized in their particulars to be clearly distinguished. Dr. Goodman explicates identity (extensional, intensional, and/or identity in empirical validating evidence), but in telling us that the theory of mental-physical identity pertains to both extensional identity and "metaintensional" hypothesized isomorphic correspondence "between configurational (gestalt) features of the mental conceptual network and certain configurational features of the physical conceptual network" (4, p. 556), he is making a compound claim. This does not, as advertised, "[circumscribe] the mind-body problem . . . to the realm of logical analysis" (4, p. 557) but leaves attached those hypotheses of isomorphic correspondence, plausibly but not necessarily at the neurophysiological level, which are subject to empirical investigation. Dr. Goodman does elsewhere grant this (4, p. 557, 559), but in his thorough explanations we are still left with a doctrine of "identity *and* correspondence," subject both to linguistic conceptual analysis and empirical study. This level of sophistication is fine for the philosopher but brings me to the second stated concern, which is didactic.

Engel, who was clearly antidualistic (2), intended his biopsychosocial model for a wide audience, prominently including mental health profession trainees and nonpsychiatric physicians. He felt that all health professionals needed an alternative to the biomedical model and a handy mnemonic to remind them that the patient is a person with a mind (no dualism intended) and has a family and relevant sociocultural context, obvious verities all too easy to forget when one is intensely trained to address one focused perspective and must evaluate and treat patients quickly (1–3, 5). Mental-physical identity is another important lesson, but I fear that "organic unity theory" lacks the euphony and self-obvious descriptiveness of Engel's wonderfully chosen term, which has also been selected in our current APA presidential theme. Elaborate on Engel's "person (experience and behavior)," but don't rob us of "biopsychosocial" in giving us "organic unity"!

WILLIAM M. GREENBERG, M.D.
*Paramus, N.J.*

## Dr. Goodman Replies

Sir: Dr. Greenberg's observation that my formulation is "a doctrine of 'identity *and* correspondence,' subject both to linguistic conceptual analysis and empirical study" is astute and underscores a critical and sometimes difficult distinction. Earlier in the same paragraph, however, his discussion of my ideas blurs this distinction in a way that could promote a misunderstanding of them. He refers to "hypotheses of isomorphic correspondence, plausibly but not necessarily at the neurophysiological level, which are subject to empirical investigation." In my essay, the hypothesis "that there exist isomorphisms between certain configurational (gestalt) features of the mental conceptual network and certain configurational features of the physical conceptual network" (p. 556) is a linguistic/conceptual hypothesis that refers to relationships between conceptual networks; it is not an empirical hypothesis and is not subject to empirical investigation. Hypothesized configurational isomorphisms would be of the following form: If *a* and *b* are concepts in the mental conceptual network, then there exist some concepts *c* and *d* in the physical conceptual network for which the relationship between *c* and *d* is isomorphic with the relationship between *a* and *b* (e.g., *a* is an element of *b*, or *a* is a property of *b*, or *a* occurs after *b*, etc.). This hypothesis is not identical to a hypothesis that variables *a* and *c* or *b* and *d* correspond to each other (i.e., have the same putative referent), and it certainly is not identical with a hypothesis that any specific terms A and C or B and D correspond to each other. Only the last of the three types of hypothesis would be subject to empirical investigation.

Not until the next page and in another context did I introduce the term "correspondence," when I discussed Feigl's "'empirical identifications'—statements functioning as hypotheses of correspondence between phenomenal concepts and physical concepts, the substantiation of which requires empirical evidence" (p. 557). I then proceeded to discuss "the important distinction between mental-physical identity theory and hypotheses of mental-physical correspondence" (p. 557). Mental-physical identity theory describes a relationship between the mental and physical conceptual networks, while a hypothesis of correspondence is a statement that a specific mental concept and a specific physical concept refer to the same event or process. Hypotheses of correspondence are grounded on the putative extraconceptual referent which both the mental and physical terms are hypothesized to designate, and their validation thus depends on empirical evidence. Mental-physical identity theory, meanwhile, remains within the realm of linguistic-conceptual analysis, and its validation depends on its explanatory power rather than on the confirmability of predictions derived from it (philosophers of science are increasingly recognizing the distinction between explanatory power and confirmability of predictions, and that the scientific value of a theory has more to do with the former than the latter [1–3]). Mental-physical identity theory does not necessarily indicate that any hypotheses of correspondence will be empirically confirmed, only that no other kinds of hypotheses relating mental to physical are logically sound.

In response to Dr. Greenberg's comments, I recognize that Engel was antidualistic, and I hope that my contribution helps make his biopsychosocial model more completely consistent with his antidualistic intent. In integrating the biopsychosocial model with mental-physical identity theory, organic unity theory rectifies what I believe was a flaw in the biopsychosocial model that, while subtle, undermined the integrity of the model. Organic unity theory was not intended to detract from or to supplant Engel's pioneering work but rather to supplement it. I also recognize that the concepts of mental-physical identity are difficult to grasp, to a great extent because they contradict the dualistic philosophy embodied in our language, and that they are unlikely to be embraced by the wide audience that has accepted the biopsychosocial model. Please rest assured that robbery is not on my agenda.

## Clonidine and Stuttering

Sir: John Paul Brady, M.D., recently gave an excellent review of the pharmacology of stuttering (1). He cited Swift et al. (2) who pointed out that haloperidol is helpful in stuttering and in two other disorders which share several characteristics with stuttering: motor tics and Tourette's disorder. Indeed, stuttering is often known to occur in combination with other motor activities such as swallowing, coughing, eye blinking, and grimacing. Comings and Comings (3) reported that 31% of 26 patients with Tourette's disorder stuttered or had stuttered in the past. In our clinical practice with children with Tourette's disorder, we also found the combination with stuttering. Our first choice of medication for children with Tourette's disorder is clonidine, an $\alpha_2$-noradrenergic agonist (4). In the population of those children who showed the combination of Tourette's disorder with stuttering, we observed not only a decrease of tics and hyperactivity but also a decrease in stuttering. Based on these findings, we started an open trial, treating children who stutter with clonidine medication (4 μg/kg per day). The children were referred to our clinic because of their stuttering. No Tourette's disorder symptoms were reported in the children or in their relatives. The group consisted of five boys aged 8–14 years and two girls aged 9 and 14.

The degree of stuttering was judged on a 5-point scale by clinically experienced speech pathologists on the basis of standardized assessment sessions in which the child was to read and talk spontaneously. The behavioral changes were spontaneously reported by the children as well as their parents when interviewed by a child psychiatrist. Five children were observed to show an obvious decrease in stuttering after 2.5 months of clonidine administration. The other two children (13 and 14 years old) did not show a significant decrease in stuttering. However, all children reported improvement with respect to at least one of the following behavioral aspects: sustained attention, fine motor activity (handwriting), hyperactivity, anxiety, sleep pattern, social engagement, and school performance.

The results of this open trial were considered encouraging enough to start a double-blind crossover study to investigate systematically whether stuttering children do indeed receive any benefit from clonidine administration.

Clonidine is a centrally active compound that stimulates presynaptic α-adrenergic receptors and reduces the firing rate of cells in the adrenergic nucleus locus ceruleus. Clonidine has previously been shown to benefit children with Tourette's disorder (5) and children with attention deficit hyperactivity disorder (6). Our preliminary findings suggest that clonidine may also be a useful agent for the treatment of stuttering in children.

## Dr. Brady Replies

SIR: I find the observations of Dr. Vink and associates of great interest. If their double-blind trial confirms their earlier study, and their results are confirmed by others, another category of pharmacologic agent will have been identified which ameliorates stuttering in some persons. Add $\alpha_2$-noradrenergic agonists to neuroleptics, calcium channel blockers, and possible cholinergic drugs. The intriguing question is, What do all these agents have in common? Alternatively, is stuttering the recognizable, symptomatic manifestation of any number of different CNS pathologies, each responsive to a different category of pharmacologic agent?

## Body Dysmorphic Disorder

SIR: The findings described by Katharine A. Phillips, M.D. (1) in her excellent review article on this interesting disorder closely parallel those I have encountered with the four patients I have seen with it in the past 20 years. Two of the four individuals I treated were men. One complained about the "repulsively aberrant" shape of his nose and the second about the "minuscule size" of his penis. The two women I have seen with this disorder both repeatedly bemoaned their fates because of the "repugnant" and "sexually shameful" size of their breasts.

Three of the four patients showed frequent mirror checking, and all four were concerned that others would mock them if they saw them in public or in a locker room type of setting. As a consequence, these three individuals suffered from considerable social withdrawal. All four patients had seen at least one plastic surgeon prior to being referred to me for treatment, and three of the four had managed to convince these doctors to perform a "cosmetic" surgical procedure on them.

In all four of these cases, there was no evidence of a thought disorder in any other area than that of the bodily preoccupation, and the most reasonable diagnosis for all four individuals seemed to be obsessive-compulsive disorder. In all four instances, the symptoms became more intense in direct proportion to the degree of intensive psychotherapeutic probing which I attempted. When the disorder became most pronounced, it was accompanied by depression in three of the four cases. This did not respond readily to tricyclic antidepressant medications in the first two patients with depression whom I saw quite some time ago. The most recent patient did show a rather rapid and positive response to fluoxetine.

It is hardly possible from my material to determine whether body dysmorphic disorder is actually a discrete syndrome or is a symptom found in a number of different nosologic entities. Only further case reports can be of help in solving this and some of the other intriguing questions which Dr. Phillips posed in her article.

### REFERENCE

WAYNE A. MYERS, M.D.
*New York, N.Y.*

SIR: Dr. Phillips is to be commended for her thorough review of body dysmorphic disorder. This entity is characterized by constant and intense preoccupation with a body "defect" which is, in fact, quite minor or even imagined. Although Dr. Phillips mentioned briefly (p. 1141) that in a nonclinical population, up to 70% of college students expressed dissatisfaction with some aspect of their appearance, she did not make sufficiently clear that true dysmorphophobia is, so to speak, only the tip of the iceberg and that it is part of a much broader clinical phenomenon whose features, though recognizable, are not as compelling.

A majority of patients seen in intensive psychoanalytic therapy or psychoanalysis express at some point in their treatment dissatisfaction with some bodily feature. The principal differences between these patients and true dysmorphophobic patients are as follows:

1. Concern with the "defect" or physical imperfection is not a constant preoccupation, marked by intensely painful affects.
2. Reference to the "defect" is made in passing in the course of treatment and may be missed by the therapist because it is not accompanied by a striking affective display. The "defect" may not be spontaneously mentioned again by the patient for some time.
3. Reference to the "defect" usually occurs as part of a relevant associative chain. For example, an adult man mentioned that he had prominent ears in connection with material about shame and embarrassment; when he was an adolescent his ears would "light up" when he blushed with embarrassment. The therapist, incidentally, had never noticed anything unusual about the patient's ears.
4. Conscious discomfort generally is satisfactorily defended against. Mechanisms of isolation and displacement are successfully employed to avoid constant anxiety. By contrast, in true dysmorphophobia these mechanisms do not function adequately.
5. The "defect" is almost never mentioned during the initial interview and also generally not in brief or focal psychotherapies. It surfaces during the longer and less structured forms of psychotherapy.

It is difficult to find a suitable term for these somewhat ephemeral manifestations of body consciousness. A more detailed description may be found in my review articles (1, 2). Generally, however, they are underdescribed in the literature.

## Dr. Phillips Replies

Sir: The four cases of body dysmorphic disorder described by Dr. Myers nicely and succinctly illustrate many of this disorder's common features, including the feelings of intense shame associated with the imagined physical defect, excessive mirror checking, ideas of reference, comorbid depression, social withdrawal, unnecessary cosmetic surgery, and possible response to serotonergic antidepressants. As Dr. Myers suggests, further research is needed to answer definitively the question of whether body dysmorphic disorder is a discrete syndrome or a symptom found in a variety of different nosologic entities. However, it appears that many cases of this disorder do represent a discrete syndrome. Preliminary evidence suggests that body dysmorphic disorder may respond to serotonergic medications, regardless of the "primary" or "secondary" nature of the symptoms (1), and that it may respond to treatment independently of comorbid disorders (2). It also appears that body dysmorphic disorder is often chronic, regardless of the onset or resolution of accompanying disorders, and that many patients consider it their most severe and primary problem (2). In addition, body dysmorphic disorder's precursor, dysmorphophobia, has historically been classified as a discrete disorder.

Dr. Castelnuovo-Tedesco touches on another important issue raised in my review: the similarities and differences between body dysmorphic disorder and relatively "normal" concern with appearance. Although the distinction between disorder and no disorder is inherently fuzzy for many psychiatric disorders, it may be especially so for body dysmorphic disorder, given that concern with appearance is so common.

Nonetheless, as Dr. Castelnuovo-Tedesco points out, body dysmorphic disorder can be differentiated in various ways from relatively "normal" concern with appearance, including the fact that it causes intense pain and is time-consuming. I would also add that this disorder often causes substantial impairment in functioning—individuals may drop out of school, stop working, become socially isolated or housebound, or be hospitalized because of their preoccupations. In fact, it has been proposed that, to better differentiate body dysmorphic disorder from "normal" concern with appearance, the following criterion be added to *DSM-IV*: "The preoccupation causes significant impairment in social or occupational functioning, or causes marked distress" (3).

However, I would disagree with Dr. Castelnuovo-Tedesco on one point. The literature and my experience suggest that patients with body dysmorphic disorder may make reference to their "deformity" only in passing or may never mention it to their therapist at all. While some patients vociferously complain, in a despairing fashion, about their "ugliness," others are so ashamed of and humiliated by their concerns that they keep them a secret—from family, friends, and therapists—sometimes for decades. As one patient, who took 2 years to tell me about his supposed physical defects, stated, "I didn't have the guts to talk about it." Patients may instead seek treatment for associated disorders, such as depression or anxiety. Therapists therefore need to inquire specifically about the presence of this disorder, since patients may not volunteer their preoccupations and may instead suffer silently with them for years, if not decades.

## Dissociative Experiences Scale

Sir: The findings of Marlene Steinberg, M.D., and her associates (1) concerning the use of the Dissociative Experiences Scale (DES) as a screening instrument to detect patients at high risk for dissociative disorders are of interest. However, the methodology of the study is problematic in one respect. The Structured Clinical Interview for DSM-III-R Dissociative Disorders (SCID-D), administered by a clinician and used as the diagnostic standard, should have been administered *after* the patient filled out the self-report DES, not before. As it stands, the study examined the utility of the DES in detecting dissociative experiences in a population possibly sensitized to those issues by having been through a SCID-D. It is therefore difficult to generalize to other populations not so intensively interviewed. Administering the DES first would have avoided this problem.

MICHAEL R. LIEBOWITZ, M.D.
*New York, N.Y.*

## Dr. Steinberg and Associates Reply

Sir: Dr. Liebowitz raises an important issue. It is possible that the administration of the SCID-D prior to the DES could have increased the patients' awareness of dissociative experiences investigated by the DES. On the other hand, it is also possible that this was not the case. Because this is an important empirical question, we have been conducting an ongoing investigation during the past year in which we have administered the SCID-D after any screening instruments have been given. We look forward to publishing further reports on these investigations.

## Anxiety Disorders and Parkinson's Disease

Sir: We found of great interest the article by Murray B. Stein, M.D., and colleagues (1) and the letter from Edward C. Lauterbach, M.D., and Roger C. Duvoisin, M.D. (2), who found a high prevalence of anxiety disorders in patients with Parkinson's disease. Dr. Stein and associates speculated that this high prevalence might be due to some common pathophysiologic mechanism in both disorders, and they suggested that this mechanism could be a dopaminergic deficit.

Along this line, Cash et al. (3) found that in the locus ceruleus of normal human brains there is a high dopamine/norepinephrine ratio (range, 14%), and in the locus ceruleus of nondemented patients with Parkinson's disease there is a 42% reduction in dopamine but not in norepinephrine concentrations. We believe this could be due to loss of dopamine cells in the mesencephalon that project to the locus ceruleus.

Cedarbaum and Aghajanian (4) pointed out that dopamine decreases the firing rate of the locus ceruleus. The loss of dopaminergic inhibition of the locus ceruleus could in part explain the high prevalence of anxiety disorders, especially panic attacks, in patients with Parkinson's disease. This would be consistent with Dr. Stein and associates' speculations and with recent works which find dopamine regulation of the locus ceruleus to be relevant in the pathophysiology of anxiety disorders and panic attacks in particular (5, 6).

It would be of interest to determine whether the prevalence of anxiety disorders is high only in nondemented Parkinson's disease patients. This would concur with the findings of Cash et al. that the imbalance of dopamine/norepinephrine concentration in the locus ceruleus, mentioned above, occurs only in nondemented patients, as in demented patients with Parkinson's disease there is a reduction in both dopamine and norepinephrine (this would be inconsistent with the appearance of anxiety disorders).

## Dr. Stein and Dr. Uhde Reply

SIR: We appreciate Dr. Iruela and colleagues' comments regarding the relationship between anxiety disorders and Parkinson's disease. They speculate that an abnormality of dopaminergic regulation of locus ceruleus firing may be a core pathophysiologic feature in these cases. They predict that only parkinsonian patients without dementia would suffer from a high rate of anxiety disorders, based on the work of Cash et al. In our study we only examined patients with Parkinson's disease who were not cognitively impaired. Consequently, we are unable to provide any data to confirm or disconfirm this very interesting hypothesis.

In addition to generating this testable hypothesis, the comments of Dr. Iruela and colleagues highlight the evolving body of research data which tentatively implicates a dopaminergic deficit in some forms of anxiety (1), perhaps especially social anxiety (2, 3). In our study, we found remarkably high rates of social phobia (which, in our opinion, could not be totally accounted for on the basis of self-consciousness regarding parkinsonian symptoms) in the patients with Parkinson's disease. We would be especially eager to have other investigators attempt to replicate this finding, inasmuch as the DSM-IV Task Force is interested in the relationship between social phobia and axis III disorders such as Parkinson's disease. We hope that the comments by Dr. Iruela and colleagues will serve as an impetus to the further study of dopaminergic function and anxiety at both the preclinical and clinical level.

## Corrections

In the article "Controlled Investigation of the Amobarbital Interview for Catatonic Mutism" by W.V. McCall, M.D., et al. (February 1992 issue, pp. 202–206), under the *Subjects* section on p. 203, the first sentence of the third paragraph should read "Each patient at the state hospital was examined by a neurologist at the time of the interview and was found free of localizing signs." On the same page, under the *Procedure* section, the fourth sentence of the first paragraph should read "A second psychiatrist (W.V.M.) conducted the interview, and a third physician administered the intravenous infusion."

In the reply by Joel Paris, M.D., and Hallie Zweig-Frank, Ph.D., to the letter "Borderline Patients' Perceptions of Their Parents" from Rex William Cowdry, M.D., and Kathleen M. O'Leary, M.S.W. (March 1992 issue, p. 427), there was a typographical error in the number of years in the next-to-last sentence of the second paragraph. The sentence should read as follows: "Our instrument, the Parental Bonding Index, is designed to measure recollections of abnormal parenting over the first 16 years of life."

# AIDS Policy:
# Guidelines for Outpatient Psychiatric Services

*This revision of the statement originally adopted in September 1988 was proposed by the Commission on AIDS.*[1] *It was approved by the Board of Trustees in December 1991.*

Psychiatrists providing outpatient psychiatric care to HIV-infected patients and those at risk are faced with several important tasks: to ensure care of the highest quality, to respect the confidentiality and rights of infected patients, and to protect others from outpatients whose behaviors could transmit HIV infection.

## PATIENT CARE

All available evidence indicates that AIDS is a disease of low transmissibility in the medical setting. Education and counseling regarding HIV transmission must be provided to psychiatrists and other medical personnel.

1. All psychiatric patients should be treated on the basis of their clinical condition; HIV infection, serologic status (e.g., HIV status), or suspicion that the patient is at risk for HIV infection should not, in and of itself, impede the delivery of appropriate medical-psychiatric treatment.

2. In therapeutic relationships, the psychiatrist should work with patients to reduce risk behavior regardless of serologic status.

3. Psychiatrists should be competent in counseling patients regarding seeking HIV serologic testing. Psychiatrists should be well informed about the need for pre- and posttest counseling. Psychiatrists should be able to distinguish anonymous and confidential testing and should know the implications and limitations of confidentiality.

4. In situations where a psychiatrist has received convincing clinical information that the patient is infected with HIV, the psychiatrist should advise and work with the patient either to obtain agreement to cease behavior that places others at risk of infection or to notify individuals who may be at continuing risk of exposure. If a patient refuses to agree to change behavior or to notify the person(s) at ongoing risk or if the psychiatrist has good reason to believe that the patient has failed to or is unable to comply with this agreement, it is ethically permissible for the psychiatrist to notify identifiable persons who the psychiatrist believes to be in danger of contracting the virus, or to arrange for public health authorities to do so.

5. Although HIV is an infection of low transmissibility in the medical setting, psychiatrists have a responsibility to reduce risk of HIV transmission from patient to patient, patient to staff, and staff to patient.

All patients and staff should be considered potentially at risk for transmitting or receiving HIV infection. A minimal standard of care should include the following:

   a. Implementation and monitoring of infection control procedures as outlined by current Centers for Disease Control standards.
   b. Appropriate management of affective, cognitive, and behavioral disturbances to ensure risk reduction for both patients and personnel.

6. AIDS education is important in the treatment of all psychiatric patients. Culturally sensitive and age-appropriate educational and supportive services for patients, families, and staff should be available. Such services would include the following:

   a. Printed educational materials readily available to patients and staff.
   b. Education regarding behaviors that place an individual at risk for HIV infection, and alternative behaviors.
   c. Evaluation of a patient's behavior for assessment of risk to self or others.
   d. Discussions of HIV testing that include indications for and consequences of such testing.

7. Psychiatrists should obtain consent to contact and communicate with the medical care providers of HIV-infected patients and to facilitate a referral if medical care is inadequate or nonexistent.

## CONFIDENTIALITY AND RIGHTS

Psychiatrists and other members of the clinical team should respect the patient's right to privacy. Disclosure of a patient's serologic status (e.g., HIV status) should be limited to those staff directly involved in the patient's care when such disclosure is appropriate for diagnosis, management, and treatment. Disclosure to other clinic or office staff is not appropriate. Psychiatrists and HIV-infected patients should appreciate the problems associated with unwarranted disclosure of serologic status. Psychiatrists should further be aware of regional legislation or statutory regulations regarding disclosure of serologic status. Patients should be made aware of clinic or office policy regarding documentation of serologic status in medical records. If clinic or office policy compels documentation of HIV serologic status in the medical record, the patient should be informed of such policy before initiating treatment.

# AIDS Policy: Guidelines for Inpatient Psychiatric Units

*This revision of the statement originally adopted in December 1987 was proposed by the Commission on AIDS.[1] It was approved by the Board of Trustees in December 1991.*

Psychiatrists providing inpatient psychiatric care to HIV-infected patients and those at risk are faced with several important tasks: to ensure care of the highest quality, to respect the confidentiality and rights of infected patients, and to protect other patients and staff from behaviors that could transmit HIV infection.

## PATIENT CARE

1. HIV-infected patients are entitled to the same standard of care as other patients. This includes rigorous diagnosis and treatment of mental disorders. In addition, psychiatrists should understand how HIV-related medical conditions may affect psychiatric diagnosis and treatment.
2. HIV serologic testing of psychiatric inpatients should be performed on a case-by-case basis when medically indicated and with informed consent. HIV serologic testing should not be performed solely for the purpose of routine screening or staff awareness.
3. In addition to treating the psychiatric disorders of HIV-infected persons, inpatient psychiatric care should also include counseling regarding risk reduction measures and education about medical treatment for HIV infection and its complications. Discharge planning should address the patient's needs for ongoing medical care. Family members and significant others should be involved in counseling and education, if appropriate.
4. Sex and needle sharing do occur in psychiatric inpatient settings. It is unacceptable to fail to protect patients from such high-risk behaviors. However, in acknowledging our limitations, we must develop strategies for safeguarding patients while they are in the hospital and for preparing them to safeguard themselves when they leave the hospital. Certain populations, such as youth, the chronically mentally ill, the developmentally disabled, and the chemically dependent, may be particularly vulnerable to unwanted sexual advances or may not be able to make free and informed choices regarding consensual sex. This issue will be addressed in full in a separate document.
5. When discharge is otherwise clinically appropriate, and if the patient represents a substantial risk of danger to others by virtue of behavior known to transmit the virus and if this danger is not related to a specific mental condition, it is inappropriate to retain the patient in the hospital solely for the purpose of quarantine or preventive detention.

## CONFIDENTIALITY AND RIGHTS

Psychiatrists and other members of the clinical team should respect the patient's right to privacy. Disclosure of a patient's serologic status (e.g., HIV status) should be limited to those staff directly involved in the patient's care when such disclosure is appropriate for diagnosis, management, and treatment. Disclosure to other hospital staff (e.g., housekeeping staff, attending physicians on other services) is not appropriate. Psychiatrists and HIV-infected patients should appreciate the problems associated with unwarranted disclosure of serologic status. Psychiatrists should further be aware of regional legislation or statutory regulations regarding disclosure of serologic status. Patients should be made aware of hospital policy regarding documentation of serologic status in medical records. If hospital policy compels documentation of HIV serologic status in the medical record, the patient should be informed of such policy before admission.

## PROTECTION OF PATIENTS AND STAFF

1. Although HIV is an infection of low transmissibility in the medical setting, psychiatrists have a responsibility to reduce risk of HIV transmission from patient to patient, patient to staff, and staff to patient.
2. All patients and staff should be considered potentially at risk for transmitting or receiving HIV infection. A minimal standard of care should include the following:
   a. Implementation and monitoring of infection control procedures as outlined by current Centers for Disease Control standards.
   b. Appropriate management of affective, cognitive, and behavioral disturbances to ensure risk reduction for both patients and personnel.
   c. Appropriate education and supportive services for patients, families, and staff.
3. If a patient known to be HIV infected engages, or threatens to engage, in behavior that places other individuals at risk, the responsible physician should assure that appropriate steps are taken to control the behavior and, if necessary, isolate and/or restrain the patient. Adequate supervision must be available to ensure that all patients, regardless of serologic status, are not able to engage in behavior likely to transmit HIV in the inpatient setting. Disclosure of a patient's HIV status to other patients is not a substitute for adequate clinical care and supervision (see APA "AIDS Policy: Confidentiality and Disclosure"—currently under review).
4. Should a health care worker or patient come into significant contact with blood or other potentially infective body fluids, the source should be approached regarding voluntary HIV serologic testing.

# APA Actions on Reproductive Rights

*This statement was proposed by the Committee on Women*[1] *of the Council on National Affairs. It was approved by the Board of Trustees in September 1991 and by the Assembly of District Branches in November 1991.*

## BACKGROUND

The APA position statement on abortion states,

> The American Psychiatric Association 1) opposes all constitutional amendments, legislation, and regulations curtailing family planning and abortion services to any segment of the population; 2) reaffirms its position that abortion is a medical procedure in which physicians should respect the patient's right to freedom of choice—psychiatrists may be called on as consultants to the patient or physician in those cases in which the patient or physician requests such consultation to expand mutual appreciation of motivation and consequences; and 3) affirms that the freedom to act to interrupt pregnancy must be considered a mental health imperative with major social and mental health implications.

It has also been shown that the children of unwanted pregnancies are at high risk for abuse, neglect, illness, and deprivation of a high quality of life. Despite such data, there are still efforts by individuals, groups, and governments to restrict family planning information, research on abortion methods, and a woman's right to have accurate information about her various reproductive options, including her choice to terminate her pregnancy.

## PROBLEM

A number of recent events threaten to erode the rights of women to freedom of choice concerning reproductive options. These include the recent Supreme Court decision resulting in a "gag rule" for information about pregnancy termination options in clinics receiving federal funds, the most recent Supreme Court appointment, and the publicity about RU-486 research.

## ACTIONS

The APA Board of Trustees pledges to immediately take the following actions congruent with the APA position statement on abortion.

1. APA will align with the AMA and other groups through appropriate lobbying efforts in Congress to prevent a veto of the recently passed legislation striking down the regulations that restrict professionals' freedom of speech in discussing therapeutic abortion as a reproductive option.
2. APA will support access to family planning services both domestically and internationally by requesting the Medical Director to write to Louis Sullivan, M.D., Secretary of the U.S. Department of Health and Human Services, and to Antonia Novello, M.D., the U.S., Surgeon General, stating APA's position on abortion and expressing our concern about the adverse effects on women and children's mental health of the "gag rule."
3. APA will become an active participant with organizations such as the American Association for the Advancement of Science, the American Pediatric Society, the Society for Pediatric Research, the American Institute of Biological Sciences, and the Cancer Patient Action Alliance in their efforts to lobby the government to permit research in North America on the efficacy and benefits of RU-486.
4. APA will continue to work vigorously at the local and national levels by having the Joint Commission on Public Affairs promulgate APA's position statement on abortion in the service of improving currently attenuated and threatened access to the full array of reproductive services. For example, APA should circulate copies of the position statement to the district branches and ask them to be active at the local level in affirming this position. APA should also actively respond to possible restrictions on women's rights to abortion by assertively stating and explaining its position.

Chang, M.D., Kathleen McKenna, M.D. (consultant), Mai-Phuong Nguyen, M.D. (APA/NIMH Fellow), and Yvonne B. Ferguson, M.D. (Assembly liaison).

# Position Statement on the Care of Pregnant and Newly Delivered Women Addicts

*This statement was proposed by the Committee on Women*[1] *of the Council on National Affairs. It was approved by the Board of Trustees in June 1991 and by the Assembly of District Branches in November 1991.*

## RATIONALE

The substance abuse epidemic, especially the use of crack cocaine and including alcohol, has resulted in tragic damage to and neglect of users and their children. This epidemic, which disproportionately affects women of color, is a social, medical, and legal crisis.

Substance abuse is a psychiatric disorder. Many of the women affected suffer from psychiatric comorbidity. Many suffer from abuse and deprivation.

Many of the children of these mothers suffer from arousal and affective regulatory problems, language disorders, and impulsive and hyperactive behavioral difficulties that require psychiatric assessment and intervention.

There has been a recent trend toward prosecution, on grounds of child abuse, of pregnant and/or postpartum women who use illegal substances, with subsequent incarceration, either in prison or in locked psychiatric units. This seriously disrupts the incipient or nascent maternal-infant bond.

In many or most geographic areas, there are few voluntary treatment facilities or far fewer beds than the number of affected women. This is unfortunate as evidence shows that during pregnancy and the 2 years postpartum women are particularly open to treatment and it is highly effective.

## ACTIONS

The APA Board of Trustees intends to take a leadership role in advocating on behalf of both these mothers and their children with departments of social services or their agencies that are legally responsible for the safety of these children. This advocacy will serve to enhance these mothers' parenting, to preserve the integrity of their families whenever possible, and to ensure the safety of their children. APA also takes the following specific positions.

1. APA opposes the criminal prosecution and incarceration of pregnant and/or newly delivered women on child abuse charges based *solely* on substance abuse. (Child abuse charges may be appropriate when a substance abuser goes on to neglect or abuse her child.)
2. APA advocates that adequate prenatal care be available to all pregnant women, including pregnant addicts, irrespective of ability to pay and without fear of punitive consequences.
3. APA urges that societal resources be directed not to punitive actions but to adequate preventive and treatment services for these women and children. APA strongly advocates the development and funding of the necessary inpatient, outpatient, and residential programs for mothers with their children. Services should address and foster the parental function, as well as the care of individual mother and child.

---

# Philippe Pinel's "Memoir on Madness" of December 11, 1794: A Fundamental Text of Modern Psychiatry

Dora B. Weiner, Ph.D.

*Philippe Pinel's "Memoir on Madness" can now be precisely dated. It was read to the Society for Natural History in Paris on Dec. 11, 1794, soon after the fall of the Jacobin dictatorship. It is thus a* political *document, an appeal to the Revolutionary government to build asylums where the mentally ill could be decently treated. It is translated here for the first time. Philippe Pinel (1745–1826) served as "physician of the infirmaries" at Bicêtre, the public hospice for men near Paris, from 1793 to 1795. In the "Memoir on Madness" he explains his "psychologic treatment," the principles of the humane method that made him the founder of psychiatry in France. Pinel states that mental illness is often* curable. *To arrive at a diagnosis, the physician must carefully observe a patient's behavior, interview him, listen carefully, and take notes. He must understand the natural history of the disease and the precipitating event and write an accurate case history. Diagnosis and prognosis can then be made. Periodic patterns of mental illness can be helpful for therapy. Usually only one faculty is affected. Patients with delusions may be malicious or murderous. They may have to be restrained; it was Pinel's assistant, Jean Baptiste Pussin, who removed the chains from the insane men at Bicêtre Hospice in 1797 and replaced them with straitjackets. Pinel followed suit at the Salpêtrière, the public hospice for women, 3 years later. Pinel here states that one must "dominate agitated madmen while respecting human rights."*

(Am J Psychiatry 1992; 149:725–732)

The essay presented here for the first time to the English-speaking reader should be considered as a fundamental text of modern psychiatry because of its author, its contents, and the extraordinary historic circumstances under which it was first read to a Revolutionary audience in Paris. It is a classic text for psychiatry. It was recently published in French, but only now can a precise date be given for its public presentation, thus establishing its full meaning, professional impact, and political purpose (1).

The author was then a physician just short of his 50th birthday, known in Paris medical circles as the editor of the *Gazette de santé* and among natural scientists as a regular contributor to the *Journal de physique.* His M.D. degree from the University of Toulouse, awarded on Dec. 21, 1773, licensed him to practice in that town only. So he supported himself for the subsequent 20 years in Montpellier and Paris with lessons in mathematics and the translation of medical works such as

William Cullen's *First Lines in the Practice of Physic* in 1785 (2). He also practiced a little medicine on the sly and served as consultant at the nursing home of Jacques Belhomme (1737–1824), where some mental patients attracted his attention. Meanwhile, his research interest veered toward natural history.

Pinel's systematic involvement with nature began on botanizing expeditions under the leadership of Louis Guillaume Dubernard, professor of pharmacy and chemistry at Toulouse. What a revelation the botanical gardens at Montpellier must have been when Pinel first visited them in 1774! Here the great botanist Joseph Tournefort (1656–1708) had arranged over 10,000 species in the order in which he believed the Almighty had created them. The Royal Botanical Gardens in Paris, directed by Georges Leclerc, count de Buffon (1707–1788), were a grander establishment to be sure, but no richer in plant varieties. The main difference was the large number of brilliant naturalists and *philosophes* interested in nature whom Pinel met in Paris, with whom he could interact at the Gardens as well as in salons and coffee houses, academies, and societies. A topic of lively discussion in the 1770s and 1780s was species formation—whether God had created nature once and for all times, or whether new plant or animal species might have been formed after the Flood. Pinel inclined toward the latter view: he studied animal skulls, particularly the articulation of the jaw, and found it to be adapted to the mastication of specific foodstuffs. He measured the skulls for shape and dimensions, musing about the size and functions of the brain in a search for classificatory clues.

The Paris Botanical Gardens evolved into a scientists' haven in the early 1790s when radical revolutionaries abolished most learned institutions of the old regime, perceiving them as centers of elitism and privilege. But some naturalists with good political connections convinced the Jacobins that natural history was a democratic pursuit, in contrast to science and medicine. This odd theory worked, with the result that the Botanical Gardens—now the Muséum national d'histoire naturelle—and the Society for Natural History, to which Pinel belonged, attracted a growing number of physicians such as Félix Vicq d'Azyr (1748–1794) and Jean Noël Hallé (1754–1822), who now mingled with naturalists and other scientists including Jean Baptiste de Lamarck (1744–1829), Etienne Geoffroy St. Hilaire (1772–1844), Georges Cuvier (1769–1832), and Antoine Laurent Lavoisier (1743–1794). The controversy over classification involved them all, as we learn from the minutes of the Society, some of them in Pinel's hand.

Pinel was appointed "physician of the infirmaries" at Bicêtre, the public hospice for men near Paris, on Aug. 6, 1793, and entered that forbidding fortress on Sept. 11. His attention immediately focused on the seventh ward, where 200 mentally ill men were housed. He asked for a report on the inmates and within a few days received a table with comments from the "governor," Jean Baptiste Pussin (1745–1811), the man who would become his trusted collaborator (3). In the introduction to his famous *Treatise on Insanity* of 1800, Pinel explained that he "abandoned the dogmatic tone of the physician and . . . talked repeatedly with the man who was most familiar with [the inmates'] previous state and their delirious thoughts . . . in order to ask him numerous and repeated questions . . . . " His ultimate purpose, Pinel announced, was to "enrich the medical theory of mental illness with all the insights that the empirical approach affords." At the same time he aimed at "providing practice with the general principles that it lacked" (4). A comparison of Pinel's "Memoir on Madness" with "Observations of Citizen Pussin on the Insane" shows how much the two men learned from each other (5).

While thus honing his understanding of the mentally ill, Pinel transferred his interest in natural history from the botanical garden to the mental hospital. It was not long before he measured human heads, shifting his concern from the classification of animals to a triage of patients and their division into "distinct species." He jotted down an initial, crude classification in a "General Table of the Madmen at Bicêtre Numbering about 200," which has been preserved (6).

Within a year his attention would again be diverted, this time to the classification of all diseases. His appointment to a professorship in "internal pathology" at the new Revolutionary Paris Health School led him to compose a textbook of nosology in clear and simple French. The *Philosophic Nosography* became a fundamental text for a whole generation of French medical students, as the demand for six editions from 1798 to 1818 indicates (7). He also published a second, much enlarged, edition of the *Treatise on Insanity*, and this book was translated into several European languages (8).

But during his 19 months at Bicêtre Pinel's preoccupation remained focused on pathologic human behavior, the study of what he would soon call "mental alienation." He detected in specific behaviors the signal of malfunction or abolition of one or another mental faculty. This perception derived from the observation of the patients in relation to their natural surroundings, and he combined this with the concept that diseases also have a natural history. Therefore each illness represented the intersection of a human being at a specific moment in life with a disease at a particular stage of its development. That is why Pinel meant his memoir to be a "contribution to the natural history of man." It goes without saying that this approach blurred distinctions between somatic and psychologic signs and symptoms. As clinician, author, and professor of "internal pathology" for 30 years, Pinel never concentrated on diseased limbs and organs, as would his students, for example, Xavier Bichat (1771–1802) and René Théophile Hyacinthe Laënnec (1781–1826). The hundreds of case histories in Pinel's book *Clinical Medicine* show that he always approached the patient as an integral human being (9).

It is from the minutes of the Society for Natural History that we garner new information about Pinel, for example, from 16 autograph folio pages entered when he served as secretary for the first 6 months of 1792. His appearances at the society became rare after his appointment as physician at Bicêtre. But on the first of December 1794 he announced personally that he wished to speak on the 11th—the society then met every *décadi.* The date itself is revealing, for on the fourth—Frimaire 14, Year III of the Revolutionary calendar—the government published legislation creating the new Health Schools and on Dec. 14 Pinel was named associate professor of medical physics, second in command to the famous hygienist Jean Noël Hallé. (Pinel rose to professor of "internal pathology" 6 months later.)

The inference is obvious. His sponsors in the Committee of Public Instruction and in the Paris Hospital Commission—Michel Augustin Thouret (1748–1810), Jacques Cousin (1739–1800), and Georges Cabanis (1757–1808)—thought it politic that their professorial candidate have some public exposure. Pinel seized the occasion to announce his pathbreaking innovations at Bicêtre: the long-term observation and individual management of the mentally ill, even the poorest among them, in a psychologically sensitive manner and without violence—he called this "*traitement moral.*" He stated publicly that mental illness may be curable. He explained the main categories adopted in his classificatory scheme; his concurrence in the view that mental illness usually involves specific mental faculties, not the mind as a whole; his differential diagnosis between continuous and "periodic" insanity (which he named); and the importance of heeding the signs and symptoms that signal the onset and resolution of violent attacks. These concepts, some traditional, some original, blossomed into three papers that Pinel presented to the Society of Medical Emulation and became three chapters of the *Treatise on Insanity.* It is important to point out that "*traitement moral*" meant psychologic treatment, in contrast to physical treatment, and the term should not be translated into the English "moral" with its connotation of moralizing, which the French does not convey. As for periodic insanity, it was a new concept with profound implications for therapy. If the patient was intermittently insane, then he or she was intermittently sane. Knowing this, the therapist could attempt to establish confidence and a good relationship with the sane part of the person and involve the patient in the therapeutic process. Gladys Swain has brilliantly analyzed this idea in *Le sujet de la folie,* revealing that as great a thinker as Georg Wilhelm Friedrich Hegel (1770–1830) singled out Pinel's innovative concept (10, 11).

No physician had yet written case histories as sympathetic and eloquent as the ones that Pinel read to the Society for Natural History in December 1794. We turn, for example, to the vignette of the clockmaker who believed himself seized by perpetual motion or the white-haired 70-year-old who was convinced that he was a young woman. These would soon be quoted in the whole Western literature of the nascent psychiatric specialty. By speaking of these destitute mentally ill men with understanding and respectful kindness toward each inmate, Pinel initiated a new tone, lowered fear of the insane, and facilitated a more evenhanded, democratic approach to public medicine in large hospitals. He paid tribute to Jean Baptiste Pussin, whose reliance on firm and even authoritarian behavior Pinel adopted when this seemed necessary to ensure everyone's safety. Although condemning physical mistreatment, Pinel condoned the exceptional use of threats and chains when all other means failed: for example, he cites in this memoir three patients shackled for 15, 25, and even 45 years, and he made no move at that time to eliminate the iron shackles or to replace them with straitjackets. It was Pussin who initiated these humane measures at Bicêtre in May–June of 1797, as he records in his "Observations," dated Dec. 21, 1797. Pinel followed Pussin's example 3 years later at the Salpêtrière, the public hospice for women, where he then served as physician-in-chief. Pinel recorded these crucial, humane changes in the second edition of his *Treatise* in 1809 (where he mistakenly gives the date of Pussin's initiative as 1798, instead of 1797) (p. 201 and introduction, p. xxxi). The "governor" set the example that the physician incorporated into broadly conceived reforms.

Several jibes at England for keeping her successful methods secret remind us that the two countries were then at war and that, among other things, this memoir was a political document. It also points to Pinel's awareness of his colleagues' efforts across the channel. Addressing the French government directly, Pinel presented a plan for improvements, demanding more funds and facilities, an asylum worthy of the French nation. As Jacques Postel rightly remarks, this memoir is "the matrix of the future *Treatise on Insanity*" (1, p. 233). One must not forget that these statements came from the government-appointed physician at the largest French public asylum for men, with some 4,000 inmates. The response of the Society for Natural History adds a further political dimension: "The Society voted to forward this Memoir to the Committee of Public Safety." Unfortunately, the most diligent searches in the Archives nationales have not yet turned up the manuscript (12).

The major part of this essay has been available since 1910, when René Semelaigne presented it to the French Society for the History of Medicine; Georges Bollotte republished it in *Information psychiatrique* in 1976. But not until now is there an explanation as to when and why Pinel wrote this memoir. These circumstances as well as the contents make this a pivotal text in the history of psychiatry. It expresses the fundamental new ideas and attitudes elaborated in Pinel's *Treatise on Insanity* 6 years later; it may well have been responsible for his appointment to a prominent professorship and thus have led him to compose the *Philosophic Nosography.* The date of Dec. 11, 1794, pinpoints Pinel's appearance among the reformers of mental health care in the Western world. It places him well before the opening of William Tuke's Retreat at York and makes Pinel's initial formulations exactly contemporaneous with Vincenzo Chiarugi's *Della pazzia,* thus ending

Italian claims of priority once and for all. But mainly the "Memoir on Madness" gives us what historians and psychiatrists prize: the earliest formulation of important new concepts and attitudes. Pinel, physician of the Enlightenment and the French Revolution, expresses a genuine empathy with the sufferings of ordinary men—a distraught father, a jilted lover—and points out that gifted and sensitive persons are particularly vulnerable to mental anguish. He claims for them the attention and care that the natural rights of man imply. This is a classic text because of its permanent human and humane qualities. It deserves to be known in the English-speaking world.

## "MEMOIR ON MADNESS: A CONTRIBUTION TO THE NATURAL HISTORY OF MAN," DECEMBER 11, 1794, BY PHILIPPE PINEL, M.D., PHYSICIAN OF THE INFIRMARIES, BICÊTRE HOSPICE, SEINE DEPARTMENT

When I was appointed physician of the infirmaries at Bicêtre over 1 year ago, the division for madmen attracted my special attention. I had undertaken some preliminary studies and felt the strong urge to try every means of restoring alienated reason. Thus I looked upon Bicêtre as a source of new enlightenment and instruction and a most welcome opportunity to contribute to public usefulness. But successive changes in the administration of Paris hospitals have deprived me of several facilities. I have neither baths nor showers: these were only authorized a few days ago. I have therefore restricted my activities this year to a thorough study of the true nature and varieties of madness, to the effort of obtaining for the insane everything that might improve their condition and especially to a search for fixed principles derived from nature on which to base their management and supervision, which contribute so much to the recovery of reason. I had the satisfaction of seeing 25 of 200 inmates—that is 1/8 of them—recover. I shall therefore present the result of my observations and efforts on this subject during the Year II of the Republic [Fall 1793–Fall 1794].

### I

A large gathering of madmen inspires an undefinable thoughtful tenderness when one realizes that their present state derives only from a vivid sensitivity and from psychologic qualities that we value highly. I find that truth ever more convincing and confirmed by my daily notes. Here is the father of a family whom unexpected losses have thrown into despair; here a son exhausted by work and vigils to provide for his parents' subsistence; elsewhere a passionate and sensitive young man, victim of unrequited love; there a tender husband, distracted by suspicions and the justified or false umbrage of jealousy; a young warrior thirsting for glory whose vast and ambitious projects failed, his spirit crushed by the harsh experience. Religious zeal claims its victims, as does ardent military fervor, which often expresses all the reveries and excesses of manic fanaticism. Man is most often led from the free use of reason to madness by overstepping the limits of his good qualities and of his generous and magnanimous inclinations.

The excessive sensitivity that characterizes very talented persons may become a cause for the loss of their reason: I mention this as a well-meant warning without the intention of discouraging them. Groups as diverse as investigators, artists, orators, poets, geometers, engineers, painters, and sculptors pay an almost annual price to the hospice for the insane. I have on more than one occasion stopped at the cell of a madman speaking about current affairs in the most elaborate terms and with great verve. The exalted imagination of poets also leads sometimes to madness, and I am often importuned by a confabulator who urges me to read his productions, while I see only the urgent need to subject him to treatment for madness. Recently I watched one of the most distinguished sculptors of the Pantheon die in the hospice for the insane. One of the most skillful clockmakers of Paris, infatuated with the fantasy of perpetual motion, spent a long time in the hospice but has now been returned to his family. Patriotism is pained to find among the inmates an engineer employed during the siege of the town of Condé who exhausted himself by work and sleep deprivation. There are usually some famous painters, at the moment two skilled artists named after the famous Le Sueur. I also give special care to a man versed in the most profound mathematical meditations who lost his reason because of ever-renewed fears that Vandalism visited upon true Knowledge. How many talents lost to Society and what great efforts are needed to salvage them!

Madness may be continuous during a large part of life or show long remissions, increase steadily, without interruption, or occur in regular or irregular attacks. This points to two kinds of madness: one continuous or chronic, the other intermittent or characterized by the most violent recurring symptoms.

In continuous insanity, the madman is ceaselessly preoccupied by an exclusive thought or a fixed sequence of thoughts or else led to acts of violence while his reasoning faculties appear intact. He seems dominated by a sinister tendency to harm and to destroy. This derangement of his psychologic faculties stays with him for a large part of his life, with very little change. In this hospice for the insane there is a melancholic inmate with sinister looks who has been chained for 25 years and who tries to vent his fury on anyone daring to set foot in his cell. He relents only in the presence of women, toward whom he behaves in a gentler manner. Another madman who is just as agitated and violent has been chained for 45 years, and it is only since the harsh winter of 1788 that he is calmer, or rather, advancing age has rendered him harmless. In contrast, neither the change of seasons nor the passage of time has markedly altered the condition of an Irish priest chained for 15 years: he combines a deadly inclination to harm with perfidious cunning, and his polite behavior is designed to detect opportunities for venting his fury. The insanity caused by religious fervor or a zeal for devout thoughts usually persists without interruption until the end of life. Puffed-up ambition or the mad thought of believing oneself a king or prince is just as hopeless, an almost indestructible and seductive illusion. The madman who believes he is Louis XIV and who often hands me Dispatches for the Governments of his provinces is so enchanted with his exalted power that his imagination holds on to it: he would make too great a sacrifice in stepping down from his imaginary throne.

One cannot ignore a striking analogy in nature's ways when one compares the attacks of intermittent insanity with the violent symptoms of an acute illness. It would in either case be a mistake to measure the gravity of the danger by the extent of trouble and derangement of the vital functions. In both cases a serious condition may forecast recovery, provided one practices prudent management. These bouts often depend on the seasons and should not be confused with the passing effervescence and tumultuous agitation caused by the state of the atmosphere. The fact is that in very hot weather or during thunderstorms, almost all the madmen in the hospice turn garrulous, vociferate ceaselessly, and show an agitation comparable to the violent state. But this kind of nervous excitement ends with its cause. A purely automatic imitation may also involve the madmen's limbs, imparting a temporary perturbation. Suppose a madman on the ward unexpectedly seized by an attack or, between attacks, exploding indignantly with shouts and vociferous threats against the employees or directors. It is then quite usual to see all the madmen crowd around him, share in his mental state, and participate for a few moments in this mad delirium.

The idea of madness should by no means imply a total abolition of the mental faculties. On the contrary, the disorder usually attacks only one partial faculty such as the perception of ideas, judgment, reasoning, imagination, memory, or psychologic sensitivity. A madman who died this year and who thought that he was Louis XVI was a living example of the nonconformity of ideas with the objects that occasioned them, since he saw in all persons who entered the hospice so many Pages or Guardsmen come to receive his orders. Should I give examples of errors of judgment? I found them in a rather frequent kind of madness that consists of the unfounded association of poison with food and the consequent refusal to take any nourishment. Errors of reasoning are much rarer among madmen than is commonly thought, for they derive reliable inductions from a particular sequence of ideas that preoccupies them. The white-haired 70-year-old still living at Bicêtre who believes that he is a young woman is in perfect agreement with himself when he obstinately refuses other than feminine clothing, adorns himself with care, is flattered by the polite behavior of the staff and their talk of his prospects of an approaching marriage, or when his modesty seems alarmed at the least indecent gesture. How many examples I could cite of illusions or flights of the imagination, this being one of the human faculties most susceptible to madness. A total upheaval of the rational faculty, or rather, a bizarre association of the most incongruous and incoherent ideas is quite rare, and I confine myself to citing the example of a madman whom I transferred to the infirmary a few months ago and who presents a veritable image of chaos, with the most absurd and ridiculous aberrations unconnected to any of his previous thoughts.

Madness is by no means characterized by a constant uniformity of willed physical actions or inclinations of the heart. Some madmen, possessed by a somber misanthropy, seek only solitude and live withdrawn in their cells; others remain motionless and take on a stupid expression if one speaks to them; others talk, shout, and rant day and night and appear continually agitated, but they are not to be feared unless provoked. It is distressing to see others, apparently possessed by the demon of malice, always do the opposite of what they are told in order to try the patience of the administrators, spy on the employees to trick them in mean ways or dump garbage on them, in other words, derive odious pleasure from disorder and trouble. Another much more dangerous madness seems connected with a blind rage and a kind of destructive instinct that impels to tear everything reachable to pieces and inspires the most bizarre cruelties, as some unfortunate madmen confess after their attacks subside. How often delirious fury is the product of the mystical dreams of fanaticism! One of the madmen who must be kept tightly locked up is subject to visions at night, and during these ravishing ecstasies he believes that an order from heaven commands him to bestow the Baptism of Blood and merciless immolation upon all those whose happiness in the next life he craves. How much supervision such madness demands! In the horrible derangement of his reason this wretch plunged a dagger into the hearts of his own children.

I have tried to understand how attacks of madness usually begin and have been surprised by the diversity of signs that foretell an approaching explosion of manic delirium in a variety of madmen. Sometimes there are futile excesses of fervid joy and immoderate bursts of laughter, at other times a somber taciturnity or extreme anxieties and groundless tears; a readier anger, a livelier glance, or brusque replies often lead me to predict an approaching attack and the urgent need to use coercive measures. But what seems to me likely to frustrate all human prudence is that sometimes the attack occurs with lightning speed. The eyes begin to glint, the face turns fiery, all muscles tense up violently and acquire extreme strength while the madman's single wish seems to be to tear and to destroy. What a contrast when one compares this delirious fury with the raptures of a man rendered mad by love who, the day before his attack, confided to me a dream designed to make his lifelong happiness: his love had appeared to him with features of the most ravishing beauty, and he believed that she promised soon to unite her destiny to his. I have never heard love spoken of with such ardor.

The ways of nature are no less admirable in the termination of attacks of madness than in the critical resolution of other illnesses and the gradual recovery of health. These attacks sometimes end in a kind of progression, and the madmen who had remained for a long time in a turbulent agitation or who tore everything become calmer; but they still feel troubled, their thoughts are disordered, and they themselves know that they are not sufficiently in control of themselves to be responsible for their willed behavior; each day the movements and actions that impelled them beyond the bounds of reason grow more temperate and all the mental faculties recover their rights; some of them indicate the exact moment when one can give them their freedom within the hospice, while others demand it too soon, when it would be very dangerous to turn them loose.

One can observe at Bicêtre a different outcome of madmen's attacks that requires great vigilance from the staff because it demands the most active intervention. This termination is quite abrupt and succeeded by a certain atony, a state of dejection and cold when one must warm the madman and even cover him with three or four woolen blankets to prevent his demise. The remission of maniacal delirium is most frequent in fall and early winter; if this sudden change occurs at night it can become fatal for lack of help; this happens every year, whatever precautions one may take.

To consider madness as a usually incurable illness is to assert a vague proposition that is constantly refuted by the most authentic facts. An understanding of the varieties of madness teaches one to identify the almost certainly curable cases, the doubtful ones, those where relapses are to be feared, and those without any hope of cure. If a mature man has a strong constitution, if the cause of his madness is a violent passion and the attacks recur periodically, then reason eventually regains its rights provided the madman is guided wisely and pursues work or a hobby with regularity. But what are the prospects of insanity that is hereditary or that derives from an organic flaw? Sometimes the reiterated attacks degenerate into dementia or lead slowly to the tomb. Two kinds of madness seem, more than any other, made to last a lifetime: the first springs from puffed-up self-importance, making believe that one is a prince or a divinity; the other derives from the derangements and frenzies of fanaticism. What to do for a madman grown old in the belief that he is Louis XVI who, confusing times and places, wishes me to attend him at court and thinks that he is alternately at Bicêtre, in Paris, or in Rome? But nothing is more atrocious and savage than the somber dreams and fanatical madness of an atrabilious worshiper. I have already mentioned a madman who became the executioner of his own children, seeking only to dispense a Blood Baptism that brings eternal bliss. Recently the director of the hospice was attacked by one of these pious visionaries while he was making his rounds. The madman seized him by the hair from behind, hit him repeatedly with the back of a Bible till he lost consciousness, and would unquestionably have beaten him to death had the employees not come to the rescue. When questioned a few moments later about the motive that had compelled him to commit this furious act, the madman coolly cited examples from the Bible and added that, moreover, he should be considered another Maccabaeus.

## II

The hospice for madmen at Bicêtre was considered under the old régime as no more than a place of sequestration and imprisonment for a class of dangerous men who needed to be segregated from Society. It was deemed sufficient to subject them first to a rough treatment at the Hôtel-Dieu consisting of bleedings, baths, and showers. They were then abandoned to the incompetence of a callous director and to the cold brutality of servants who opposed a premeditated force of their own to impetuous acts of a blind and seemingly automatic violence. No one paid heed to the only means of restoring deranged reason firmly; I mean the art of studying the tastes and inclinations of the various madmen in order to guide them in a contrary direction, and the even more difficult art of combining affability with firmness in a well-timed manner, distracting the exclusive thoughts that preoccupy them, using only innocent repressive means, never blows or harsh treatment: these serve only to exasperate madness and often render it incurable.

It is true that a person who seeks to acquire the right ideas and fixed principles about the psychologic treatment of madness hardly knows where to turn. Medical treatises offer only general views, and in specialized treatises one finds only isolated observations irrelevant for a large group of maniacs. Travelers have not yet brought us specific enlightenment in their reports about various European institutions of this kind. The rights of man are too little respected in Germany to make the study of their ways of handling the insane in public establishments worthwhile. Spain has taken only a few steps toward this great goal, as I showed a few years ago in a periodic publication: the inmates of a public asylum dedicated to their custody are managed with the greatest gentleness and assigned to regular work which has served to cure most of them. But it is mainly England one must envy for the artful wisdom of managing a large group of madmen and effecting the most unexpected cures. Why does that haughty and self-righteous nation spoil such a great gift to humanity by keeping a mysterious silence and guiltily casting a veil over its skill to restore distracted reason? The English proudly display the majestic sight and the internal arrangements of the asylums that Philosophy has dedicated to the unfortunate insane. But they keep the art of managing the insane a deep secret which they apparently want to control and keep from other peoples. I have therefore been restricted this first year to the slim resources of the preliminary studies I had done and to the observations I was making daily; I have carefully examined and compared the several varieties of insanity to deduce firm rules for managing all of them. I summoned new courage for the endless fight against all kinds of obstacles, be they unsuitable lodgings or the kind of neglect from which madmen still suffer because of inveterate prejudices. I shall now indicate how their lives have been improved, until we can do better still.

I asked that the registers be used to establish an exact count of the numbers of deaths in the hospice for the insane during the years immediately preceding the Revolution. I must say that there is no more convincing evidence of the flagrant neglect to which the old regime abandoned this part of suffering humanity. Of 110 madmen admitted to the hospice during the year 1784, 57, i.e., more than one-half, died. The proportion was even worse in 1788 when 95 of 151 died, a frightening result in a group of men who are usually full of life. In contrast, during this past year, I only lost 28 of 200—and if one were to count only those who died of an illness, this would mean deducting eight who succumbed a few days after their arrival because of the violent treatment administered at the Hôtel-Dieu and four who died during epileptic fits. Among the causes that exerted such a fatal influence on the lives of the insane at Bicêtre under the old régime, one must count the lack of food, since the daily ration of bread was only one and one-half lb, with an ounce or so of a carelessly prepared dish. This ration was distributed in the morning, or rather, it was instantly devoured and the rest of the time was spent in a ravenous delirium. This only served to exacerbate their madness and caused most of them to die of exhaustion. In 1792 the hospital administration hurried to do away with this unnatural outrage, and for approximately 2 years the daily ration of bread has been raised to 2 lb, while care was taken to distribute part of it in the morning and part at night. That has stopped all complaints about the dearth of food.

True friends of humanity should also learn of the attentive empathy that the directors of the hospice for the insane have displayed in order to implement the government's wishes. One rarely sees such untiring devotion combined with resourcefulness, industry, and wise economy. To watch with scrupulous care that no foodstuffs be spoiled, to keep some reserves for difficult days and thus compensate for the unevenness of the supplies, always to serve succulent and tasty soup, as good, I daresay, as any citizen may desire, to make up for the shortages of lean days by setting aside soup bones from previous days and skillfully extracting their gelatin, intelligently to regulate the heat at which the meat is cooked by raising it first very high and then keeping it moderate for several hours, to find ingredients for two meals a day when the rest of the institution gets only one, in a word, to bring the small attentions and constant care of domestic economy to a large establishment—such is the arduous and touching task accomplished daily and modestly by the director of the hospice for the insane and his esteemed wife, in the midst of all kinds of vexations and obstacles: I present the summary of a conduct that I could document more fully, with details pried out with some insistence.

The true principles of managing the insane in a psychologically sensitive manner are also well understood at Bicêtre. I mean a kind of supervision adapted to the nature of their madness, the prevention of dangerous consequences of their impetuous outbursts without any mistreatment, a timely deprivation of liberty, or permission to move about freely within the hospice. If a madman suddenly experiences an unexpected attack and arms himself with a log, a stick, or a rock, the director—always mindful of his maxim to control the insane without ever permitting that they be hurt—would present himself in the most determined and threatening manner but without carrying any kind of weapon, so as to avoid additional vexation. He speaks with a thundering voice and walks closer toward the maniac in order to catch his eye. At the same time the servants converge on him at a given signal, from behind or sideways, each seizing one of the madman's limbs, an arm, a thigh, or a leg. Thus they carry him to his cell while thwarting his efforts and chain him if he is very dangerous or merely lock him up. That is how one dominates agitated madmen while respecting human rights. The employees are expressly forbidden to retaliate even if they are hit, but they must use force and cunning to avoid this. This is another point that I can guarantee and that I have verified several times because malevolence has ceaselessly spread rumors to the contrary.

One of the fundamental principles of the conduct one must adopt toward the insane is an intelligent mixture of affability and firmness. When they are obstinate one must sound totally superior and unshakable so as to convince them to bow to the will of the directors. But one must avoid any unnecessary constraints and use only enough force to restrain them. In order to avoid vague precepts I shall cite some facts, and I could add many more.

A soldier becomes insane and is sent to the hospice. Obsessed with the thought of his imminent departure, he obstinately refuses to go to bed in the evening or even to enter his cell, and he threatens the servants. When repeated entreaties and all other expedients prove useless, the director finds it necessary to take urgent measures. Assuming the most firm and imposing tone and surrounded by the employees, he adds threats to these terrifying preparations and has the man tied down. The madman tears everything to pieces during the night and turns so violent that recourse to chains becomes necessary. He is thus given time to expend his mad fury, and they check every day to see if he is calming down. On the eighth day, during the director's rounds, he appears submissive, kisses his hand, and says, "You promised to set me free if I was calm; well, I call on you to keep your word." The other responds in the friendliest and most fraternal manner and sets the madman free, first in his cell and then within the hospice.

Another man, dominated by religious prejudices and appalled by the abolition of the Catholic religion in France, is sent to the hospice with all the symptoms of totally alienated reason. He remains for almost 3 months in a state of somber taciturnity and hardly leaves his cell. Solitude excites his imagination, and he is ceaselessly terrorized by torments concerning the next life. Thinking about the mortifications of the saints' penitential lives, he obstinately refuses any kind of food and appears close to death. All admonitions, all enticements are in vain; he even rejects a little succulent bouillon and brushes away the straw so as to sleep on the bare floor. The director concluded that the only way to save the man is to terrorize him so as to change the direction of his sinister thoughts. He addresses him with a thundering voice, assembles all the staff, and threatens him with the harshest measures. Disconcerted and intimidated by this firm tone, the madman resolves to take nourishment and accept a softer bed than the bare floor. Sleep gradually returns, he regains strength, and escapes certain death. After recovering his reason, he admitted that he owed his cure to the measures taken to confront his derangement. He described the cruel hesitations he felt during more than 24 hours and the kind of inner struggle he experienced between the resolve to die from total abstinence and the harsh measures he faced if he refused to eat. This terror finally won out and allowed him to take substantial food, and from then on calm and sleep prepared the return of his strength.

Thus one of the major principles of the psychologic management of the insane is to break their will in a skillfully timed manner without causing wounds or imposing hard labor. Rather, a formidable show of terror should convince them that they are not free to pursue their impetuous willfulness and that their only choice is to submit. If a madman ruled by his wild extravagance sees only two or three employees advance toward him, he senses his superior strength. He will attack, wound, and crush them, and this kind of triumph will only heighten his delirium. If, on the contrary, he sees a large number of employees converge on him, he foresees a strikingly uneven contest. His agitation appears disarmed by the idea of his impotence, he will submit without resistance and grow more quiet and calm. Great skill is required to retain the insane locked in their cells only for the necessary length of time and only while they are capable of extreme acts of violence. The general rule in well-run hospices is to watch all phases of their attacks closely, anticipate their termination, and, generally speaking, grant as much freedom as possible to those madmen who content themselves with mere gesticulations, loud declamations, and acts of extravagance that hurt no one. To lock up this kind of madman on the pretext of maintaining order means to impose needless constraints that provoke his rebellion and violence and render his madness more inveterate and often incurable.

This summary review of my observations on the insane at Bicêtre indicates that we are well on our way toward the great principles of their management of which England does not hold the exclusive secret. My dedication to improving the fate of these unfortunates and enabling a large number to return to Society has been spurred by various obstacles and hurdles that hoary prejudice has raised. I wish to acknowledge the humane intelligence of the hospice's director who has assisted me. But how limited my means have been because of the unsuitable and restricted space, the impossibility of dividing the insane into general classes, the unrealized although long-held project of therapeutic baths and showers, the idleness of the inmates, and the lack of some manual labor to provide useful distraction from their somber thoughts. The Commission on Public Aid is beginning to turn its attention toward this important matter of public usefulness. But it is the Legislative Body itself that should endow a public asylum for the insane with the well-planned grand design that this nation requires. May it create magnificent establishments like those that Philosophy has erected in another country. Renouncing sumptuous ostentation that strikes the senses with vain splendor, this institution should reflect a well-ordered wisdom corresponding to the varied needs of the insane and proclaim from afar the respect due to distress and misfortune.

# Psychotic (Delusional) Major Depression: Should It Be Included as a Distinct Syndrome in *DSM-IV*?

Alan F. Schatzberg, M.D., and Anthony J. Rothschild, M.D.

*To review data supporting or not supporting the designation of unipolar psychotic major depression as a distinct syndrome in* DSM-IV, *the authors used computerized literature searches to identify reports of studies that have directly compared the characteristics, biology, familial transmission, course/outcome, and response to treatment of psychotic and nonpsychotic major depression. The review showed that statistically significant differences between the two types of depression have been found on each of these dimensions. There are greater guilt feelings and psychomotor disturbance, among other features, in psychotic depression. Studies have found significant differences between patients with psychotic and nonpsychotic depression in glucocorticoid activity, dopamine β-hydroxylase activity, levels of dopamine and serotonin metabolites, sleep measures, and ventricle-to-brain ratios. Family studies show higher rates of bipolar disorder in first-degree relatives of probands with psychotic major depression than of probands with nonpsychotic major depression. Greater morbidity and residual impairment have also been reported in patients with psychotic major depression, and they respond more poorly to placebo and to tricyclic antidepressants. Differences between patients with psychotic and nonpsychotic major depression on many of these measures were not due to differences in severity or endogenicity. Since the data indicate that psychotic and nonpsychotic major depression can be separated, the frequency with which the diagnosis of psychotic major depression is missed and its unique course and response to treatment point to the practical importance of a separate diagnosis for this disorder. However, further studies are needed to resolve important methodological issues and to develop an optimal set of operational criteria.*

(Am J Psychiatry 1992; 149:733–745)

In recent years, considerable attention has been paid to psychotic or delusional depression as a distinct subtype of major depression. This disorder is quite common, representing some 25% of consecutively admitted depressed patients (1). In *DSM-III-R*, it is generally referred to as major depression with psychotic features. Data from studies on clinical signs and symptoms, biology, familial transmission, course of illness, and response to treatment suggest that delusional depression now comes close to meeting the requirements for designation as a distinct syndrome (2). In this article we review data both for and against such designation and propose that there are sufficient data and clinical reasons to include major depression with psychotic features as a distinct depressive syndrome in *DSM-IV*.

## HISTORY

Delusional or psychotic depression is a severe form of mood disorder characterized by delusions or hallucinations. The view that delusional depression is a distinct disorder has largely emerged during the era of psychopharmacology (3), and the renewed interest in this disorder rests heavily on observations made by Glassman and colleagues in their classic studies of plasma imipramine levels. The history of this syndrome has been reviewed in detail by Kantor and Glassman (3), as well as by our group (4). The significance of psychotic symptoms as predictors of outcome was explored in early studies, before the introduction of ECT. In these studies, patients with what today would be called psychotic major depression often did more poorly than

their counterparts with nonpsychotic major depression, but the presence of delusions was by itself "not a clear predictor of outcome" (3). Patients with delusions without prominent mood symptoms, however, generally had poor outcomes.

After the introduction of ECT, interest in psychotic depression waned considerably when a number of early studies (in the 1950s and 1960s) reported that delusions predicted neither good nor poor response to ECT (3). Patients with psychotic major depression and patients with nonpsychotic major depression both responded well (about an 80% response rate) to this powerful treatment (3). (Several later studies, however, questioned these earlier findings, as we discuss later in this article.) The introduction of tricyclic antidepressants led to renewed interest in psychotic depression, as it did with other disorders, such as panic. However, in contrast to panic disorder or agoraphobia with panic attacks, which were noted to be highly responsive to imipramine, psychotic depression was, in a sense, reborn as a syndrome because it responded unexpectedly poorly to tricyclic antidepressants. This lack of response has led to numerous recent studies on clinical characteristics, biological measures, course, and familial history, many of which have argued that psychotic depression is a distinct subtype of depression and should be designated as such.

There has, however, been a longstanding debate about whether psychotic depression is indeed a distinct syndrome or merely represents a severe subtype of depression. In the European literature, "psychotic depression" generally has been used to indicate a syndrome characterized by pronounced neurovegetative signs and symptoms, with or without a thought disorder. This approach was carried over into *DSM-II* (1968), in which patients with psychotic depressive reactions were those who demonstrated severe depressive episodes in response to one or more identifiable stressors. Delusions or hallucinations were not required for fulfilling the criteria for this diagnosis. In *DSM-III* (1980) and *DSM-III-R* (1987) the dimensional qualifier "with psychotic features," as part of the fifth-digit severity code, denotes a thought disorder (i.e., the presence of hallucinations or delusions) that primarily reflects the severity of the depressive disorder rather than a distinct characteristic. However, data reviewed in this article strongly suggest a predictive validity for psychotic major depression that is more consistent with considering it as a categorical entity than as defined merely by being positioned at one end of a severity dimension. Moreover, the finding that psychotic major depression, unlike nonpsychotic major depression, does not respond particularly well to tricyclic antidepressants, but does respond to other treatment approaches, underscores the importance of careful assessment of this disorder.

We reviewed all available English-language studies on delusional (psychotic) major depression, using computerized searches of *Index Medicus* (MEDLINE) to help identify studies. Emphasis is placed on studies that directly compared samples of delusional and nondelusional patients with major depression. Tables identifying the diagnostic instruments, the diagnoses of the subjects, and the specific findings in the studies discussed in text are available from the first author on request.

## CHARACTERISTICS

The hallmark feature separating patients with psychotic major depression from those with nonpsychotic major depression is the occurrence of delusions or hallucinations in the former. Delusions can be classified broadly as guilty, paranoid, or somatic. Hallucinations are divided into auditory, visual, and somatic types. Generally, delusions are viewed as mood-congruent if they reflect lowered mood and/or underlying nihilistic, overly self-deprecatory, or guilty beliefs.

Psychotic depressions are often severe in nature, with patients demonstrating relatively high total scores on the Hamilton Rating Scale for Depression (5, 6)—often significantly higher than those of comparison groups with nonpsychotic major depression (1, 6–9). Although these observations could be interpreted as supporting the notion that psychotic depression is merely a more severe variant of depression, a number of investigators have argued that psychotic depression is a separate disorder. Studies of depression have identified patients with nonpsychotic major depression who have total Hamilton depression scores in the range seen among patients with psychotic major depression (9). Thus, the development of delusions must rest with risk factors or biological processes other than severity of depression. Moreover, in studies reporting greater overall severity of illness in patients with psychotic major depression, these patients do not demonstrate greater severity on all symptoms. Rather, differences between patients with psychotic and nonpsychotic major depression appear to occur primarily in particular symptoms or symptom clusters. For example, our group (10) reported that patients with psychotic major depression had significantly higher total Hamilton depression scores than patients with nonpsychotic major depression ($p=0.005$). This was primarily because the patients with psychotic major depression had significantly greater Hamilton depression scale factor scores for retardation ($p=0.01$) and cognitive disturbance ($p=0.005$). The Hamilton depression scale factor scores for anxiety/somatization, weight, diurnal variation, and sleep disturbance were not significantly different between the patients with psychotic and nonpsychotic major depression. On the Brief Psychiatric Rating Scale, the patients with psychotic major depression had a higher mean total score than the patients with nonpsychotic major depression ($p<0.001$) and higher factor scores for thinking disturbance ($p=0.02$), withdrawal/retardation ($p=0.02$), and hostility/suspiciousness ($p=0.009$). The two groups did not differ on the factor score for anxiety/depression.

In regard to specific symptoms, patients with psychotic major depression demonstrate significantly more severe or more common psychomotor disturbances (retardation or agitation) than do patients with nonpsychotic major depression (1, 6, 8, 9, 11, 12). Some studies (8, 11, 12) have reported greater agitation in psychotic major depression, while others (9) have reported greater retardation. At least two studies (6, 12) have reported both greater agitation and greater retardation. Only one (retrospective) study (13) failed to find significant differences in either retardation or agitation. Greater agitation or retardation in psychotic major depression does not appear to be due to increased severity. Glassman and Roose (9) reported that when patients with psychotic and nonpsychotic major depression were matched for total Hamilton depression scores, the patients with psychotic major depression still had significantly greater psychomotor retardation or agitation scores. Similar data were reported by Lykouras et al. (6). Several investigators (1, 6, 8, 9, 12) have also reported significantly greater feelings of guilt among patients with psychotic depression than among those with nonpsychotic major depression, but at least one study (14) failed to confirm this finding.

A number of other symptoms have been reported to be more pronounced in psychotic than in nonpsychotic major depression: depressed mood (1, 6, 9), paranoid symptoms (6, 8), hopelessness (8), hypochondriasis (1, 9), anxiety (9, 12), early insomnia (6, 8), and middle insomnia (6). However, the data supporting the idea that each of these is more pronounced in psychotic major depression are less robust and less consistent than are the data in support of greater psychomotor disturbance or guilt. Lykouras et al. (6) reported several differences between patients with psychotic and nonpsychotic major depression on specific symptoms (e.g., insomnia). However, after overall severity was covaried out, only depressed mood, psychomotor retardation, and paranoid symptoms remained significantly greater in patients with psychotic major depression.

Risk of suicide has been reported to be greater among hospitalized patients with psychotic major depression than among their counterparts with nonpsychotic major depression (15), and suicidal ideation has also been reported to be significantly greater among patients with psychotic major depression (7). However, other studies that compared the two groups on suicidal ideation or suicide attempts failed to find statistically significant differences between them (1, 8, 9, 11, 12, 14). These data suggest that most somatic depressive symptoms and suicidal ideation/behavior cannot be used to separate consistently patients with psychotic and nonpsychotic major depression, but that psychomotor disturbance, guilt, and psychotic symptoms do appear to separate these two groups of depressed patients.

Although psychomotor agitation and guilt appear to help separate psychotic from nonpsychotic major depression even after covarying out for overall severity, one may argue that these symptoms are merely separating patients with endogenous or melancholic major depression from their counterparts with the nonendogenous type. Although few studies have specifically examined an "endogenous" dimension separately from that of severity, it could be argued that a high proportion of severely ill, hospitalized patients with nonpsychotic major depression would also meet criteria for endogenous depression, and that these various symptoms are in fact separating psychotic major endogenous depression from nonpsychotic major endogenous depression. Still, without applying specific criteria for endogenous depression to define the nonpsychotic sample, this question is moot.

Recently, Parker et al. (16) reported on differences in symptoms between delusional and nondelusional patients, all of whom met both the *DSM-III* criteria for melancholia and the Research Diagnostic Criteria (RDC) for definite endogenous syndromes. In contrast to patients with endogenous nonpsychotic major depression, patients with endogenous psychotic major depression demonstrated significantly more frequent psychomotor disturbance, an absence of diurnal variation in mood, fixed depressive thought content, and constipation. The authors used latent class analyses and reported that psychotic features (i.e., hallucinations or delusions) were sufficient but not necessary to characterize individual patients as being "psychotic." These data suggest that psychosis is a separate dimension from endogenicity and that psychomotor disturbances do not merely separate patients with endogenous and nonendogenous disorders.

Cognitive impairment, measured objectively/quantitatively, has been less well studied than have specific symptom characteristics. We reported (17) that patients with psychotic major depression demonstrated greater impairment on neuropsychological testing than did patients with nonpsychotic major depression when severity, as measured by total Hamilton depression score, was partialed out. We hypothesized that cognitive deficits in psychotic (and in some nonpsychotic) depressed patients reflect significantly increased cortisol activity. Neuropsychological performance may provide greater specificity in separating patients with psychotic major depression from those with nonpsychotic major depression than do specific symptoms.

The studies we have described frequently compared clinical populations in tertiary care or academic settings, and in several, the study groups were identified retrospectively. Such approaches have a number of limitations, particularly potential selection bias toward patients who are more refractory to treatment or more severely ill. The Epidemiological Catchment Area study (18) recently reported that patients with psychotic major depression did not have more symptoms overall than did patients with nonpsychotic major depression, nor did the two groups differ in symptom patterns other than the presence of a thought disorder. (Specific depression rating scales were not used in that study, however.) Patients with psychotic major depression did differ significantly from patients with nonpsychotic major depression in demonstrating greater morbidity at 1 year, including more frequent suicide attempts, (see section on Course and Outcome for further discussion).

## FINDINGS IN BIOLOGICAL STUDIES

### *Studies of HPA Axis Activity*

There is now abundant evidence for specific abnormalities in patients with psychotic major depression on measures of hypothalamic-pituitary-adrenal (HPA) axis activity. Many centers have reported that patients with psychotic major depression are among those with the highest rates of nonsuppression of cortisol on the dexamethasone suppression test (DST) and/or that patients with psychotic major depression have markedly elevated postdexamethasone cortisol levels (19–29), although not all studies are in agreement (1, 7, 30, 31). Significant differences between patients with psychotic and nonpsychotic major depression have been observed on 24-hour measures of urinary free cortisol (32). Although patients with other affective psychoses such as mania show high nonsuppression rates (33), patients with nonaffective psychoses such as schizophrenia do not (24, 33).

The elevated cortisol levels after dexamethasone administration in patients with psychotic major depression are not merely due to greater severity of depressive illness or to the presence of endogenous symptoms. For example, Evans et al. (26) did not find significant differences in the rates of postdexamethasone nonsuppression between patients with nonpsychotic major depression with melancholia and patients with nonpsychotic major depression without melancholia. The two groups also did not differ on mean postdexamethasone cortisol levels, yet both groups had significantly lower mean postdexamethasone cortisol levels than did patients with psychotic major depression. Rihmer et al. (29) reported significantly higher rates of nonsuppression on the DST among psychotic endogenously depressed inpatients than among their nonpsychotic counterparts. Furthermore, Brown et al. (34) used a stepwise multiple regression analysis to examine the effects of severity, agitation, delusions, melancholic subtype, age, and weight loss on postdexamethasone cortisol levels in 93 patients with unipolar major depression. They reported that agitation predicted 22%, melancholia predicted 27%, and the presence of delusions predicted 34% of the variance in morning postdexamethasone cortisol levels. Severity of illness, age, and weight loss added no further significant predictive value and did not affect cortisol levels when examined separately from the other variables.

In summary, the vast majority of studies point to significantly greater HPA axis activity in psychotic major depression than in nonpsychotic major depression, although not all studies agree. Specific differences in patient samples (e.g., the relative proportions of unipolar and bipolar patients [1, 27] or drug-free status) could help account for the lack of consistency. The literature does not support the notion that the greater HPA activity seen in patients with psychotic major depression is merely the result of greater severity of depression, the presence of endogenous features, or the psychosis per se but, rather, is related to the interaction between the affective disorder and the psychosis. Our group (35) has hypothesized that the development of delusions in depressed patients is due to the effects of hypercortisolemia on dopaminergic systems, since glucocorticoids increase levels of dopamine in human plasma (36) and rat brain (37) and levels of homovanillic acid (HVA) in rat brain (38) as well as human CSF (39).

### *Studies of Dopaminergic Activity*

Several studies have demonstrated that in psychotic major depression there is an activation of the dopaminergic system which is not seen in nonpsychotic major depression. Patients with psychotic major depression demonstrated significantly higher levels of unconjugated plasma dopamine both before and after administration of dexamethasone (40). Studies measuring the dopamine metabolite HVA have also reported higher levels in patients with psychotic major depression. Sweeney et al. (41) reported that the probenecid-induced accumulation of HVA in CSF was higher in psychotic major depression than in nonpsychotic major depression. Furthermore, Aberg-Wistedt et al. (42) reported that patients with psychotic major depression had significantly higher concentrations of HVA in CSF than did patients with nonpsychotic major depression. Higher CSF levels of 5-hydroxyindoleacetic acid (5-HIAA) were also found in the patients with psychotic major depression (see section on Measures of Serotonergic Function).

Studies of plasma HVA also indicate that patients with psychotic major depression have greater activation of dopaminergic systems than do patients with nonpsychotic major depression. Devanand et al. (43) reported that plasma HVA levels were significantly higher in women with psychotic major depression than in women with nonpsychotic major depression. Mazure et al. (44) reported that plasma HVA levels were significantly higher in patients with psychotic major depression than in melancholic patients with nonpsychotic major depression, who in turn had higher levels than nonmelancholic patients with nonpsychotic major depression. Finally, Wolkowitz et al. (45, 46) demonstrated a trend toward relative blunting of the plasma HVA response to dexamethasone in patients with psychotic major depression compared to patients with nonpsychotic major depression. One study (47) reported no baseline differences in urinary levels of HVA in patients with psychotic versus nonpsychotic major depression. Overall, the data indicate that psychotic major depression can be distinguished biologically from nonpsychotic major depression on measures of dopaminergic activity. Although studies have generally emphasized the possible role of severity rather than that of endogenicity, the data of Mazure et al. (44) suggested that elevated plasma HVA levels in psychotic major depression are not due to the presence of endogenous features.

### *Enzyme Studies*

There has been growing evidence that certain biochemical enzyme abnormalities may be specific to psychotic major depression. Previous studies have shown that patients with unipolar psychotic major depression have lower serum dopamine β-hydroxylase activity (48, 49) and patients with unipolar nonpsychotic major depression have higher dopamine β-hydroxylase activity (49, 50) than do healthy control subjects. The low levels of serum dopamine β-hydroxylase activity in patients with unipolar psychotic major depression have been hypothesized to be a potential marker of relative risk for developing pronounced increases in dopamine levels when there is chronic elevation of cortisol levels (35).

### *CT Scans*

Several studies have reported differences on CT scans between patients with psychotic major depression and those with nonpsychotic major depression. Targum et al. (51) studied 38 melancholic depressed inpatients (unipolar and bipolar) and found that the mean ventricle-to-brain ratio (VBR) of the patients with psychotic major depression was greater (although not significantly so) than that of the patients with nonpsychotic major depression and that of comparison subjects with neurological disorders. Five (25%) of the 20 patients with psychotic major depression had VBRs greater than two standard deviations from the mean of the 26 subjects with neurological disorders, whereas none of the 18 patients with nonpsychotic major depression did. Luchins and Meltzer (52) examined VBRs in 18 depressed patients. Five (56%) of the nine patients with psychotic major depression, but only one (11%) of the nine with nonpsychotic major depression, had VBRs one standard deviation outside the control mean ($p<0.05$, Fisher's exact test). However, there was no difference in mean VBR between groups. Subsequently, Schlegel and Kretzschmar (53) reported that patients with psychotic major depression had significantly greater mean VBRs than did control subjects, whereas patients with nonpsychotic major depression did not.

We have reported (17) on VBRs in a sample of delusional and nondelusional unipolar depressed patients. Statistically significant differences between the patients with psychotic major depression and those with nonpsychotic major depression were observed in VBRs as well as in ratings of inferior parietal atrophy. The patients with unipolar psychotic major depression had significantly greater mean anterior pole and cella media VBRs and more left and right inferior parietal brain atrophy than did their counterparts with unipolar nonpsychotic major depression. The enlarged VBRs and greater inferior parietal brain atrophy in the patients with unipolar psychotic major depression were correlated with poorer performance on neuropsychological testing. Interestingly, the enlarged VBRs seen in patients with unipolar psychotic major depression were also associated with higher levels of plasma cortisol in this study (17) as well as others (54). The possible effects of endogenous symptoms generally have not been explored in these studies. Still, the data overall do suggest an association in patients with unipolar major depression between symptoms of psychosis and greater VBRs. This is in contrast to psychotic schizophrenic patients, in whom positive symptoms (delusions and hallucinations) have been associated with smaller ventricles (55, 56).

### *EEG Sleep Profiles*

Comparisons of EEG sleep profiles of patients with psychotic major depression and those with nonpsychotic major depression have also indicated differences between the two groups. Patients with psychotic major depression exhibit significantly diminished slow wave sleep, poorer sleep efficiency, and a reduced percentage of REM sleep time in comparison to patients with nonpsychotic major depression (57–60). However, these findings may have reflected differences in age, severity, and agitation between the two groups (61). In a study that specifically controlled for the effects of age, severity, agitation, and other clinical characteristics (62), patients with psychotic major depression were found to have greater wakefulness, a higher percentage of stage 1 sleep, a smaller percentage of REM sleep, and less REM activity when compared to patients with nonpsychotic major depression. A more recent study (63) found a greater percentage of intermittent wakefulness in patients with psychotic major depression than in patients with nonpsychotic major depression. When EEG spectral analysis was used, more specific, significant differences between patients with psychotic and nonpsychotic major depression emerged. The patients with psychotic major depression had greater power in the higher band widths, or "micro arousals," which could not be attributed to actual differences in awake time, since manually scored records did not show that awake time was significantly different between the two patient groups. The greater power observed in the higher band widths among the patients with psychotic major depression suggested that the arousal level may be a potentially distinguishing feature of these patients. The patients with psychotic major depression also appeared more likely to have extremely short sleep-onset REM latencies than the patients with nonpsychotic major depression. One study (64) did not find any statistically significant differences in sleep profiles between patients with psychotic and nonpsychotic major depression.

The diminished generation of REM sleep seen in patients with psychotic major depression may indicate a functional hyperactivity of central dopaminergic systems, since administration of dopaminergic agonists to normal control subjects results in increased arousal and considerable suppression of REM sleep (65). It is also of interest that a 1-mg dose of dexamethasone results in a 20% reduction of REM sleep in patients with nonpsychotic major depression (66), a reduction of about the same magnitude as the difference observed between patients with psychotic and nonpsychotic major depression (62). Thus, the decreased generation of REM sleep in patients with psychotic major depression may be secondary to corticosteroid/dopamine interactions (see preceding section). In any case, sleep EEG studies provide further evidence for considering psychotic major depression as a distinct subtype of major depression.

### *Measures of Serotonergic Function*

Differences between patients with psychotic and nonpsychotic major depression on measures of serotonergic function have also been reported. Healy et al. (67) reported on measures of platelet serotonin uptake in a group of 28 patients with endogenous depression. Delusional and nondelusional patients differed in absolute values for rate of serotonin uptake into platelets. In addition, the delusional patients did not show the lowering of serotonin uptake rate that was observed in the endogenously depressed group as a whole. The difference between the patients with psychotic and nonpsychotic major depression was maintained after treatment was started but was not present after clinical recovery, suggesting a state rather than trait phenomenon.

Patients with psychotic major depression demonstrate higher CSF 5-HIAA levels than do patients with nonpsychotic major depression. In the study by Aberg-Wistedt et al. (42), a strong positive correlation between CSF levels of 5-HIAA and HVA was observed. These authors noted that the higher HVA/5-HIAA ratio in their patients with psychotic major depression suggested a primary problem in dopaminergic neurotransmission and a secondary effect on serotonergic neurons. The higher HVA/5-HIAA ratio in the patients with psychotic major depression is consistent with results of another study (68), which found that hallucinations in depressed patients were strongly associated with higher HVA/5-HIAA ratios. In contrast, one study (41) did not find that patients with psychotic and nonpsychotic major depression differed on measures of CSF 5-HIAA, and another study (47) did not observe differences between patients with psychotic and nonpsychotic major depression in urinary 5-HIAA levels. It is difficult at this point to determine whether differences in serotonin transmission between patients with psychotic and nonpsychotic major depression are independent of a disturbance in dopaminergic neurotransmission.

### *Summary*

In summary, a growing body of evidence from studies of the HPA axis, studies of dopaminergic activity, enzyme studies, CT and magnetic resonance imaging scans, EEG sleep profiles, and measures of serotonergic function points to distinct biological abnormalities in psychotic as compared to nonpsychotic major depression. Although many of the studies did not explore the possible effects of endogenous states on specific differences, several did, and these results suggest that biological differences between psychotic and nonpsychotic major depression are not due to differences in relative endogenicity (26, 29, 31, 44).

## FINDINGS IN FAMILY STUDIES

First-degree relatives of patients with psychotic major depression demonstrate higher rates of depression (7, 69) and the psychotic subtype (69) than do members of the families of patients with nonpsychotic major depression, although not all studies are in agreement (70). In addition, the relatives of patients with psychotic major depression are significantly (six times) more likely to have bipolar disorder than are the relatives of patients with nonpsychotic major depression (71). In some ways, the limited family data are less compelling than are the data from other categories of studies, and further studies are needed to confirm and extend these findings. The higher prevalence of bipolar disorder in the families of patients with psychotic major depression is intriguing in light of the association of bipolar illness with early-onset psychotic major depression (72, 73).

## COURSE AND OUTCOME

### *One-Year Follow-Up*

The course, prognosis, and outcome of patients with psychotic and nonpsychotic major depression differ. Several studies have noted poorer short-term outcome in psychotic than in nonpsychotic major depression. Robinson and Spiker (74), in a prospective study, found that significantly more patients with psychotic major depression showed a pattern of chronic illness during the first posthospitalization year. They compared 52 patients with unipolar psychotic major depression and 52 patients with unipolar nonpsychotic major depression who were matched for sex, age at index episode of depression, and age at first episode of depression. In a 1-year follow-up after discharge from inpatient treatment, the patients with psychotic depression had a significantly higher rate of episodes of major depression lasting longer than 9 months than did the patients with nonpsychotic depression. The patients with psychotic major depression also were more likely to be in a major depressive episode at 1-year follow-up. Consistent with the poorer clinical response of the patients with psychotic major depression, there was a trend for them to have a higher total number of hospitalizations over the 1-year follow-up period. Murphy (75) also reported a poorer 1-year outcome for geriatric patients with psychotic major depression than for those with nonpsychotic major depression. Kettering et al. (76) found that the course of psychotic and affective symptoms in psychotic major depression differs from that in nonpsychotic major depression. In their study of patients with psychotic and nonpsychotic major depression, affective and anxiety symptoms made a smaller contribution to the total clinical picture in the patients with psychotic major depression 1 year after discharge. However, these patients were more likely to demonstrate mood-incongruent delusions at 1 year.

Recently, our group (77) reported that at 1-year follow-up, patients with the diagnosis of psychotic major depression at baseline did not differ from patients with nonpsychotic major depression on measures of depressive, anxious, or psychotic symptoms. However, the patients who had originally met the criteria for psychotic major depression demonstrated significantly poorer functioning at 1 year, as measured by the total score on the Social Adjustment Scale. There were significant correlations between higher urinary free cortisol levels at 1 year and poorer overall functioning at 1 year.

Recent data from the Epidemiological Catchment Area study (18) provide further evidence for a different course of illness in psychotic and nonpsychotic major depression. Patients with psychotic major depression had a greater risk of multiple episodes of depression than patients with nonpsychotic major depression (73.7% versus 61.9%, $p<0.05$). In addition, the patients with psychotic major depression had significantly greater economic impairment: more of them were receiving public assistance (17.5% versus 7.2%, $p<0.01$) and/or disability payments (15.9% versus 6.7%, $p<0.01$). Psychotic major depression was not associated with significantly more reports of economic impairment due to emotional, alcohol, or drug problems than was nonpsychotic major depression (5.7% versus 3.6%, n.s.). The patients with psychotic major depression had a higher lifetime rate of psychiatric hospitalization (22.8% versus 14.7%, $p<0.05$) and a greater risk of hospitalization for medical reasons in the last year. At 1-year follow-up, the patients with psychotic major depression were more likely to be currently depressed (in the last month, 18.7% versus 11.1%, $p<0.05$) and to be still financially dependent (27.4% versus 11.2%, $p<0.01$).

### *Longer-Term Follow-Up (2 Years or More)*

In the Iowa 500 study, Coryell and Tsuang (78) found that the initial presence of delusions predicted a poorer short-term (2–5-year) outcome, whereas a 40-year follow-up with structured interviews found no consistent trends distinguishing psychotic from nonpsychotic patients with major depression on ratings of marital, occupational, residential, or symptom outcome. In the National Institute of Mental Health (NIMH) Clinical Research Branch Collaborative Program on the Psychobiology of Depression study, Coryell et al. (79) reported that despite substantially greater levels of impairment during the 5 years preceding intake into the study, patients with unipolar psychotic major depression were as likely to recover as were patients with unipolar nonpsychotic major depression during a 2-year follow-up period. The patients with psychotic major depression were more psychosocially impaired at 6 months, but these differences resolved during the ensuing 18 months. In a 5-year follow-up of the patients reported previously by Coryell et al. (79, 80), significantly greater social impairment, but not depression, was observed in the patients with psychotic major depression (81).

### *Bipolar Disorder*

Psychotic major depression with onset in adolescence or young adulthood appears to be related to bipolar disorder. Akiskal et al. (73) reported on the follow-up of a group of depressed patients who had not had histories of mania at the time of the index study (i.e., they had unipolar illness). The prevalence of baseline psychotic depression was significantly greater ($p<0.01$) among the patients who developed bipolar illness during follow-up (42%) than among those who did not (15%). Similarly, Strober and Carlson (72) reported that the appearance of bipolar disorder in adolescents originally studied when depressed was predicted by a depressive symptom cluster comprising mood-congruent psychotic features, rapid symptom onset, and psychomotor retardation. These data suggest that psychotic major depression in a young adult may often prove to be the first episode of a bipolar disorder.

### *Recurrent Psychotic Episodes*

Studies have demonstrated a remarkable consistency over time in the clinical presentation of patients with psychotic major depression. Charney and Nelson (12), reporting on 54 patients with unipolar psychotic major depression and 66 patients with unipolar nonpsychotic major depression, found that for the patients with psychotic depression, 89% of all prior depressive episodes were psychotic, compared to only 12% for the group with nonpsychotic depression ($p<0.001$). In addition, examination of the prior depressive episodes of the patients with psychotic major depression indicated that the delusions of these patients tended to be of similar form and content from episode to episode. An earlier study (11) of 14 patients with unipolar psychotic major depression also found that the episodes of depressive illness in each patient were characterized by similar symptoms (including the specific content of the delusions).

## TREATMENT

The patterns of response to somatic therapies among patients with psychotic major depression are quite different from those among patients with nonpsychotic major depression (for reviews of this subject, see 3–5, 9, 11, 82, 83). Although most reports on somatic therapy of psychotic major depression have been the result of open trials or retrospective reviews, the past few years have witnessed a few double-blind studies. Overall, the literature points to a number of reasonable conclusions regarding the somatic treatment of psychotic major depression.

1. Patients with psychotic major depression respond

poorly to placebo. Placebo response rates appear higher among patients with nonpsychotic major depression.

2. In contrast to patients with nonpsychotic major depression, patients with psychotic major depression respond poorly (or at best very slowly) to tricyclic antidepressants when these are administered alone.
3. Patients with psychotic major depression who fail to respond to tricyclic antidepressants respond to ECT. However, ECT may not be more effective in these patients than in patients with nonpsychotic major depression.
4. Patients with psychotic major depression respond better to the combination of a tricyclic antidepressant with a neuroleptic than they do to a tricyclic antidepressant alone.
5. Patients with psychotic major depression respond as well to amoxapine (a four-ring tricyclic-like antidepressant with serotonin-2 receptor-blocking properties and a neuroleptic metabolite) as to the combination of a tricyclic antidepressant and a neuroleptic.

### *Placebo*

Glassman and Roose (9) reported that patients with psychotic major depression did not demonstrate responses to placebo. The placebo washout period was the initial phase of protocols designed to explore the relation of plasma levels of imipramine to response to antidepressants. Eighteen (30%) of 60 patients with nonpsychotic major depression responded to placebo, in contrast to none of 21 patients with psychotic major depression. In a recent study, Anton and Burch (83) reported that 10% of patients with psychotic major depression responded during placebo washout. Unfortunately, these studies were single-blind during the placebo phase, making definitive conclusions difficult. In another study, Chan et al. (82) reported that 19 of 59 nonpsychotic depressed patients responded during a 2-week washout period, in contrast to three of 16 patients with psychotic major depression. These three patients with psychotic major depression demonstrated only partial responses.

### *Tricyclic Antidepressants Alone*

Early studies on tricyclic antidepressant therapy in depression noted that depressed patients with psychotic features responded poorly to imipramine or amitriptyline (84–86). Those observations were largely overlooked until the studies by Glassman et al. of plasma levels of imipramine. These investigators administered fixed milligram-per-kilogram doses of imipramine to both psychotic and nonpsychotic patients with major depression and also observed that patients with psychotic major depression responded more poorly to imipramine (87). Specifically, three (23%) of 13 patients with psychotic major depression responded, in contrast to 14 (67%) of 21 patients with nonpsychotic major depression. This difference was statistically significant and was not due to severity of illness.

In a landmark study, DeCarolis (88) administered imipramine to 437 depressed patients. The patients were treated with 200–350 mg/day of the drug for at least 25 days, and those who did not respond after 30 days were treated with ECT. Patients with psychotic major depression did more poorly on the regimen of imipramine (40% response rate) than did endogenous and neurotic-reactive depressed patients (61% and 60%, respectively). Subsequently, a number of studies (many of them retrospective reviews) again confirmed that patients with psychotic major depression respond more poorly to tricyclic antidepressants alone than do patients with nonpsychotic major depression (8, 12, 82). Indeed, in their report, Chan et al. (82) reviewed response data on more than 1,000 depressed patients from 12 studies, including their own (7, 12, 82, 85, 86, 88–94). They calculated that 127 (35%) of 363 patients with psychotic major depression responded to tricyclic antidepressant therapy, in contrast to 464 (67%) of 691 patients with nonpsychotic major depression ($\chi^2$=104.2, df=1, $p<2\times10^{-24}$). These results do not appear to be due to a general pattern of underdosing.

We have identified an additional two studies that were not included in the review by Chan et al. One (8) appeared before the Chan et al. study; the other (95), after. Both studies found lower response rates to tricyclic antidepressants among patients with psychotic major depression than among patients with nonpsychotic major depression. Frances et al. (8), in a retrospective chart review, reported that three of 18 patients with psychotic major depression responded to tricyclic antidepressants, in contrast to 17 of 23 patients with nonpsychotic major depression ($\chi^2$=10.8, df=1, $p<0.001$). In the NIMH Collaborative Program on the Psychobiology of Depression study (95), imipramine or amitriptyline was administered for 4 weeks to 132 patients. We recalculated the response rates of the patients with psychotic and nonpsychotic major depression in this study and found that they were lower (albeit of trend significance, p=0.06) among those with psychotic major depression (32% versus 55%). In addition to all these reports of studies that have compared patients with psychotic and nonpsychotic major depression, there have been several other reports that patients with psychotic major depression respond poorly to tricyclic antidepressants (96–98).

There are two notable exceptions to the finding that patients with psychotic major depression respond more poorly to tricyclic antidepressants than do patients with nonpsychotic major depression. Quitkin et al. (99) reanalyzed a previous study by Klein (100) that had compared 6 weeks of treatment with imipramine versus placebo for depressed patients. They concluded that delusions did not predict poor response to imipramine and argued that patients with psychotic major depression often required treatment for prolonged periods and at higher dosages. (Most studies have used 4 weeks of treatment with tricyclic antidepressants.) This reanalysis has been criticized for its retrospective definition of psychotic and nonpsychotic groups, which used the F factor of the Lorr Multidimensional Scale for psychiatric patients. The F factor includes items that do not concern delusions (e.g., poor orientation and hostile impulses), raising questions about the accuracy of the retrospectively performed diagnoses (8, 9, 82). However, Klein, in a personal communication to us, has indicated that these patients were psychotic.

In a retrospective review of patients treated for up to 9 weeks, Howarth and Grace (94) reported that patients with psychotic major depression responded significantly better to tricyclic/tetracyclic antidepressants than did patients with nonpsychotic major depression. Twenty-one (62%) of 34 psychotic patients responded, in contrast to nine (41%) of 22 nonpsychotic patients. The patients with psychotic major depression, however, responded more slowly to treatment; the authors estimated that more than 40% may require treatment for at least 4–9 weeks. Many of the other previous studies had used shorter treatment periods, e.g., 4 weeks. These data indicate that the nature of the response to tricyclics differs in the two groups but that some delusional patients may do well when given tricyclic antidepressants if they are prescribed for sufficient periods.

Several studies have explored whether the poorer responses observed with tricyclic antidepressant therapy were due to the effects of severity or endogenicity. Glassman et al. (90) noted slightly lower response rates (56%) for patients with more severe nonpsychotic major depression (total Hamilton Rating Scale for Depression score greater than 27) than for patients with less severe nonpsychotic major depression (75%); however, this difference was not statistically significant. Chan et al. (82) reported that degree of incapacitation or endogenous status failed to predict poor response to tricyclic antidepressants, in contrast to delusional status, which did.

On the other hand, in the NIMH Collaborative Program on the Psychobiology of Depression study (95), the response rate to tricyclic antidepressant therapy differed significantly among patients with psychotic major depression, nonpsychotic moderately depressed patients (defined as having a total Hamilton depression score of 26 or less), and nonpsychotic severely depressed patients (Hamilton depression score greater than 27). The nonpsychotic severely depressed patients did not differ significantly from the patients with psychotic major depression in their response rates (32% and 39%, respectively). The total Hamilton depression scores of the nonpsychotic severely depressed patients were similar to those of the patients with psychotic major depression, suggesting that general severity of illness could be a factor in why patients with psychotic major depression respond poorly to tricyclic antidepressants. The nonpsychotic moderately depressed patients did significantly better than the combined group of patients with psychotic major depression and nonpsychotic severely depressed patients. There are a number of caveats regarding this study. In contrast to most of the other studies, it combined patients with unipolar and bipolar illness. In addition, the severely ill nonpsychotic group was significantly older than the moderately ill nonpsychotic group and the patients with psychotic depression.

The DeCarolis study (88) also suggested that severity may predict poor response. As we have indicated, patients with psychotic major depression responded more poorly on a regimen of imipramine (40% response rate) than did endogenous and neurotic-reactive depressed patients (61% and 60%, respectively). However, patients designated as being severely depressed also did poorly (35% response rate). Since in this study patients may not have been placed into discrete categories for analyses (i.e., the same patients were probably classified as both delusional and severely ill), it is difficult to comment on the relative effects of severity on response to treatment. The data from this study suggest, however, that the poorer responses to imipramine among patients with psychotic major depression are not merely due to endogenous symptoms. The role of severity in determining poor responsiveness of patients with psychotic major depression to tricyclic antidepressants requires further study.

### *ECT*

A number of lines of investigation suggest that ECT is an effective treatment for psychotic major depression. Many retrospective clinical reports point out that patients with psychotic major depression who respond poorly to tricyclic antidepressants do well when subsequently treated with ECT (6, 8, 12, 87, 92, 93, 96, 97, 101). For example, Glassman et al. (87) reported that nine of the 10 patients with psychotic major depression who had failed to respond in their prospective imipramine study responded well to ECT. This finding was perhaps most dramatic in the DeCarolis study (88). As we have mentioned, in that study only 40% of the patients with psychotic major depression responded to initial treatment with imipramine. However, 83% of the nonresponders then responded to ECT. A high rate of response to ECT was also observed among severely depressed patients who had responded poorly to imipramine, although, again, there may have been great overlap between the psychotic and severely depressed groups of patients. In contrast, patients with neurotic-reactive depressions responded well to imipramine, and patients who failed to respond to imipramine generally did not respond to ECT.

Avery and Winokur (91) reviewed hospital records of 59 depressed patients hospitalized between 1959 and 1969. Forty-two percent of the depressed patients with delusions responded to ECT; in contrast, only 18% responded to adequate antidepressant trials ($p<0.05$). The delusional group included some patients with nondepressive hallucinations or delusions (i.e., schizoaffective patients), making comparison of this study to others somewhat difficult.

Four studies have compared response to ECT among patients with psychotic versus nonpsychotic major depression. Rich et al. (102, 103) and Brown et al. (93) found ECT to be equally effective for patients with psychotic and nonpsychotic major depression. However, Charney and Nelson (12) reported that response to

ECT was better in patients with psychotic major depression than in their counterparts with nonpsychotic major depression. Taken together, these data suggest that ECT is an effective treatment for psychotic depression. However, it may not be more effective for patients with psychotic major depression than for nonpsychotic severely depressed patients.

### *Tricyclic Antidepressant/Neuroleptic Combination*

In both retrospective and prospective studies, the combination of a tricyclic antidepressant and a neuroleptic has been reported to be an effective treatment for psychotic major depression. Several groups have reported that patients who had failed to respond to tricyclic antidepressants alone went on to respond to the combination of a tricyclic antidepressant and a neuroleptic (8, 12, 96).

Spiker et al. (5) compared the combination of amitriptyline and perphenazine, amitriptyline alone, and perphenazine alone in the treatment of patients with psychotic major depression. Mean daily doses were 218 mg of amitriptyline alone, 50 mg of perphenazine alone, and for the combination, 170 mg of amitriptyline and 54 mg of perphenazine. The protocol called for 35 days of active treatment. Fourteen (78%) of 18 patients treated with the combination responded, in contrast to seven (41%) of 17 patients treated with amitriptyline and three (19%) of 16 patients treated with perphenazine. Seven of the 13 patients who failed to respond to perphenazine were not psychotic at the completion of the study but were still depressed. A high proportion of the patients who had failed to respond to either amitriptyline or perphenazine alone responded when the other drug was added. Differences between responses to the combination and to each ingredient alone were not due to one compound raising the blood level of the other. This study included patients with both bipolar and unipolar psychotic depression.

### *Amoxapine*

Recently, Anton and Burch (83) reported that in psychotic depression, amoxapine, a four-ring compound that is related to the antipsychotic loxapine, was comparable in efficacy to the combination of amitriptyline and perphenazine. This study was undertaken after open trials suggested 60%–80% response rates to amoxapine in patients with psychotic major depression (104). After a single-blind, 5-day placebo washout period, patients were randomly assigned to receive amoxapine or the combination of amitriptyline and perphenazine under double-blind conditions. The maximum daily dose of amoxapine was 400 mg; for the combination, the maximum was 200 mg of amitriptyline and 32 mg of perphenazine. Eighty-two percent of the amoxapine group and 85% of the amitriptyline/perphenazine group demonstrated moderate to marked improvement. The combination produced significantly more extrapyramidal side effects, and there was a tendency for it to produce more anticholinergic side effects. The authors noted that the ratio of serotonin-2 to dopamine-2 receptor blockade of amoxapine was similar to that of a number of atypical neuroleptics, suggesting a possible mechanism of action for the antipsychotic effect of this compound.

### *Summary*

In summary, studies on psychotic depression indicate that the condition responds 1) infrequently to placebo, 2) poorly (or, at best, very slowly) to tricyclic antidepressants alone, and 3) well to ECT, to the combination of a tricyclic antidepressant and a neuroleptic, and to amoxapine alone. In contrast, patients with nonpsychotic major depression demonstrate higher response rates to both placebo and tricyclic antidepressants alone than do patients with psychotic major depression. The relative contribution of severity of illness as a factor in lowering responsiveness to tricyclic antidepressant therapy still requires further study.

## DISCUSSION AND CONCLUSIONS

The major efforts expended in recent decades toward developing clinically valid classification systems resulted in the inclusion of a large number of syndromes in *DSM-III-R*, for many of which there are relatively limited data on the key dimensions (e.g., biology and response to treatment) that are necessary for validating their designation as distinct disorders. Indeed, some investigators have argued that many *DSM-III-R* disorders would be better classified under a broader rubric of affective disorder (105). In contrast, the data reviewed in this article strongly suggest that unipolar major depression with psychotic features is a disorder that can be differentiated from unipolar major depression without psychotic features on a number of important dimensions—particularly symptoms, biological characteristics, course/outcome, and response to treatment.

Still, a number of questions can and should be raised about a separate designation. For one, could the so-called differentiating characteristics of psychotic versus nonpsychotic major depression merely be separating a more severe from a less severe disorder rather than demarcating a truly distinct syndrome? As we have indicated in detail, severity alone did not appear to account for the differences between psychotic and nonpsychotic major depression. For example, in regard to symptom characteristics, Coryell et al. (1) reported significantly higher total scores on the 17-item Hamilton Rating Scale for Depression among patients with psychotic major depression than among patients with nonpsychotic major depression, but these differences were mainly due to three items concerning delusions. In that study, psychomotor disturbance was the only somatic symptom to separate the two groups. Patients with psychotic major depression did not demonstrate significantly higher scores on the remaining neurovegetative symptoms. The differences in HPA activity (34), sleep (62), and response to treatment (82, 90) between patients with psychotic and nonpsychotic major depression also did not appear to be due to differences in severity. However, particularly in regard to treatment, further prospective investigation is required, since some studies have also reported poor responses to tricyclic antidepressants in severely ill patients with nonpsychotic major depression (88, 95).

Could the differences between psychotic and nonpsychotic major depression be due to differences in endogenicity? This is an important issue, since guilt feelings and psychomotor disturbance are clearly endogenous symptoms. A few studies explored the specific role of endogenicity, and these also failed to demonstrate that differences between psychotic and nonpsychotic major depression were due to more intense endogenous-type symptoms in the former. Indeed, the recent article by Parker et al. (16), on a well-defined group of patients who met the RDC for endogenous depression and the *DSM-III* criteria for melancholic depression, clearly indicated that the differentiating symptoms do not merely separate endogenous from nonendogenous (or more endogenous from less endogenous) disorders. Moreover, data from a number of studies on HPA activity (26, 29, 34) and response to treatment (82, 88) also failed to substantiate that differences were due to endogenicity and not to psychosis.

The findings that young patients with psychotic major depression are at high risk for developing bipolar disorder (72, 73) and that there is increased risk of bipolar disorder in the families of patients with psychotic major depression (71) could suggest that psychotic major depression should be classified as a bipolar disorder. There are a number of arguments against this designation, however. For one, the relatively high risk of a switch into mania has been described in adolescent but not older patients. Thus, only in younger patients does psychotic major depression potentially signify the first episode of a bipolar disorder. Although the prevalence of psychotic major depression is higher among bipolar than unipolar patients (1), this observation does not negate the observations that unipolar psychotic and nonpsychotic major depressive disorders can be differentiated. One could argue that the differences between psychotic and nonpsychotic major depression merely reflect the differentiation of a forme fruste bipolar psychotic depression from unipolar nonpsychotic major depression. However, data from our group and others point to differences between patients with unipolar and bipolar psychotic major depression in cortisol (27) and dopamine β-hydroxylase (49, 106) activity. Although further studies are required, the limited data gathered so far suggest that unipolar psychotic major depression differs from bipolar psychotic major depression.

An argument can be made that there is little to be gained from having another *DSM-IV* category rather than continuing a dimensional designation for psychosis. Although many technical issues regarding a categorical versus a dimensional designation of psychotic major depression (107) have not been explored, data on morbidity and response to treatment point to the practical need for clearer separation of this disorder. Furthermore, the difficulty in making the diagnosis results in its being frequently missed in the clinical setting, with patients receiving less than optimal treatment and having poorer outcomes (108). A separate designation with clear criteria would assist patients and practitioners alike.

Although we believe that a separate designation would be beneficial, further research on the potentially demarcating symptoms as well as other key dimensions (e.g., biology and response to treatment) is necessary to develop an optimal set of criteria and to resolve lingering questions about severity, endogenicity, bipolarity, and optimal treatment. Nevertheless, the data reviewed in this article point to both the rationale and the need for designating psychotic major depression as a distinct syndrome in *DSM-IV*.

# G Proteins: Implications for Psychiatry

Husseini K. Manji, M.D.

*There is mounting evidence that a family of guanosine triphosphate binding proteins (G proteins) play an obligatory role in the transduction of a vast array of extracellular, receptor-detected signals across cell membranes to intracellular effectors. The author reviews the literature dealing with G protein coupling to second messenger generation, the role of G proteins in regulating both the convergence and divergence of neurotransmitter action in the CNS, and the involvement of G proteins in a variety of clinical conditions, with an emphasis on psychiatric conditions and their treatments. G proteins form the basis of signal integration in the CNS, endowing the neuron with a large degree of functional diversity. Abnormalities in the function and/or expression of G proteins have been implicated in a variety of pathophysiologic states, and a number of currently available psychotropic drugs affect G proteins. The understanding of the mechanisms by which G proteins modulate neuronal activity may be one of the keys to understanding the functioning and the complexities of the nervous system. Given their widespread, critical roles in the regulation of neuronal function, it seems likely that G proteins are involved in the pathophysiology of various major psychiatric illnesses. The development of novel, site-specific drugs with primary G protein targets remains an exciting prospect for the future.*

(Am J Psychiatry 1992; 149:746–760)

One of the most exciting recent advances in neuroscience has been the elucidation of the molecular mechanisms underlying neuronal communication. Although rapidly increasing numbers of potential neurotransmitters and receptors continue to be identified, it has become clear that the translation of the extracellular signals (into a form that can be interpreted by the complex intracellular enzymatic machinery) is generally achieved in relatively few ways. Generally speaking, these transmembrane signaling systems, and the receptors that use them, can be divided into two major groups:

1. Those with relatively self-contained structures and messages that take the form of transmembrane ion fluxes.
2. Those with multiple components and messages that generate various intracellular "second messengers."

The first class of receptors contain in their stable molecular complex an intrinsic ion channel. Receptors of this class include those for a number of amino acids—including glutamate, γ-aminobutyric acid (GABA) (through the $GABA_A$ receptor), and glycine—the nicotinic acetylcholine receptor, and the $5\text{-}HT_3$ receptor (1). Receptors of this type have also been described as "ionotropic" and are generally composed of four or five subunits surrounding a central ionic pore, which opens transiently when the transmitter binds, allowing ions to flow either into the neuron (e.g., $Na^+$, $Ca^{+2}$, $Cl^-$) or out of it (e.g., $K^+$), thereby generating synaptic potentials. Neurotransmission of this type is very fast: ion channels open and close within milliseconds (2).

Most receptors, however, do not have ionic conductance channels within their structure; rather, they regulate cellular activity by generating various second messengers. In general, receptors of this class do not directly interact with the various second-messenger-generating enzymes but transmit information to the appropriate "effector" by the activation of interposed "coupling proteins." It is now clear that a family of structurally related, guanosine-triphosphate-binding proteins (or G proteins) play an obligatory role in the transduction of a vast array of extracellular, receptor-detected signals across cell membranes to intracellular effectors. Indeed, Birnbaumer (3) has suggested that about 80% of all known hormones, neurotransmitters, and neuromodulators (numbering around 100) elicit cellular responses through G proteins coupled to a variety of cellular effectors, including adenylyl cyclase (frequently referred to as adenylate cyclase), phospholipase C, phospholipase $A_2$, and several ion channels (4). Receptors coupled to G proteins include those for catecholamines, serotonin, acetylcholine, various peptides (e.g., vasopressin, substance P), and even sensory signals, such as light and various odorants (3). Receptors coupled to G proteins are prototypic "metabotropic" receptors. Activation of these receptors initiates a cas-

Received May 22, 1991; revision received Nov. 6, 1991; accepted Nov. 21, 1991. From the Section on Clinical Pharmacology, Experimental Therapeutics Branch, NIMH. Address reprint requests to Dr. Manji, Section on Clinical Pharmacology, Experimental Therapeutics Branch, NIMH, Bldg. 10, Rm. 2D46, 9000 Rockville Pike, Bethesda, MD 20892.

The author wishes to thank Drs. William Z. Potter and John K. Hsiao for their helpful suggestions, input, and encouragement.

cade of events, usually through regulation of intracellular second messengers, that lead to modification of enzymatic phosphorylation of various membrane and cytosolic proteins (enzymatic activation or inhibition), including receptors, ion channels, and possibly G proteins themselves (1). As might be predicted, receptors coupled to G proteins generate electrical signals much more slowly, often with a latency of signal onset of at least 30 msec (2). The ability of many G proteins to interact with multiple receptors also provides an elegant mechanism for the neuron to respond to a large number of stimuli and to regulate both the convergence and divergence of neurotransmitter action (5, 6). The high degree of complexity generated by the interactions of G-protein-coupled receptors may be one mechanism by which neurons acquire the flexibility necessary for generating the wide range of responses observed in the nervous system; this has led to the suggestion that G-protein-coupled receptors may be involved in pathways regulating such diverse vegetative functions as mood, appetite, and wakefulness (2).

Thus, understanding the mechanisms by which G proteins modulate neuronal activity is one of the keys to understanding the functioning and the complexities of the nervous system. Additionally, there is a growing body of evidence implicating both quantitative and qualitative G protein abnormalities in a variety of clinical disorders. Similarly, there is increasing evidence that a number of psychotropic agents exert their clinically relevant effects at postreceptor sites, including G proteins. The identification of these putative G protein targets may thus lead not only to the development of more potent, site-specific treatments but also to the localization of molecular and biochemical factors predisposing individuals to various psychiatric illnesses.

This overview will explore the growing knowledge of G protein coupling to chemical and ionic second messenger generation. Specifically, I will discuss the biochemistry of second messenger synthesis, the role of G proteins in neurotransmitter-neurotransmitter interactions, and the possible involvement of G proteins in a variety of clinical conditions, with an emphasis on psychiatric conditions and their treatments.

## WHAT ARE G PROTEINS?

The G proteins are a family of GTP-binding proteins that play an obligatory role in the transduction of extracellular, receptor-detected signals across the cell membrane to various intracellular effectors (3, 4). These proteins have been the focus of extensive research since the demonstration that stimulation of adenylyl cyclase (the enzyme which generates cAMP) activity requires both hormones and GTP. It was subsequently demonstrated that β-adrenergic agonists stimulated GTPase activity (discussed later) in erythrocytes and that guanine nucleotides—such as GTP or similar nonhydrolyzable analogues [Gpp(NH)p or GTPγS]—modulated the affinity of this receptor for agonists but not antagonists. These and other indirect observations led to the proposal that the site of GTP's action is on a protein distinct from both the hormone receptor and adenylyl cyclase.

This hypothesis was confirmed by the subsequent purification of a GTP-binding protein from liver. By using the S49 cell mutant (deficient in hormone- and GTP-dependent activity), now termed "cyc$^-$," it was possible to demonstrate that the addition of the purified "transducer protein" restores hormone- and GTP-dependent adenylyl cyclase activity. Since the addition of this purified protein stimulated adenylyl cyclase activity, it was termed "$G_s$" (s=stimulatory) (reference 7 is an excellent historical overview). Shortly thereafter, the purification of a protein necessary for inhibition of adenylyl cyclase ("$G_i$") provided a mechanistic explanation for the bidirectional regulation of this enzymatic activity (8). $G_i$-like proteins were shown to activate a phospholipase C that hydrolyzes phosphatidylinositol 4,5-bisphosphate to generate diacylglycerol and inositol 1,4,5-trisphosphate and to modulate the activity of specific ion channels (3, 4, 9, 10). Subsequently, another G protein for which no obvious function was evident was purified from brain (11); this protein was named "$G_o$" (o=other protein). The identification of $G_o$ led to the realization that the G proteins are, in fact, a family of homologous proteins serving diverse roles in a wide variety of receptor-mediated extracellular signals to various intracellular second messenger systems (3, 4, 9, 10). It is now clear that G proteins involved in signal transduction are αβγ heterotrimers. The greatest diversity observed thus far is with α subunits, which are generally believed to directly modulate the activities of various effectors (discussed later), but diversity also exists for β and γ subunits (see table 1).

## MECHANISM OF G PROTEIN ACTIVATION

The molecular events underlying G protein activation/deactivation have been best characterized for G-protein-mediated regulation of adenylyl cyclase (3, 4, 13), but the following sequence of events is assumed to occur for most (if not all) G proteins (see figure 1).

The G protein α subunit cycles between an inactive GDP-bound oligomeric (αβγ) form and an active GTP-bound monomeric form. Gilman (4, 13) has described these two forms of the α subunit as the "off" and "on" positions of a carefully timed molecular switch. Activation of a receptor by an agonist induces a conformational change in the receptor, allowing it to interact with the G protein, and forms a short-lived "high-affinity ternary complex" consisting of these components. The interaction of the receptor with the G protein in turn results in a conformational change in the α subunit of the G protein, which facilitates the displacement of GDP by GTP. The binding of GTP is a crucial step in the activation cycle and has two major consequences.

1. The G protein dissociates from the receptor. This destabilization of the high-affinity ternary complex re-

**TABLE 1. Key Features of G Protein Subunits[a]**

| Subunit | Molecular Weight ($\times 10^{-3}$) | Toxin Targeting Subunit (cholera or pertussis) | Effector(s)[b] | Examples of Receptors |
|---|---|---|---|---|
| $G\alpha_s$ (four types) | 44.5–46 | Cholera | AC (+); L-type $Ca^{+2}$ channels (+) | $\beta_1$, $\beta_2$, $D_1$, $A_2$, $H_2$, ACTH, CRH, $V_2$, $PGE_1$ |
| $G_{s,olf}$ | 44.7 | Cholera | AC (+) | Olfactory signals |
| $G\alpha_i$ (three types) | 40.4–40.5 | Pertussis | AC (–); $K^+$ channels (+) | $\alpha_2$, $D_2$, $A_1$, $\mu$, $M_2$, $5\text{-}HT_{1A}$ |
| $G\alpha_{t,r}$ | 40.5 | Both | Cyclic GMP phosphodiesterase (+) | Retinal rods (rhodopsins) |
| $G\alpha_{t,c}$ | 40.5 | Both | Cyclic GMP phosphodiesterase (+) | Retinal cones (rhodopsins) |
| $G\alpha_o$ (two types) | 39.9 | Pertussis | $K^+$ channels (+); $Ca^{+2}$ channels (–); PLC (+) (sensitive to pertussis toxin) | $\alpha_2$, $\mu$, $GABA_B$ |
| $G\alpha_z$ | 40.9 | Neither | PLC (+)[c] (insensitive to pertussis toxin) | Unknown |
| $G_q$, $G_{11}$, $G_{14}$ | 42 | Neither | PLC (+) (insensitive to pertussis toxin) | Thromboxane $A_2$, vasopressin |
| $\beta$ (four types) | 37.4 | Neither | Direct interaction with AC (–)[c]; inactivates $\alpha_s$ | |
| $\gamma$ (three types) | 8–10 | Neither | $\beta\gamma$ required for interaction of $\alpha$ subunit with receptor | |

[b] AC=adenylyl cyclase, PLC=phospholipase C, +=stimulatory effect of subunit on effector, –=inhibitory effect.

[c] Finding uncertain.

sults in the receptor's reversion to the low-affinity conformation and the dissociation of the agonist from the receptor. Thus, the receptor is not permanently associated with the $G_s$-adenylyl cyclase complex, and this allows the receptor to recycle and function catalytically, activating several G proteins during the time that one $G_s$ remains active.

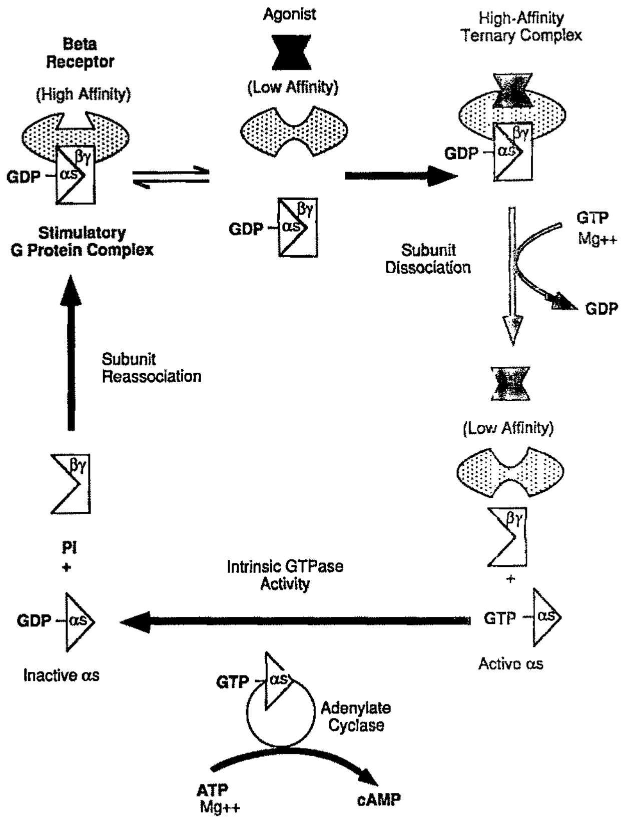
2. The second major consequence of GTP binding to the G protein is to promote dissociation into $\alpha$-GTP and $\beta\gamma$ subunits. It is generally accepted that, for a number of effector systems, the $\alpha$-GTP complex activates the effector enzyme by an as yet undetermined mechanism. The continued activation of adenylyl cyclase by $\alpha$-GTP is terminated by the action of a GTPase enzyme intrinsic to the $\alpha$ subunit, which hydrolyzes GTP to GDP. However, this process is relatively slow, allowing for additional amplification of the signal. The formation of $\alpha$-GDP is presumed to cause dissociation of $\alpha_s$ from the effector (which is now free to interact with additional activated $\alpha$-GTP subunits); the reassociation of $\alpha$-GDP with $\beta\gamma$ is thermodynamically stable and completes the cycle with the formation of the inactive GDP-bound holo-G protein.

Receptors appear to exert their inhibitory effects on adenylyl cyclase by two distinct mechanisms. First, in a manner closely paralleling that just outlined for $G_s$, there appears to be a direct inhibitory effect of $\alpha_i$ on the catalytic unit of adenylyl cyclase. Gilman (4, 13) has proposed that, in addition to the direct inhibition by $\alpha_i$, the $\beta\gamma$ subunits, released by receptor activation of $G_i$, may by mass action attenuate the dissociation of $G_s$. Since the quantity of $G_i$ is considerably greater than the quantity of $G_s$ in most tissues and $\beta\gamma$ subunits appear to be largely interchangeable, this sequestration model has received much acceptance. Although some debate persists as to whether the $\alpha_i$ or $\beta\gamma$ subunits have the greater role in the inhibition of adenylyl cyclase, more studies suggest that they exert distinct but complementary effects in the inhibition of adenylyl cyclase. Thus, $\beta\gamma$ subunits may be more potent inhibitors of receptor-independent stimulation of adenylyl cyclase (14). It is thus possible that $\alpha_i$ is the primary mediator of inhibition of adenylyl cyclase when $G_s$ is stimulated by a hormone or neurotransmitter but that $\beta\gamma$ exerts a major role in the inhibition of basal and postreceptor-stimulated adenylyl cyclase activity.

## G PROTEINS AS TARGETS FOR BACTERIAL TOXINS

The discovery that certain bacterial toxins (in particular, pertussis and cholera) can covalently modify selected G proteins has been invaluable in the delineation of various structural and functional aspects of highly homologous G proteins. In brief, both cholera toxin and pertussis toxin catalyze the transfer of an adenosine diphosphate ribose (ADP-ribose) moiety onto the $\alpha$ subunits of various G proteins. These ADP-ribosylation reactions, and their subsequent effects on signal transduction, are believed to be responsible (at least in part) for the pathophysiology of the diarrhea and whooping cough caused by cholera toxin and pertussis toxin, respectively. A major difference between the stimulatory ($G_s$) and other subtypes of G proteins is their susceptibility to toxin-catalyzed ribosylation. The $\alpha$ subunits of $G_s$ and $G_t$ (transducin, the major retinal G protein) are substrates for ADP-ribosylation by cholera toxin (3, 13). $G_i$ is not generally a target of cholera toxin; rather, it is preferentially ADP-ribosylated in an analogous manner by pertussis toxin. ADP-ribosylation by pertussis toxin appears to stabilize the G protein in its inactive $\alpha\beta\gamma$ undissociated conformation. Additionally, pertussis toxin "uncouples" receptors from $G_i$ (3, 4, 7), thereby attenuating receptor-mediated inhibition of adenylyl cyclase. Studies using cDNA cloning have shown that several G proteins are substrates for pertussis toxin, namely, $G_{i1}$, $G_{i2}$, $G_{i3}$, $G_t$, and $G_o$ (15). Thus, additional techniques have to be used to distinguish between the various pertussis toxin substrates. Nevertheless, the relative selectivity of these toxins has resulted in their extensive use in identifying the presence of $G_s$ and $G_i$ in various tissues, as well as the coupling of various receptors to these G proteins.

**FIGURE 1. Mechanisms of G Protein Activation/Deactivation**[a]



[a] At rest an equilibrium exists between the receptor in the high-affinity state (coupled to the G protein) and the low-affinity state. Activation of receptors by an agonist induces a conformational change in the receptor, allowing it to interact with the G protein, and forms a short-lived "high-affinity ternary complex" consisting of these components. The receptor-G protein interaction facilitates the replacement of GDP by GTP on the guanine nucleotide site (on the α subunit of the G protein). Binding of guanine nucleotides to the G protein causes a destabilization of the high-affinity complex and a dissociation of the G protein into α-GTP and βγ subunits. For most effector systems, the α-GTP complex activates the enzyme or ion channel. The continued activation is terminated by the action of a GTPase enzyme intrinsic to the α subunit, which hydrolyzes GTP to GDP; the reassociation of GDP-α with βγ completes the cycle with the formation of the inactive G protein.

## G PROTEIN REGULATION OF PHOSPHOLIPASE C

The phosphoinositide pathway is a major signal-transducing pathway that has a ubiquitous role in the regulation of various aspects of cellular and neuronal function. The binding of hormones and neurotransmitters to a variety of cell surface receptors—e.g., $\alpha_1$-adrenergic, serotonin ($5\text{-HT}_{1c}$, $5\text{-HT}_2$), and muscarinic ($M_1$, $M_3$)—activates, through interposed G proteins, a phosphoinositide-specific phospholipase C (16). This enzyme hydrolyzes phosphatidyl inositol 4,5-bisphosphate ($PIP_2$) to generate two second messengers: inositol 1,4,5-trisphosphate ($IP_3$), which mobilizes $Ca^{+2}$ from intracellular stores, and 1,2-diacylglycerol, which activates protein kinase C (16). Protein kinase C occupies a pivotal position in the biochemical pathways that relay information into the cell, because it is able to influence the cellular response to numerous other stimuli. Indeed, activation of protein kinase C has been linked to the regulation of cell surface receptors, ion channels, secretion, gene expression, and neuronal plasticity (17). The details of the phosphoinositide turnover pathway have been outlined previously in an excellent review in the *Journal* (17) and will not be repeated here.

The G protein that stimulates phosphoinositide turnover has been termed "$G_p$" (p=phosphoinositide), although its exact nature remains to be determined. What is clear, however, is that there appears to be more than one type of G protein activating phospholipase C, since pertussis toxin (which ADP-ribosylates and inactivates several G proteins [see preceding discussion]) inhibits agonist-stimulated $PIP_2$ hydrolysis in some cell types but not others (16). Indeed, functionally distinct G proteins may even selectively couple different receptors to $PIP_2$ hydrolysis in the same cell (18). Studies using *Xenopus* oocytes (large frog eggs frequently used in transfection studies) suggest that $G_o$ rather than $G_i$ may represent the pertussis-toxin-sensitive "$G_p$," at least in certain cell types (16). The identification of a novel G protein termed "$G_z$," which is not a substrate for ribosylation by either cholera toxin or pertussis toxin, has led to the proposal that $G_z$ may represent the "$G_p$" in a variety of tissues, including brain (where it is abundant) and platelets (19). More recently, however, several groups have purified and cloned members of a novel, ubiquitously distributed family of G proteins known as $G_q$. The α subunits of this family, including $\alpha_q$ and $\alpha_{11}$, have unequivocally been shown to stimulate phospholipase C, making them leading candidates for the heretofore elusive G proteins coupled to stimulation of phospholipase C in a pertussis-insensitive manner (12). Similar to the dual regulation of adenylyl cyclase, a number of receptors appear to inhibit phosphoinositide turnover, including receptors for adenosine, dopamine, 5-HT, and glutamate (20). In addition, evidence has accumulated that similar to the regulation of phospholipase C, G proteins may couple various receptors to phosphatidylcholine by means of phospholipase D (21). The existence of this signal transduction pathway has generated considerable interest, since it provides a mechanistic explanation for the frequently reported temporal dissociation between production of diacylglycerol and $IP_3$ (21).

## G PROTEIN COUPLING OF RECEPTORS TO ION CHANNELS

It has become increasingly clear in recent years that a large number of ion channels are regulated both directly and indirectly by G proteins; at least 12 separate ion channels appear to be directly regulated (under cell free conditions) by G proteins (3, 22). In the CNS, a variety of receptors regulate neuronal $K^+$ conductances by means of pertussis-toxin-sensitive G proteins. Activation of these $K^+$ channels results in neuronal hyperpolarization and is an important element in the regulation of the neuronal firing rate (23). Although both $\alpha_i$ and $\alpha_o$ are able to activate inwardly rectifying $K^+$ currents in neurons, $\alpha_o$ is markedly more potent. This is of considerable interest since $\alpha_o$ can be said to be predominantly localized in the nervous system (24), where its major role may be to regulate ion channels. Indeed, the most abundant G protein in the brain is $G_o$, which comprises 0.5%–1.0% of the total membrane protein (24). Within the brain, $G_o$ has a heterogenous distribution; it is particularly rich in the hippocampus and frontal cortex but is also widely distributed in other areas of the brain (25). This distribution parallels that of protein kinase C (but not adenylyl cyclase) in the brain, leading to the suggestion that $G_o$ may represent the pertussis-toxin-sensitive "$G_p$" in the brain (25). In addition to regulating $K^+$ channels, G proteins (in particular, $G_o$) also directly modulate neuronal $Ca^{+2}$ channels (3, 22, 26, 27). Voltage-activated $Ca^{+2}$ channels are present throughout neurons and regulate a variety of cellular functions, including, of course, neurotransmitter release. A variety of neurotransmitter receptors (including $\alpha_2$-noradrenergic, $GABA_B$, and adenosine A1) inhibit neuronal voltage-sensitive $Ca^{+2}$ channels, and this receptor-stimulated modulation of $Ca^{+2}$ ion channels may be (at least in part) the molecular mechanism whereby nerve terminal autoreceptors inhibit neurotransmitter release (26, 27).

## REGULATION OF G PROTEINS BY HORMONES

The CNS is a major target for the actions of glucocorticoids, thyroid hormones, and gonadal hormones, but the biochemical alterations ultimately responsible for producing the effects remain unclear. Malbon et al. (28, 29) coined the term "permissive hormones" to describe agents such as glucocorticoids and thyroid hormones that modulate the actions of a variety of agents acting through cAMP. Increasing evidence suggests that these modulatory actions are exerted to a significant degree through G protein regulation. Thus, in vivo alterations of hormonal levels have been demonstrated to alter the steady-state levels of several G protein subunits and thereby regulate the overall sensitivity of transmembrane signaling in a variety of peripheral tissues (30–32). Less information is available about the effects of hormonal manipulation on G protein regulation in the CNS. However, it has been demonstrated that 7-day administration of corticosterone increases the transcription and expression of $G\alpha_s$ while decreasing both the mRNA and immunoreactivity of $G\alpha_i$ in rat cerebral cortex (33). Moreover, adrenalectomy without corticosterone replacement results in a significant 20% decrease in $G\alpha_s$ mRNA, suggesting in vivo physiologic regulation (33). It has also been demonstrated that pretreatment of mouse striatal neurons in primary culture with 17 β-estradiol or testosterone increases the pertussis-toxin-catalyzed ADP-ribosylation of $G\alpha_o$ and/or $G\alpha_i$ subunits (34).

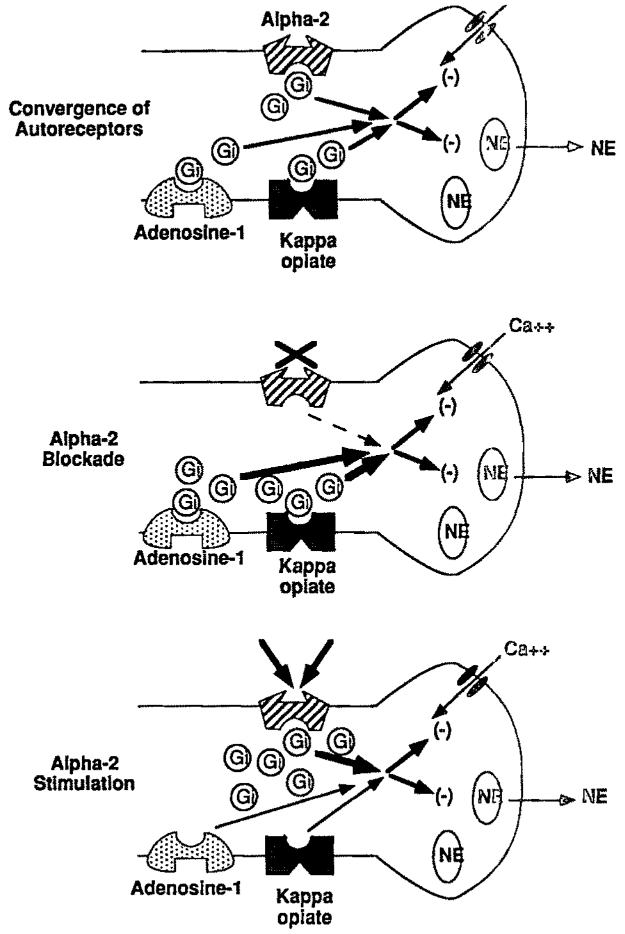
Abundant evidence supports an interaction between thyroid and adrenal hormones and psychiatric illness, particularly in affective disorders. Thus, primary disorders of both the thyroid and hypothalamic-pituitary-adrenal (HPA) axis have been linked with depressive, manic, and anxiety symptoms. Additionally, there is general agreement that more than 50% of patients with major depression exhibit hyperactivity of the HPA axis, as evidenced by hypercortisolemia, ACTH hypersecretion, and nonsuppression of plasma cortisol after dexamethasone administration (35). Similarly, at least some studies have shown the administration of thyroid hormones to be beneficial in the treatment of refractory depression and rapid-cycling bipolar disorder. Although a variety of biochemical effects may contribute to the CNS manifestations of abnormalities in thyroid or corticosteroid status, alterations of G protein function or content (with the inherent amplification of receptor responses) by these permissive hormones are an attractive mechanism. Similarly, the effects of gonadal hormones on G proteins, resulting in subsequent modification of signal transduction (34, 36), may be one mechanism by which biological maturation (puberty or menopause) triggers the expression of certain psychotic illnesses (e.g., schizophrenia in late adolescence, melancholic depression in late adulthood).

## G PROTEINS AS MEDIATORS OF NEUROTRANSMITTER-NEUROTRANSMITTER AND RECEPTOR-RECEPTOR INTERACTIONS

Most clinical studies in psychiatry, even when multiple measures are obtained, analyze data primarily in terms of independent measures, e.g., Is norepinephrine deficient? Is serotonin deficient? However, considerable preclinical evidence shows that monoamine systems interact, and a major question for neuroscience is emerging with regard to elucidating the mechanism(s) by which one neurotransmitter influences the response of a neuron to all the other converging afferent inputs.

The CNS is extremely complex, both anatomically and chemically, and there is a remarkable convergence of different receptors in common cortical layers (37) and a considerable convergence of neurotransmitter action (38). A single neuron in the brain receives thousands of synaptic inputs on the cell body and dendrites, and neuronal response is also modulated by a variety of hormonal and neurohormonal substances not dependent on synaptic organization. The neuron needs to integrate all the synaptic and nonsynaptic inputs impinging on it; this integration of a multitude of signals determines the ultimate excitability, firing pattern, and response characteristics of the neuron, and the neuron's response is then conveyed to succeeding targets by means of synaptic transmission. How does the single neuron decipher and integrate the multitude of signals it receives and, additionally, generate unique responses to each of these signals or combinations of signals? Not only do G proteins amplify signals, they also appear to form the basis of a complex information processing network in the plasma membrane (39). Thus, the ability of G proteins to interact with multiple receptors provides an elegant mechanism to organize the signals from these multiple receptors and to transmit them to a relatively much smaller number of effectors. Signals from a variety of receptors can be "weighted" according to their intrinsic ability to activate a given G protein and integrated to stimulate a single second messenger pathway. Similarly, the dual (positive and negative) regulation of adenylyl cyclase and perhaps of phospholipase C by G proteins allows stimulatory and inhibitory signals for these pathways to be balanced at the G protein level, yielding an integrated, dampened output (39). Convergence of a variety of neurotransmitters on the same ion channel has been demonstrated to occur in the locus coeruleus, hippocampus, thalamus, and substantia nigra (38, 40–43). Thus, it appears that a variety of receptors which coexist on neurons and mediate similar responses may share signal transduction mechanisms (38, 40, 43, 44). This convergence may occur at the level of the G protein or the effector itself. In both the cortex and the hippocampus, $\alpha_2$-adrenergic, adenosine $A_1$, and K-opiate receptors appear to compete for the same pool of G proteins to modulate $Ca^{+2}$ influx through voltage-sensitive $Ca^{+2}$ channels, thereby decreasing norepinephrine release (44–46). Additionally, there is mutual antagonism between these receptors with respect to modulating both $Ca^{+2}$ influx and norepinephrine release. That is, stimulating one of these receptors diminishes the effectiveness of the other receptors; this may be a mechanism for allowing neurons to "escape" from excessive inhibitory input (46) (see figure 2). Similarly, heterologous desensitization (a form of desensitization whereby exposure to a desensitizing agent leads to diminished responsiveness to a number of stimuli, apparently through postreceptor mechanisms) may be a compensatory mechanism designed to protect the neuron from the deleterious effects of overstimulation by multiple receptors. Thus, G proteins provide the first opportunity for signals from different receptors to be integrated; this complex web of interactions linking receptors, G proteins, and their effectors with signals converging to shared detectors appears to be crucial for the integrative functions performed by the CNS (39, 47, 48).

**FIGURE 2. Integration of Receptor-Receptor Interactions by a Common G Protein-Effector System**[a]

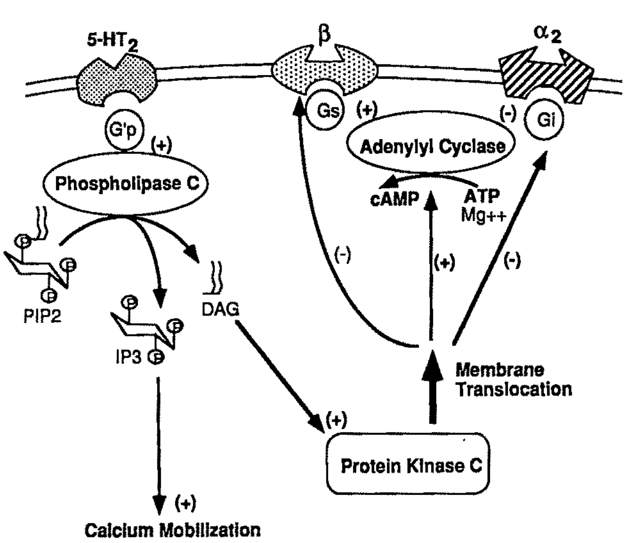


[a] Receptors that coexist on neurons and mediate similar responses may share signal transduction mechanisms. The top portion of the figure depicts a neuron with $\alpha_2$-adrenergic, adenosine $A_1$, and K-opiate receptors all converging onto a common pool of $G_i$-like proteins to inhibit $Ca^{2+}$ influx and norepinephrine (NE) release. Alpha-2-adrenergic antagonism increases the effectiveness of the other receptors (middle), possibly by making available a greater proportion of the shared G protein pool. In an analogous manner, stimulation of $\alpha_2$ receptors (bottom) diminishes the effectiveness of the other receptors through a disproportionate use of the common pool of G proteins. This may be a mechanism for allowing a neuron to "escape" from excessive inhibitory input.

## G PROTEINS AS MEDIATORS OF RECEPTOR-EFFECTOR CROSS-TALK IN THE CNS

In addition to their role as receptor-effector couplers, G proteins also serve as targets for regulating cross-talk between various second messenger systems. There are a number of potential sites of interaction of protein kinase C with the cAMP-generating system (49, 50; see figure 3). A large body of evidence suggests that phosphorylation of the β-adrenergic receptor by various kinases, including protein kinase C, desensitizes the receptor (50). Indeed, evidence suggests that the most commonly observed biochemical effect of antidepressants, namely, down-regulation of β-adrenergic receptors, may be mediated by cross-talk through protein kinase C (51, 52). Increasing evidence has also accumulated that the potentiating effects of protein kinase C on cAMP accumulation are mediated by $G_i$. Thus, in a number of cell types, including hepatocytes and striatal membranes (30, 53–55), activation of protein kinase C appears to

**FIGURE 3. Mediation of Receptor-Effector Cross-Talk in the CNS by G Proteins**[a]



[a] The figure depicts the complex intracellular cross-talk between receptors activating the phosphoinositide turnover pathway and receptors coupled to adenylyl cyclase. Receptor activation of phospholipase C results in the generation of $IP_3$ (IP3), which mobilizes $Ca^{+2}$ from intracellular stores, and diacylglycerol (DAG), which activates protein kinase C. There are a number of potential sites for the interaction of protein kinase C with the cAMP-generating system. Protein kinase C phosphorylates the β-adrenergic receptor, causing an uncoupling of the receptor from $G_s$. It also appears to phosphorylate adenylyl cyclase, resulting in an enhancement of adenylyl cyclase activity. Finally, at least in certain systems, it appears to phosphorylate and inactivate $G_i$, thereby removing its inhibitory tone. The net effect of the various potential interactions probably depends on differences among subtypes of G proteins and the relative abundance of protein kinase C isozymes.

enhance adenylyl cyclase activity by attenuating the inhibitory influence of $G_i$. Since the susceptibility of G proteins to be phosphorylated (and therefore regulated) by protein kinase C depends in large part on their conformational state (56), the degree of cross-talk is regulated by the relative degree of simultaneous stimulation of various receptors. In sum, it is clear that interactions between distinct second-messenger-generating systems represent a fine-tuning cellular network that regulates the neuron's reactions to the large number of extracellular signals it encounters. The net effect of the various potential interactions probably depends on the summation of the effects on individual components. In this context, quantitative and qualitative (e.g., conformation states) differences among subtypes of G proteins and the relative abundance of protein kinase C isozymes (57) in various cells may be major factors in determining the final integrated output.

## CLINICAL IMPLICATIONS

Given their widespread and crucial role in the integration, regulation, and amplification of signal transduction pathways, it is not surprising that abnormalities in the function and/or expression of various G proteins have been implicated in a variety of pathophysiologic states: pseudohypoparathyroidism type I, heart failure, certain endocrine tumors, McCune-Albright syndrome, diabetes, alcoholism, schizophrenia, mitral valve prolapse, chronic cocaine/opiate ingestion, aging, hypo/hyperthyroidism, and adrenalectomy/corticosteroid administration (58–81). It should be noted that G protein dysfunction appears to be the primary pathology in Albright's hereditary osteodystrophy, McCune-Albright syndrome, and endocrine tumors; in several of the other conditions, G protein abnormalities are probably secondary but are nonetheless implicated in the pathophysiology of the condition. I will briefly highlight some of the clinical conditions with well-characterized G protein dysfunction.

The first disease in which an intrinsic G protein abnormality was found is pseudohypoparathyroidism, so called because individuals with this condition have normal (or even higher than normal) levels of parathyroid hormone but have the manifestations of the disease because of cellular resistance to the hormone. In one form of the illness (Albright's hereditary osteodystrophy), the patients demonstrate a resistance to parathyroid hormone and to a number of hormones using cAMP as the second messenger. In these patients, lower than normal expression or function (approximately 50%) of $G\alpha_s$ has been demonstrated in cultured cells and in cells from freshly obtained tissue (58 and references therein). Additionally, distinct mutations have been identified in the gene encoding $G\alpha_s$ in different kindreds with the disease (58, 59), thereby providing the first demonstrations of an inherited mutation in a human G protein gene with important implications. The existence of more than one type of mutation resulting in abnormal function of $G\alpha_s$ demonstrates the genetic heterogeneity of this autosomal dominant disease. Moreover, the presence of an identical mutation in the $G\alpha_s$ gene, both in individuals with multiple hormone resistance and in those without hormone resistance, clearly suggests that $G_s$ deficiency is necessary but not sufficient for the full phenotypic expression of the disease (59). Thus, as has been suggested for a variety of psychiatric disorders, additional factors, including modifying genes and perhaps environmental factors, appear to be involved.

Studies have also demonstrated substantial abnormalities in G proteins in failing human and animal heart. A 50% lower than normal apparent concentration and function of $G_s$ in sarcolemma from a canine model of left ventricular failure has been reported. In contrast, end-stage idiopathic human congestive failure is associated with greater than normal activity of $G_i$, suggesting that various manipulations of $G_s/G_i$ stoichiometry may result in similar pathophysiology (60). Perhaps more akin to psychiatric research with respect to the use of peripheral blood cells to represent less accessible tissue (CNS, heart), one study (60) showed 80% lower than normal lymphocyte $G_s$ levels in subjects with congestive heart failure. More intriguing, successful treatment with captopril was associated with a significant two-fold increase in lymphocyte $G_s$ levels.

The following are summaries of research on the association of G proteins to psychiatric conditions.

### *Alcoholism*

The evidence for genetic factors in alcoholism is compelling (62), and, given the widespread medical, behavioral, and societal manifestations of this disorder, it is not surprising that there has been considerable research on biological factors that may predispose individuals to alcoholism. A variety of putative electrophysiologic, biochemical, and neuroendocrine markers have been studied, but increasing research has focused on G proteins not only as the mediators of the biochemical effects of alcohol but also as possible sites of underlying pathophysiology in individuals predisposed to the development of alcoholism (63).

Ethanol can profoundly affect the G protein-adenylyl cyclase signal transduction pathway (63). Chronic ethanol ingestion or in vitro exposure results in a desensitization of cAMP production in a variety of tissues, including brain (63, 64). The heterologous nature of desensitization of the adenylyl cyclase activity following chronic in vitro exposure of neuroblastoma cells to ethanol suggests a postreceptor (e.g., $G_s$) site. Chronic exposure of cultured cell lines to ethanol results in a more than 30% decrease in both the $\alpha_s$ protein and its mRNA (65, 66). In mice chronically fed ethanol, there is a reduction in the cholera-toxin-catalyzed [$^{32}$P]ADP-ribosylation of $G_s$ and a reduction of high-affinity [$^3$H]forskolin binding (which is thought to reflect binding to the complex of $\alpha_s$ and adenylyl cyclase) (63).

Clinical studies have also implicated $G_s$-adenylyl cyclase as a putative marker in alcoholism. One study showed that basal and adenosine-receptor-stimulated cAMP levels in fresh lymphocytes of alcoholic subjects were 75% lower than those of normal subjects or subjects with nonalcoholic liver disease (67). Cultured lymphocytes from alcoholics, grown in the absence of alcohol, also show some abnormalities in the cAMP signal transduction pathway (64). Similarly, platelet membranes of alcoholics reportedly abstinent from alcohol for 12–48 months demonstrate lower receptor- and $G_s$-stimulated adenylyl cyclase activity than do platelet membranes of age- and sex-matched comparison subjects (68). These findings suggest that low platelet adenylyl cyclase activity may be a genetic marker in alcoholics; this finding is supported by studies by my colleagues and me of cholera- and pertussis-toxin-catalyzed [$^{32}$P]ADP-ribosylation of platelet $G_s$ and $G_i$, respectively, in platelet membranes from abstinent alcoholics, subjects with concomitant diagnoses of major depression and alcoholism (major depression as the primary diagnosis), and age- and sex-matched comparison subjects. We observed significantly less $^{32}$P-labeling of $G_s$ (but not $G_i$) in the alcoholic group than in the comparison subjects. These findings are entirely consistent with the platelet adenylyl cyclase findings by Tabakoff et al. already described (68).

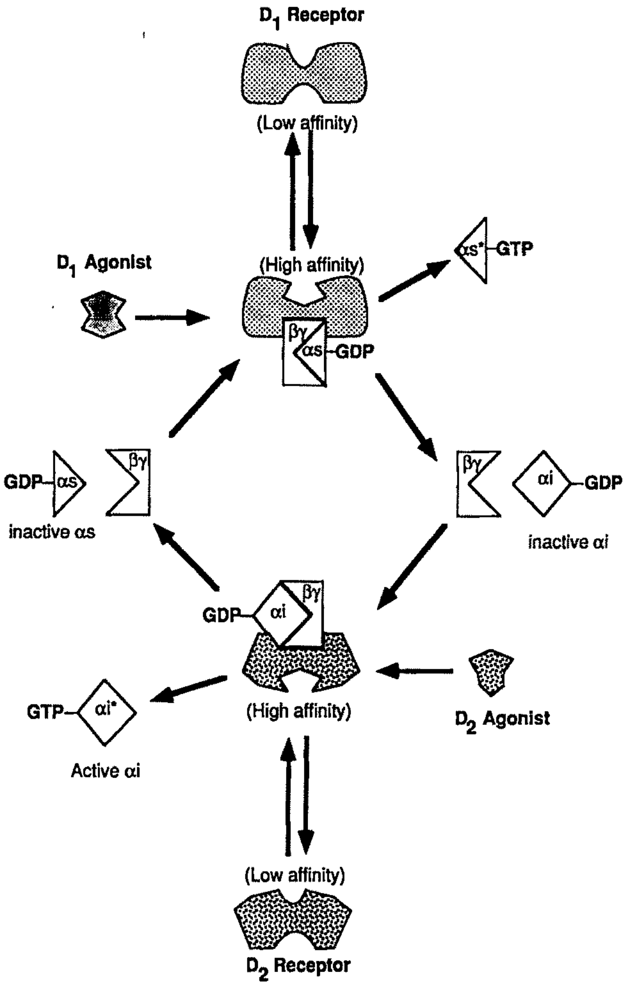
### *Chronic Opiate/Cocaine Use*

To my knowledge, there have been no clinical studies of the effects of acute or chronic opiate or cocaine ingestion on G proteins. Nevertheless, considerable preclinical evidence suggests that these substances exert at least some of their chronic effects (e.g., tolerance, dependence, withdrawal) through G proteins. A variety of opiate receptors are coupled to their effectors by G proteins, and pertussis toxin uncouples opiate receptors from the inhibition of adenylyl cyclase in cultured cells and in locus coeruleus neurons (3). Studies have shown that alterations in G protein levels are temporally correlated with neuronal activity in the locus coeruleus (more firing) and with the behavioral manifestations of the morphine withdrawal syndrome in rats (69, 70). These results suggest that alterations in the levels of G proteins may underlie the enhancement of neuronal excitability (and possibly withdrawal symptoms) observed after abrupt opiate discontinuation. In vitro studies of cultured neurons from rat spinal cord dorsal root ganglia have demonstrated that exposure to K-opiate agonists is accompanied by a 60%–70% decrease in levels of $\alpha_i$, in the absence of alterations in levels of $\alpha$, $\alpha_o$, and $\beta$ subunits (71), thereby providing a mechanistic explanation for opiate-induced heterologous desensitization. In contrast to the studies on opiates, only one recent study has directly examined cocaine's effects on G proteins, demonstrating low levels of $\alpha_i$ and $\alpha_o$ in the ventral tegmental area, nucleus accumbens, and locus coeruleus in rat brain after chronic cocaine use (72).

### *Schizophrenia*

Several years ago, studies using post-mortem human brain tissue demonstrated a greater response of adenylyl cyclase activity to fluoride stimulation (presumably acting through $G_s$) in the caudate and accumbens of schizophrenic patients than in the corresponding brain areas of comparison subjects (73). These studies suggested that a postreceptor defect may contribute to the presumed dopaminergic hyperactivity in schizophrenia, but it was several more years before they received additional, more direct support. Seeman et al. (74) used radioligand binding studies to explore the $D_1$-$D_2$ link in post-mortem human brain tissues. They proposed that the $D_1$ receptor may modulate ligand binding to the $D_2$ receptor by modifying the levels of G protein subunits ($\beta\gamma$) that these receptors share (see figure 4), and they reported that the $D_1$-$D_2$ link was missing in more than 50% of tissue samples from patients with schizophrenia and Huntington's disease, a finding apparently not due to prior neuroleptic use. In a study that examined G protein levels in post-mortem schizophrenic brains more directly, pertussis-toxin-catalyzed ribosylation in the left putamen was 42% lower in schizophrenic patients than in comparison subjects (75). These findings (suggesting low $G_i$ and/or $G_o$) would, of course, be compatible with enhanced dopamine-adenylyl cyclase function. In keeping with these lateralized abnormali-

**FIGURE 4. Reciprocal Modulation of Receptor Affinity by G Proteins**[a]



[a]The relative interchangeability of $\beta\gamma$ subunits allows further interaction of G proteins. When receptors coexist on neurons, a potential mechanism for modulation of receptor affinity by other receptors exists. Binding of an agonist to a receptor (e.g., $D_1$ receptor) promotes the dissociation of the G protein into $\alpha$ and $\beta\gamma$ subunits. The $\beta\gamma$ units thus released may drive the equilibrium for another G protein (e.g., $G_i$) toward the undissociated state and thereby modulate receptor affinity (in this case, the $D_2$ receptor). This may be one mechanism for the observed synergism between the $D_1$ and $D_2$ receptors despite opposite effects on adenylyl cyclase.

ties in postreceptor pathways in schizophrenic patients, greater than normal high-affinity [$^3$H]forskolin binding has been found in the left parahippocampal gyrus and CA1 region in post-mortem brains of schizophrenic patients (76). Since high-affinity [$^3$H]forskolin binding is thought to reflect binding to the complex of $\alpha_s$ and adenylyl cyclase, higher than normal levels of $\alpha_s$ and/or adenylyl cyclase would be the simplest explanation for these results. However, low levels of $G_i$ $\beta\gamma$ subunits would also result in a greater availability of free $\alpha_s$ to interact with adenylyl cyclase. Indeed, although this suggestion is highly speculative, a low level of $\beta\gamma$ subunits would be compatible with the higher than normal adenylyl cyclase activity (73), lower pertussis toxin ribosylation of $G_i/G_o$ (73) (since there would be fewer $\beta\gamma$ subunits available to form $\alpha\beta\gamma$ heterotrimers—the substrate for the ribosylation reaction), minimal or absent $D_1$-$D_2$ link (74), and greater [$^3$H]forskolin binding in post-mortem tissue from schizophrenic subjects (76).

### *Affective Disorders*

Two studies have directly examined G proteins in affective disorders. Young et al. (82) reported that the levels of $G\alpha_s$ in post-mortem brain tissue from manic-depressive subjects were significantly higher than those of comparison subjects. These findings are intriguing since they parallel those of Schreiber et al. (83), who reported "hyperfunctional" G proteins in manic subjects as determined by isoproterenol-stimulated [$^3$H]-GTPγS binding in leukocytes. Although these findings need to be replicated, they are exciting since lithium is reported to *attenuate* G protein function (see later discussion). Although a number of studies have demonstrated abnormalities in lymphocyte β-adrenergic receptor sensitivity and platelet $\alpha_2$-adrenergic receptor sensitivity in depressed patients (reviewed in reference 84), these abnormalities are difficult to interpret given the extensive literature documenting abnormalities in circulating catecholamines and glucocorticoids in depression. For example, significantly lower lymphocyte isoproterenol-stimulated cAMP accumulation was observed only in a subgroup of depressed patients with psychomotor agitation (and presumably high circulating catecholamine levels) (85). Similarly, a significant correlation between terminal insomnia and blunted lymphocyte cAMP accumulation in depressed patients has been observed (86). Additionally, my colleagues and I have demonstrated correlations between urinary measures of norepinephrine release and basal and postreceptor-stimulated adenylyl cyclase activity in both lymphocytes and platelets (unpublished observations). It is presently unclear whether these abnormalities in receptor and postreceptor sensitivity are primary or are the sequelae of abnormalities in circulating levels of catecholamines and/or stress hormones. Thus, studies of cultured cells from these patient populations are clearly needed to examine possible G protein defects free of the confounding effects of circulating catecholamines and hormones. Similarly, a common postreceptor abnormality (e.g., at the level of G proteins) would provide a mechanism for depressed patients' blunted growth hormone and prolactin responses to a variety of provocative challenges (35), but such an abnormality remains to be established.

### *Other Neuropsychiatric Conditions*

Lower than normal levels of platelet basal and postreceptor-stimulated adenylyl cyclase activity have been reported in both panic disorder (87) and posttraumatic stress disorder (88). Once again, one is faced with the possibility that these platelet abnormalities are secondary to abnormalities in plasma catecholamines and/or stress hormones. Another illness with a constellation of symptoms in common with panic disorder is a form of hyperadrenergic dysautonomia associated with mitral valve prolapse (77). Elegant reconstitution studies have recently demonstrated that upon reconstitution into cyc$^-$ lymphoma cells, erythrocyte $G_s$ from patients with mitral valve prolapse is hyperresponsive with respect to both adenylyl cyclase activation and receptor coupling (78). If a similar $G_s$ abnormality is present centrally in panic disorder, it would provide an attractive mechanistic explanation (i.e., desensitization of β-adrenergic-receptor-coupled adenylyl cyclase) for the therapeutic efficacy of both tricyclic antidepressants and monoamine oxidase inhibitors in this condition.

Finally, abnormalities in G proteins have also been implicated in Huntington's disease (79), Alzheimer's disease (80), and aging (81).

## G PROTEINS AS TARGETS OF PSYCHOTROPIC DRUGS

### *Lithium*

Although lithium is widely used for the treatment of recurrent affective disorders, the biochemical basis for its mood-stabilizing actions remains unknown. However, accumulating evidence suggests that lithium exerts substantial effects on second-messenger-generating systems. The discovery that lithium, at therapeutically relevant concentrations, inhibits the activity of the enzyme inositol-1-phosphatase (89, 90) has resulted in extensive research on the phosphatidylinositol signal transduction system and the generation of the inositol depletion hypothesis (since inositol does not cross the blood-brain barrier, lithium inhibition of inositol-1-phosphatase could deplete inositol and reduce phosphoinositide turnover) (91, 92). This hypothesis has been called into question, however, since alterations in brain $PIP_2$ levels have not been consistently found after lithium treatment (see 92). There has also been extensive research on lithium's effects on neuronal adenylyl cyclase. In rat brain preparations, both in vitro and ex vivo (i.e., after chronic treatment of the animal), lithium has been shown to attenuate receptor- and postreceptor-stimulated [GTP, Gpp(NH)p, fluoride, forskolin] adenylyl cyclase (93–96). In contrast to most antidepressants, lithium has been reported to induce few, if any, changes in the density of rat brain β-adrenergic receptors. Lithium also attenuates receptor-stimulated phosphoinositide turnover in rat brain and in human platelets (reviewed in references 92 and 96). Since lithium affects both phosphoinositide turnover and adenylyl cyclase, recent attention has focused on mechanisms shared by these two signal transduction systems, namely, G proteins. In this context, lithium has been reported to markedly attenuate the agonist-induced increase in [$^3$H]GTP binding in response to both isoproterenol and carbachol (97). Using a similar method, Schreiber et al. (83) observed greater isoproterenol-induced [$^3$H]GTPγS binding in leukocytes from untreated manic patients than in normal subjects or euthymic bipolar patients stabilized with lithium. In renal epithelial cells, lithium delays activation of adenylyl cyclase by Gpp(NH)p, which is compatible with attenuation of the formation of the active Gpp(NH)p-$\alpha_s$ subunit (98). Similarly, the inhibitory effects of chronic lithium use on rat brain adenylyl cyclase are reversed by increasing concentrations of GTP (93, 94). Taken together, these results suggest that the physiologically relevant effects of lithium on adenylyl cyclase may be exerted at the level of G proteins (presumably at a GTP-responsive step).

My colleagues and I have recently demonstrated significant increases in basal and postreceptor stimulated adenylyl cyclase activity in platelets (but not lymphocytes) obtained from normal volunteers after 14 days of lithium administration (95, 96). Since inactivation of $G_i$ appears to exert significant effects on adenylyl cyclase activity in platelets but not in lymphocytes (96), we postulated that the striking tissue-specific effects could be explained by a lithium-induced attenuation of $G_i$ function. To examine this more directly, we used platelet membranes from these same subjects to quantitate G proteins by using specific antibodies and toxin-catalyzed [$^{32}$P]ADP-ribosylation. We did not observe any abnormalities in immunolabeling of platelet $G_i$ but did observe a significant 37% increase in pertussis-toxin-catalyzed [$^{32}$P]ADP-ribosylation of platelet $G_i$. Since the undissociated, inactive αβγ heterotrimeric form of $G_i$ is the substrate for pertussis toxin, our results suggest that lithium inactivates $G_i$ by stabilizing the inactive, undissociated conformation. Corroborating our human platelet findings, we have recently observed similar increases in pertussis-toxin-catalyzed [$^{32}$P]ADP-ribosylation in rat cortex after 4 weeks of lithium use but no alterations in the immunolabeling of $G_s$, $G_i$, or $G_o$. Similar findings have been reported by another laboratory (R.S. Jope, personal communication). The mechanism by which lithium may inactivate $G_i$ is currently under investigation and may involve competition with $Mg^{+2}$ or cross-talk with protein kinase C (99). Whatever the mechanism, by affecting G proteins and thus multiple signal transduction mechanisms (adenylyl cyclase, phosphoinositide turnover) common to many different neurotransmitters, lithium may be in a unique position to affect the functional balance between neurotransmitter systems. One might speculate that it is precisely this effect on the functional balance between interacting neurotransmitter systems that underlies lithium's mood-stabilizing effects.

### *Antidepressants*

Despite extensive research, the molecular mechanisms of action of antidepressant drugs have not been clearly established. The most commonly observed biochemical effect of most clinically effective antidepressant treatments is a reduction in the norepinephrine-stimulated production of cAMP (desensitization), usually (but not invariably) accompanied by a reduction in the number of β-adrenergic receptors (down-regulation) (100). This has generally been regarded as an adaptation to the elevation of intrasynaptic norepinephrine through presynaptic mechanisms (e.g., reuptake blockade or monoamine oxidase inhibition). However, a direct postsynaptic effect of these drugs has been suggested by the observations that chronic in vitro exposure of human fibroblasts (101) and C6 glioma cells (102, 103) to tricyclic antidepressants leads to β receptor down-regulation. Other investigators have attempted to examine the effects of antidepressants at the level of G proteins. Desipramine appears to cause a functional uncoupling of the β receptor from $G_s$ in rat cortex (104) and interferes with the high-affinity state breakdown and subsequent activation of adenylyl cyclase, perhaps by decreasing the affinity of $G_s$ for guanine nucleotides (103, 105). Okada et al. (106) reported that pertussis toxin treatment of rats overcomes desipramine-induced β receptor desensitization (as assessed by measurements of isoproterenol-stimulated adenylyl cyclase activity) without attenuating (in fact, promoting) desipramine-induced β receptor down-regulation. While these results may suggest that $G_i$ and/or $G_0$ are involved in desipramine's effects, it is equally plausible that the removal of the inhibitory tone by pertussis toxin simply masks desipramine's desensitizing effects.

In studies using high in vitro concentrations (50–300 μM), it has been demonstrated that a variety of antidepressants interfere with $G_s$ activation of adenylyl cyclase (107). Interestingly, greater inhibition was observed when the antidepressants were added before, rather than after, the addition of GTP; this finding is also compatible with an antidepressant-induced inhibition of G protein dissociation. However, given the high doses of antidepressants used, the physiologic relevance of these findings remains unclear. It was reported (in an abstract) that chronic administration of imipramine decreased the levels of $G\alpha_s$ immunolabeling, cholera toxin ADP-ribosylation, and $G\alpha_s$ mRNA in rat brain (108). These results are difficult to reconcile with the results of some (109–111) but not all (104, 112) studies, suggesting increased postreceptor-stimulated adenylyl cyclase activity in rat cortical membranes after administration of antidepressants. Nevertheless, it remains possible that antidepressants attenuate β-adrenergic-mediated activation of $G_s$, while enhancing the effects of agents operating by pathways independent of the β-adrenergic receptor.

Like most antidepressants, electroconvulsive shock (ECS) desensitizes the β-adrenergic-mediated adenylyl cyclase activity in rat cortex and hippocampus (100). Fewer studies have investigated the effects of repeated ECS on postreceptor sites. However, repeated ECS is reported to decrease both the agonist-induced $[^3H]$GTP (113) and $[^3H]$forskolin (114) binding in rat cortex. In a study using $[^{35}S]GTP\gamma S$ binding (115), repeated ECS was found to decrease binding in prefrontal cortex and hippocampus but to have no effect in the striatum and to increase $[^{35}S]GTP\gamma S$ binding in the amygdala.

## CONCLUSIONS

Signal transduction through specific receptors plays a central role in neuronal activation. Understanding the mechanisms by which the binding of a neurotransmitter to a receptor at the cell surface is translated into a biochemical (and ultimately a physiologic) effect has clearly come a long way in the past decade. In particular, there has been dramatic progress in defining both the structure and the function of the signal-transducing G protein family. The diversity of the G protein family continues to grow. The G proteins serve the critical role of first amplifying or attenuating extracellularly generated neuronal signals and then transmitting these integrated signals to effectors, thus forming the basis for a complex information processing network (39).

The finding that the amount of G protein in a given tissue is not static, but is under the influence of physiologic, pathophysiologic, and pharmacologic perturbations, has clear implications not only for research into the etiology of various psychiatric conditions but also for the development of better treatments. Abnormalities in G protein function have now been identified in the etiology/pathophysiology of a variety of medical diseases. With the exception of chronic alcohol exposure, opiate withdrawal, and perhaps schizophrenia/neuroleptic exposure, the evidence for postreceptor dysfunction in psychiatric disorders is currently less direct. Nevertheless, given the widespread, critical roles of G proteins in the regulation of neuronal function, it seems likely that future, more sophisticated studies will yield insights into the involvement of G proteins in the pathogenesis of various major psychiatric illnesses. These putative G protein abnormalities may be subtle but sufficient to modify G protein functioning in response to neurotransmitter changes, permissive hormones, or other environmental events or stressors. Finally, given the increasing evidence that the currently available psychotropic drugs affect G proteins, the development of novel drugs with primary G protein targets remains an exciting prospect for the future. Indeed, it is intriguing that a number of the currently available pharmacologic agents, although not developed as such, appear to modify physiologic events that are linked to G proteins. These include heparin derivatives (116), volatile anesthetics (117), and caffeine-like agents (118). It has also been demonstrated that a variety of cationic amphiphilic neuropeptides activate G proteins in a receptor-independent manner (119); they represent a novel class of agents (receptomimetics, rather than receptor agonists). Interestingly, tricyclic antidepressants are also cationic amphiphilic compounds (95, 120), so they too may adopt a membrane-spanning conformation to allow for an interaction with the guanine nucleotide binding site on the G protein. Recent reports have also identified a novel class of agents that serve as allosteric enhancers and stabilize the high-affinity agonist-preferring conformation of the adenosine $A_1$ receptor (121). This may be viewed as being analogous to the manner in which benzodiazepines potentiate GABA-ergic neurotransmission. Such agents have a built-in safety mechanism, since the maximal effect of the drug depends on the availability of the endogenous ligand. This may be one mechanism underlying the relative safety of benzodiazepines in overdose. Additionally, the use of such allosteric modulators may serve to effectively re-equilibrate dysregulated neuronal systems (which are likely to be involved in psychiatric disorders) without the commonly encountered phenomena of tachyphylaxis (receptor down-regulation) and supersensitivity. Finally, given the fact that the GTPase activity serves as a "clock," allowing the system to cycle at a fixed rate, it seems likely that molecular biologic techniques will lead to the development of agents that either stimulate or inhibit GTPase by altering its catalytic rate, thereby dampening or amplifying the hormonal signal (without constitutively activating the G protein).

Appendix 1 provides more specific information on methods for G protein research.

## APPENDIX 1. Methods for Studying G Proteins in Clinical Populations

Several distinct and complementary approaches can be used to study G proteins in clinical populations. The range of techniques developed in recent years to study G protein interactions with both receptors and effectors is described in detail in an excellent review by Milligan (122); only a brief overview of clinically applicable methods is presented here. The simultaneous use of immunoblotting techniques with specific antisera and toxin-catalyzed ADP-ribosylation yields the greatest information about the quantity and conformational (and therefore functional) state of specific G proteins. Several groups of researchers have generated specific antisera against synthetic peptides corresponding to the predicted amino acid sequence of various G protein subunits.

The use of these specific antisera is clearly the method of choice for quantitating G protein subunits. Similarly, these peptide antibodies can be used as specific probes of G protein receptor-effector coupling. Thus, although human platelets contain $G_s$, $G_{i2}$, $G_{i3}$, $G_q$, and $G_z$, only $G_{i2}$ appears to functionally couple to the $\alpha_2$-adrenergic receptor and thereby mediate adenylyl cyclase inhibition (123). However, since these antisera recognize both the dissociated α subunits and the corresponding undissociated, heterotrimeric αβγ complex, they do not, when used alone, provide information about conformational changes occurring in the absence of quantitative changes. For this reason, pertussis and cholera toxin are invaluable adjunctive tools for investigating functional and structural aspects of various G proteins. By using [$^{32}$P]nicotinamide-adenine dinucleotide (NAD$^+$) and determining the transfer of its [$^{32}$P]ADP-ribose moiety to membrane components, it is possible to obtain information about functional aspects of the G protein. In such investigations, [$^{32}$P]ADP-ribosylation of membrane components can be used because both cholera and pertussis toxin preferentially catalyze the ADP-ribosylation of a given conformational state (dissociated/undissociated) of the G proteins. Cholera toxin is very effective in ADP-ribosylating $G_s$ in the activated, dissociated form. In contrast, only the inactive, undissociated form of the $G_i$ protein is ADP-ribosylated by pertussis toxin. Thus, abnormal susceptibility of the G proteins to toxin-catalyzed ADP-ribosylation has been shown to result from an abnormal conformational state and to correlate with abnormalities in relaying molecular signals from extracellular receptors to intracellular effectors (113). However, there are potential problems in the use of toxin-catalyzed ADP-ribosylation as a means of detecting and quantifying G proteins in various tissues. First, both cholera toxin and, in particular, pertussis toxin ribosylate more than one G protein. In some cases, it may be possible to separate the G protein α subunits electrophoretically. Second, [$^{32}$P]NAD+ can be degraded by endogenous NAD-glycohydrolases, thereby altering substrate availability. This potential problem can be overcome by including a large excess of cold NAD in the reaction mixture.

Another functional probe is the so-called reconstitution assay, in which the G protein from the tissue in question is extracted and used to restore deficient adenylyl cyclase activity. Thus, using membranes that lack a specific G protein but have the appropriate receptor(s) and effector(s) allows for the determination of the functional activity of a G protein. Cyc$^-$ variants of the S49 lymphoma cell line lack $G_s$ but possess β-adrenergic receptors and catalytic units of adenylyl cyclase (124). Thus, detergent extraction of $G_s$ from a donor membrane allows for the full reconstitution of β-adrenergic and GTP-dependent adenylyl cyclase activity in this cell line. Such reconstitution studies have been used to demonstrate $G_s$ abnormalities in pseudohypoparathyroidism (125, 126), heart failure (127), and mitral valve prolapse (78). At present, a "$G_i$ equivalent" of the cyc$^-$ S49 lymphoma does not exist. Although more cumbersome, such a model can be generated by treating appropriate membranes with pertussis toxin and then examining the effects of exogenous $G_i$ (122).

Certain pharmacologic agents allow for the dissection of the multicomponent receptor/G protein/effector system. For example, a comparison of the adenylyl cyclase activity in response to receptor agonists, fluoride and G protein analogues (which act at the G protein), forskolin (which acts at $G_s$ and the catalytic unit of adenylyl cyclase), and Mn$^{+2}$ (which directly stimulates adenylyl cyclase) may allow identification of abnormalities in receptor, G protein, and effector to be identified. Similarly, cholera toxin and pertussis toxin may be used as probes of the signal transduction pathway because of their ability to constitutively activate $G_s$ and to inactivate/uncouple $G_i$, respectively.

Finally, agonist-induced GTP binding, agonist-induced GDP release, and agonist-induced increase in GTPase activity should, in theory, serve as good indexes for G protein involvement in the receptor-effector coupling being studied. However, a number of practical problems exist. First, the inability of GTP or its analogues to enter intact cells across the plasma membrane necessitates the use of membrane preparations. Second, in a number of systems, the basal GTP binding and GTPase activity are high, perhaps because signal-transducing G proteins represent only one group of GTP binding and hydrolyzing proteins. Thus, in the majority of instances, the high nonspecific GTPase activities generate sufficient "noise" to preclude an accurate determination of receptor-mediated increases. This assay appears, however, to be more effective in the study of receptors linked to pertussis toxin G proteins (122), perhaps because of their greater abundance in the plasma membrane and their greater enzymatic capacity (128).

# Predicting Substance Use in Late Adolescence: Results From the Ontario Child Health Study Follow-Up

Michael H. Boyle, Ph.D., David R. Offord, M.D., Yvonne A. Racine, M.A.,
Peter Szatmari, M.D., Jan E. Fleming, M.D., and Paul S. Links, M.D.

*Objective: The purpose of this study was to evaluate the relationship between use of tobacco, alcohol, marijuana, and hard drugs (substance use) and psychiatric disorder in early adolescence and substance use in late adolescence. Method: Adolescents included in the study were identified by means of a household sampling frame and participated in the Ontario Child Health Study in 1983 and the follow-up in 1987. There were 726 12–16-year-olds (369 boys and 357 girls) in 1983 who had complete information in 1987. Data on substance use were collected from adolescents by using a structured, self-administered questionnaire. Data on psychiatric disorder were collected in 1983 from both adolescents and their parents by using problem checklists to assess conduct disorder, attention deficit disorder, and emotional disorder. Results: Prior substance use in 1983 was associated strongly with subsequent use in 1987. Among the psychiatric disorders assessed in 1983, only conduct disorder made an independent contribution to predicting use of marijuana (relative odds=3.46) and other hard drugs (relative odds=6.82) in 1987, after prior use of these substances and coexisting attention deficit and emotional disorders were controlled. Corresponding estimates of attributable risk (the expected contribution of exposure to conduct disorder to the development of substance use) were 5.7% and 11.1%, respectively. Conclusions: Although a statistically significant relationship existed between conduct disorder in early adolescence and use of marijuana and hard drugs in late adolescence, the potential is limited for preventing substance use in the general population by treating conduct disorder early on.*

(Am J Psychiatry 1992; 149:761–767)

Information on the strength of association and temporal relationship between specific types of psychiatric disorder and substance use in adolescence is important to those concerned with issues of etiology and prevention. Such information may provide a basis for developing causal hypotheses to understand better the origins of substance use, which could lead to prevention programs. The high frequency of substance use in nonreferred adolescents indicates that the general population is an important subject pool for studying this issue (1).

Research from clinical settings frequently reports a large overlap between substance abuse and other psychiatric disorders in adolescents (2). In the general population, relatively little is known about this overlap and even less about the chronology of the relationship. The studies directly relevant to this question suggest that risks for drug and alcohol abuse are elevated

among nonreferred young adults experiencing depression or anxiety (3, 4).

The research included in this report seeks to advance our understanding of the relationship between psychiatric disorder and substance use among adolescents in the general population. The specific objectives are 1) to describe the relationship between patterns of substance use in early versus late adolescence among a cohort enlisted as 12–16-year-olds, 2) to evaluate the strength of association between psychiatric disorder assessed in early adolescence and substance use reported in late adolescence, controlling for prior substance use and sex, and 3) to estimate the reduction in late substance use (attributable risk) that might be associated with effective (early) treatment of psychiatric disorder. Adolescents included in the study were identified by means of a household sampling frame and participated in the Ontario Child Health Study, an interview survey of 1,869 families with children aged 4 to 16 years in 1983. This article complements earlier ones (5, 6) that focused on the prevalence, patterns, and correlates of substance use among adolescents aged 12 to 16 years.

## METHOD

### Survey Design

Data for the analyses come from families who participated in the original Ontario Child Health Study in 1983 and the follow-up in 1987. The methodology used in the original study is described in detail elsewhere (7). Briefly, the target population of the Ontario Child Health Study included all children aged 4 to 16 years on Jan. 1, 1983, whose usual place of residence was a household dwelling in the province of Ontario. Children living on Indian reserves, in collective dwellings such as institutions, and in dwellings constructed since June 1, 1981 (census day), were excluded systematically from the survey but accounted for only 3.3% of the target population. The sampling frame (source of subjects) was the 1983 Canada census, with the sampling units being household dwellings. The sample was obtained by stratified, clustered, and random sampling from the census file.

Interviewers collected information from the female head of household (parent) and youth aged 12 to 16 during a home visit. The field work was done in January and February 1983 by Statistics Canada—responsible at the federal level for the census, labor force survey, and other data collection for government. Among all eligible households, 91.1% (N=1,869) participated.

### Sample

Eligible for the analyses in this article were adolescents aged 12 to 16 during the original Ontario Child Health Study in 1983 who were aged 16 to 20 during the follow-up in 1987. In 1983 there were 1,302 eligible adolescents in the age group who participated in the original Ontario Child Health Study. Data losses in 1983, attributable to refusal or incomplete subject response on the variables used here, reduced the sample eligible for analysis to 1,202. At follow-up in 1987, complete information was obtained on 60.4% (N=726 of 1,202) of eligible adolescents who had complete information in 1983. This group, consisting of 369 males and 357 females, formed the sample for the present study.

### Variables and Measurements

Both adolescent and parent (female head of household) responses were used in the analyses. Data were collected from adolescents by using structured, self-administered questionnaires completed at home in private by each participating youth aged 12 to 16. The Statistics Canada interviewer was available during the completion of the questionnaire to clarify wording, if required. To protect the rights of privacy of each youth, the completed questionnaire was placed in a Manila envelope, which was then sealed.

Data were collected from parents by using a structured, self-administered questionnaire nearly identical in form and content to the youth self-report. Anonymity of respondents was guaranteed. Numerical codes and record linkage were used to match questionnaires within households; household identities were withheld from the investigators. The data collection procedures were the same in both 1983 and 1987.

Brief definitions of the variables used in the analyses along with test-retest reliability estimates of measurement are given in table 1. The time period for assessing all of the variables in table 1 was the 6-month period before data collection. Substance use was measured in 1983 and 1987 by using information collected from adolescents only. Psychiatric disorder was measured by using information collected in 1983 from both adolescents and parents. For measuring the individual psychiatric disorders, we developed scales comprised of problem behaviors (items) added together to form a score, which was converted to a binary rating to indicate the presence or absence of disorder. Items for the scales were selected from the Child Behavior Checklist (8) according to their ability to describe modified *DSM-III* criteria for each of the disorders. When too few items existed in the Child Behavior Checklist for satisfactory measurement, new items were generated to complete the scale. Scale items were included in checklists with versions for both parents and youth aged 12 to 16. An adolescent was classified with the disorders in table 1 on the basis of one (i.e., parent or youth self-report) or both (parent and youth self-report) scale scores reaching or exceeding prespecified thresholds. Adolescents had to have scale scores below threshold on both assessments (i.e., parent and youth self-report) to be classified as not having a disorder. Although our classifications should not be confused with clinical diagnoses, earlier evaluation of our methods of classification in a general population sample indicated that they provided a good

**TABLE 1. Definition of Questionnaire Variables and Test-Retest Reliabilities of Measurement in a Study of Substance Use in Late Adolescence**

| Respondent Variable[a] | Description | Test-Retest Reliability[b] % Agreement | Test-Retest Reliability[b] Kappa |
|---|---|---|---|
| Adolescent substance use in 1983 and 1987[c] | | | |
| Tobacco | Smoking of cigarettes or cigars every day for a continuous 30-day period or longer | 93 | 0.54 |
| Alcohol | Consumption of alcoholic beverages at least once a week for a continuous 4-week period or longer, and intoxication or consumption of at least two drinks on at least one of those occasions | 91 | 0.63 |
| Marijuana | Any use of marijuana or hashish | 99 | 0.91 |
| Hard drugs | Any use of amphetamines, stimulants, barbiturates, sedatives, tranquilizers, hallucinogens, psychodelics, heroin, or opiates | 97 | 0.72 |
| Psychiatric disorder in 1983[d] | | | |
| Conduct disorder | Physical violence against persons or property and violation of social norms | 96 | 0.71 |
| Attention deficit disorder | Inattention, impulsivity, and motor overactivity | 91 | 0.34 |
| Emotional disorder | Feelings of anxiety and depression | 93 | 0.56 |

[a] All variables refer to the 6-month period before data collection.

[b] 1- to 3-month test-retest reliability (N=146).

[c] Adolescent report only.

[d] Adolescent and parent report.

approximation to corresponding clinical diagnoses made by child psychiatrists (7).

Estimates of test-retest reliability over a 1–3-month period were obtained in a more recent study for our measures of both substance use and psychiatric disorder. Table 1 displays percent agreement and coefficient kappa—a chance-corrected measure of agreement (9). Percent agreement exceeded 90 for all measurements. Coefficient kappa exceeded 0.50 for all measurements except attention deficit disorder, which was 0.34. (Details of this recent, unpublished study can be obtained from the authors.)

### *Statistical Analyses*

The relationship between patterns of substance use in early versus late adolescence was evaluated descriptively in a contingency table by characterizing changes in the pattern of use from 1983 to 1987. Substance use in 1983 was defined by using a 4-point cumulative scale (Guttman scale) that had the following categories: 1) no substance use, 2) tobacco and/or alcohol used, 3) tobacco and/or alcohol used *and* marijuana used, and 4) tobacco and/or alcohol used *and* marijuana used *and* hard drugs used. Substance use in 1987 was defined in precisely the same way. Only those adolescents whose responses conformed to a true cumulative scale in both 1983 and 1987 were included in this analysis.

Strength of association between psychiatric disorder in early adolescence (1983) and substance use in late adolescence (1987) was evaluated by using relative odds. Relative odds index the likelihood of an outcome in the presence compared to the absence of a predictor variable and were computed from logistic regression analyses. Only the independent contribution of each predictor variable is estimated by the relative odds in a logistic regression—the procedure makes statistical adjustments for all other predictor variables in the model. One logistic regression model was specified for each type of substance used in 1987: tobacco, alcohol, marijuana, and hard drugs. The following variables were defined as present or absent and were included in each logistic regression model: male child, use of same substance in 1983, conduct disorder, attention deficit disorder, and emotional disorder.

The psychiatric disorders that exhibited statistically significant relationships with substance use in the logistic regression analyses were retained for stratified analyses. These were done to assess the relative importance of disorder for assessing prognosis (usefulness in predicting the continuation of substance use) versus risk (usefulness in predicting the initiation of substance use). Psychiatric disorders that predicted initiation of substance use in 1987 (among nonsubstance users in 1983) were examined from the perspective of attributable risk. Attributable risk quantifies the expected contribution of an exposure to the development of new cases and is a measure of the maximum percent reduction in new cases (new substance users in the present context) that could be expected by eliminating the effects of exposure (disorder in the present context). Attributable risk is a function of strength of association—quantified here by the prevalence ratio (PR): percent of new substance users among exposed divided by the percent of new substance users among nonexposed, and the proportion of individuals exposed (p). The formula for the calculation is $[p\ (PR-1)] \div [p\ (PR-1) + 1]$.

## RESULTS

Table 2 shows the prevalences by sex for the variables used in the analyses. There were no differences between males and females in reported substance use except in

**TABLE 2. Prevalence of Substance Use and Psychiatric Disorder Among 726 Adolescents by Sex**

| Year and Characteristic | Males (N=369) |  | Females (N=357) |  |
|---|---|---|---|---|
|  | N | % | N | % |
| 1983 |  |  |  |  |
| Substance use |  |  |  |  |
| Tobacco, regular use | 33 | 8.9 | 36 | 10.1 |
| Alcohol, regular use | 26 | 7.0 | 18 | 5.0 |
| Marijuana | 27 | 7.3 | 27 | 7.6 |
| Hard drugs | 13 | 3.5 | 16 | 4.4 |
| Psychiatric disorder |  |  |  |  |
| Conduct disorder | 33 | 8.9[a] | 7 | 2.0 |
| Attention deficit disorder | 28 | 7.6[b] | 10 | 2.8 |
| Emotional disorder | 12 | 3.3 | 40 | 11.2[c] |
| 1987 substance use |  |  |  |  |
| Tobacco, regular use | 87 | 23.6 | 114 | 31.9[d] |
| Alcohol, regular use | 145 | 39.3 | 127 | 35.6 |
| Marijuana | 84 | 22.8 | 69 | 19.3 |
| Hard drugs | 33 | 8.9 | 39 | 10.9 |

[a] $\chi^2=16.99$, df=1, $p<0.001$.
[b] $\chi^2=8.38$, df=1, $p<0.01$.
[c] $\chi^2=17.26$, df=1, $p<0.001$.
[d] $\chi^2=6.33$, df=1, $p<0.05$.

1987, when more females (31.9%) than males (23.6%) reported tobacco use. In 1983, there were differences between males and females in the prevalences of psychiatric disorder. Males were classified more frequently with conduct disorder and attention deficit disorder, while females were classified more frequently with emotional disorder.

Table 3 shows the relationship between patterns of substance use in early versus late adolescence. Almost half of the adolescents who reported no substance use in 1983 were using substances in 1987. Among adolescents who reported use of tobacco and/or alcohol in 1983, only 18.9% reported no substance use in 1987, while 37.7% (22.6% plus 15.1%) reported use of substances at higher levels. Among adolescents who reported use of tobacco and/or alcohol and marijuana, 27.8% reported substance use at the same level in 1983, while the same percentage reported substance use at a higher level. Finally, among adolescents engaged in the use of all substances in 1983, 47.1% reported continued use at the same level.

The strength of association between sex, prior use of the same substance, and psychiatric disorder in 1983 and substance use in 1987 is quantified in table 4 by using relative odds. Being male was inversely related to tobacco use. Prior use of the same substance was related to subsequent use in all instances. Conduct disorder was associated with use of marijuana and hard drugs (relative odds=3.46 and 6.82, respectively) but not with use of tobacco and alcohol. The relative odds between attention deficit disorder and substance use and emotional disorder and substance use were all small (0.74 to 1.63) and statistically nonsignificant.

Table 5 shows the results of stratified analyses that examined the relative contributions made by assessments of conduct disorder in 1983 to predicting the continuation of (prognosis) and initiation into (risk) substance use in 1987. The data show that the predictive value (strength of association) between conduct disorder and use of marijuana in late adolescence was similar whether conduct disorder is used as a prognostic (prevalence ratio=2.00) or risk (prevalence ratio=2.20) indicator. The predictive value of conduct disorder was higher for use of hard drugs in late adolescence. If one assumes that conduct disorder is causal for initiation into use of marijuana and hard drugs, the attributable risk estimates suggest that reductions in the use of these substances of 5.7% (marijuana) to 11.1% (hard drugs) could be expected by effectively treating (removing the effects of) conduct disorder early on.

## DISCUSSION

Data from our research indicate that the transition from early to late adolescence in a cohort of 12–16-year-olds is marked by dramatic increases in the use of licit and illicit drugs. Although 87% (N=582 of 670) of 12–16-year-olds reported no substance use in 1983, only 54.3% of them reported no substance use 4 years later (table 3). The majority of adolescents who report early substance use will continue use in late adolescence. In particular, use of tobacco in early adolescence was a strong predictor of later use, with the relative odds in logistic regression reaching 11.01 (table 4).

Although prior use of the same substance is the strongest predictor of subsequent use, our data indicate that conduct disorder among 12–16-year-olds makes an independent contribution to predicting subsequent use of marijuana and hard drugs even after prior use of these substances and other psychiatric disorders is controlled. The predictive value of conduct disorder for subsequent use of marijuana and hard drugs is not unexpected. It confirms part of our earlier cross-sectional results in which conduct disorder was associated strongly with all categories of substance use (5) and is consistent with analyses based on both cross-sectional and prospective data that implicate behavioral deviance, delinquency, vandalism, aggression, and hostility in adolescent substance use in the general population (10–12). Although conduct disorder early on is associated with later use of marijuana and hard drugs, the reduction in substance use that might arise from effective treatment of early conduct disorder is limited. Our data indicate that the maximum reductions in use of these substances would be 5.7% (marijuana) and 11.1% (hard drugs). These reductions would only be realized if conduct disorder was causal for later substance use and the effects of exposure to conduct disorder were removed entirely by treatment. The size of attributable risk is constrained numerically by strength of association (relative risk) and frequency of exposure. In the present study, the frequencies of exposure to conduct disorder in 1983 among those not using marijuana or hard drugs (0.05 and 0.05, table 5) were relatively low; and the strengths of association between conduct

disorder and use of marijuana and hard drugs were modest.

There is little evidence to indicate that attention deficit disorder will predict substance use when adjustments are made for overlapping conduct disorder (2, 5). It is noteworthy that a follow-up study of nonreferred children identified in the community as hyperactive and control subjects reported no differences of consequence in frequency of substance use at follow-up (13).

Our finding that the presence of emotional disorder at ages 12 to 16 does not predict substance use at ages 16 to 20 is unexpected in view of our earlier cross-sectional findings that saw a doubling or more of risk for substance use in adolescents classified with emotional disorder (5) and in view of other studies that reported excess prevalence of drug use in young adults who met criteria for depressive or anxiety disorders (3, 4). Differences in study methodology may explain the discrepancy. Our analyses here are based on data collected from a young cohort, prospectively, at two time points 4 years apart. Analyses from our previous study (5) were based on cross-sectional assessments of the same cohort, while analyses from the other two studies (3, 4) were based on retrospective reports collected from young adults. Data collected cross-sectionally and retrospectively are subject to more biases than data collected prospectively (14), and these could lead to inflated estimates of association. It is also possible that our measures of emotional disorder and substance use, being less detailed than the other two studies (3, 4), led to attenuations in strength of association. The value of emotional disorder in early adolescence (or more specifically defined depressive and anxiety disorders) for predicting substance use in the general population requires further study. It will be important in such studies to include measures of conduct disorder because of its strong relationship to substance use and potential to act as a confounder in the analyses.

The central issues in prospective studies focus on the adequacy of sampling design, participation, and measurement. Despite a powerful sampling design and high participation in 1983, 39.6% (N=476 of 1,202) of the sample was lost to follow-up in 1987. The contributing factors to sample loss in 1987 were inability to locate respondents, refusals among those found, and missing data in the responses given by those agreeing to participate. To evaluate this loss, respondents and nonrespondents in 1987 were stratified by conduct disorder (present versus absent) and use of marijuana and/or hard drugs (present versus absent) in 1983 (a total of four strata), and respondents were weighted to compensate for differential exclusions across the strata. (Details of the methodology are available elsewhere [15].) The attributable risks in table 5 were recomputed by using the weights applied to respondents to compensate for sample loss. The differences between the observed estimates in table 5 and the weighted estimates were minor. The observed versus weighted attributable risks for marijuana were 5.7% and 5.9%, and for use of hard drugs they were 11.1% and 12.5%. The higher weighted estimates suggest that sample loss has led to some weakening of the associations (conservative estimates).

The adequacy of our measures also deserves comment. Our classifications of psychiatric disorder are less detailed and specific than the structured interviews that are becoming available for epidemiologic research. Despite the lack of detail, it is noteworthy that our classi-

[a] Proportion in the group classified with conduct disorder in 1983.

fications of disorder achieve levels of (test-retest) reliability commensurate with or better than available structured interviews (16). Our measures of adolescent substance use also achieved acceptable reliability. Although there is no way to be sure that our adolescent respondents reported the truth about their substance use, precautions were taken to ensure confidentiality of the youth self-report, which we believe increased the likelihood of receiving accurate information.

Longitudinal or prospective studies offer two important advantages over cross-sectional surveys in studying the origins of adolescent substance use: they provide an opportunity to evaluate chronology in the relationships among variables, and they eliminate the problem of retrospective assessments that can be distorted by problems of recall and current circumstances. Results from our analyses are clear: 1) early substance use is a strong predictor of later substance use, regardless of type, 2) conduct disorder predicts use of marijuana and hard drugs even when statistical adjustments are made for prior use of these substances and coexisting attention deficit and emotional disorders, and 3) the potential for preventing substance use in late adolescence by treating conduct disorder early on is limited.

The strong relationship that we have observed between conduct disorder and substance use suggests that future research on the predictors of adolescent substance use should include measures of this disorder in their design. In addition, the effectiveness of mental health interventions with children and adolescents, particularly studies of conduct disorder, should be careful to include adequate measures of substance use even if these behaviors are not the object of interventions. Unfortunately, we cannot be too optimistic about the prospects of preventing substance use by treating conduct disorder in childhood. In the first place, we have not identified effective interventions with conduct disorder, although the search for them should be a priority (17, 18) and some promising treatments do exist (19). Second, even if effective treatment of conduct disorder is developed, the potential for preventing use of marijuana and hard drugs in late adolescence by treating children with conduct disorder is limited.

## New Policy Regarding Letters to the Editor

Effective immediately, Letters to the Editor critical of an article published in the *Journal* must be received within 6 weeks of the article's publication; Letters from outside the United States must be received within 12 weeks. Letters received after the deadline will not be considered and will be returned unreviewed.

# A Note on Racial Bias in the Admission of Children and Adolescents to State Mental Health Facilities Versus Correctional Facilities in New York

Stuart L. Kaplan, M.D., and Joan Busner, Ph.D.

Objective: *In response to several studies suggesting that there is racial bias in the admission of proportionately more white children and adolescents to the child and adolescent mental health system than to the juvenile justice system, the authors tested whether white children and adolescents would be overrepresented compared with black children and adolescents in mental health facilities and underrepresented compared with black children and adolescents in juvenile correctional facilities when ethnic distribution in the general population was controlled.* Method: *Ethnicity, age, and sex of all white, black, and Hispanic 10–18-year-olds admitted in a 1-year period to facilities of the Office of Mental Health and facilities of the correctional system (the Division for Youth) of New York State were converted into rates per 100,000 population by using U.S. census data for the state. Admission rates per 100,000 population for ethnicity, age, sex, and source of referral were then compared in the two types of facilities.* Results: *There were no meaningful differences in population-corrected admission rates among black, white, and Hispanic children and adolescents in the state mental health system. In contrast, there was a vast preponderance of black children and adolescents admitted to the state juvenile correctional system. The systems have different points of entry: 100% of the juvenile justice admissions versus 17% of the mental health admissions were referred by the courts.* Conclusions: *Analysis of demographic variables failed to support an allegation of racial bias in admission to the child and adolescent public mental health system in New York State.*

(Am J Psychiatry 1992; 149:768–772)

Lewis et al. (1, 2) concluded in two studies that racial bias on the part of the mental health system leads to the incarceration of black children and adolescents in juvenile offender facilities while white children and adolescents with similar symptoms are more likely to be hospitalized in psychiatric facilities. These studies have been influential (3). The methodology used in the first study consisted of clinical reports of incarcerated black delinquents with serious, unrecognized psychopathology (1). In the second study, which was data based, the proportion of black admissions to a juvenile correctional institution (67%) was significantly greater than the proportion of black admissions to a neighboring state mental health facility (29%) (2). In a series of multiple regression and discriminant function analyses, with psychiatric hospitalization or incarceration in a correctional facility as the dependent variables, race explained over 17% of the variance of admission to a correctional institution or mental health facility.

An additional study using a similar methodology by Westendorp et al. (4) lent support to the conclusions of Lewis et al. In Michigan, Westendorp et al. compared psychiatrically hospitalized adolescents at admission with incarcerated adolescents at admission on a number of measures and found that ethnicity and gender accounted for a substantial proportion of the variance in a discriminant function analysis. The proportion of black adolescents entering the juvenile justice system (36%) was significantly greater than the proportion of black adolescents entering the mental health system (4.5%).

To assess the degree to which racial bias might be operating in the New York State Office of Mental Health

system, we gathered data by age, race, and sex on the inpatient population of the New York State Office of Mental Health children's psychiatric facilities and on inmates of the New York State juvenile justice system.

We hypothesized that black children and adolescents would be underrepresented compared with white children and adolescents in the mental health facilities and overrepresented compared with white children and adolescents in the juvenile correctional facilities when ethnic distribution in the general population was controlled. We also examined the relationships among age, sex, and ethnicity by institutional setting.

The methodology of our study with regard to ethnicity differed from that of the studies cited, which did not correct for the distribution of demographic variables in the general population. In contrast, we used U.S. census data to correct our results for the distribution of the demographic variables in the general population. In addition, we used an adequate sample size that included all admissions of children and adolescents to state psychiatric hospitals and correctional facilities over a 1-year period in an entire state.

Furthermore, our study focused on racial distribution within each system of care rather than comparing racial distribution between the two systems of care. Lewis et al. (1, 2) and Westendorp et al. (4) compared the racial distribution of mental health versus correctional systems. We hypothesized that the two systems of care are relatively independent and believed, therefore, that the relevant comparison groups were within the systems of care rather than between the systems of care. We tested the independence of the two systems by examining sources of admission to mental health and correctional facilities.

## METHOD

### *Settings*

The New York State Office of Mental Health operates six freestanding child psychiatric hospitals and nine psychiatric units for children and adolescents within New York State adult psychiatric hospitals. There are 731 psychiatric beds for children and adolescents operated under state auspices in New York. The beds are intended to provide longer-term psychiatric hospitalization for the more seriously emotionally disturbed children in the state. In addition, they often serve psychiatrically disturbed children whose needs cannot be met by social service agencies, county mental health agencies, or the private sector. They are most often used by the less affluent and less privileged.

The New York State Division for Youth, the juvenile correctional system, has 1,788 beds for children and adolescents between the ages of 8 and 18. Admission to Division for Youth facilities requires a hearing before a family court judge; the child or adolescent must be found guilty of violating the law and sentenced. There are several levels of restrictiveness in Division for Youth settings, ranging from open group home settings to locked, guarded, secure care settings.

### *Procedure*

To study differences in race, age, and sex distribution patterns in the facilities of the Office of Mental Health and the Division for Youth, we used the state's computerized databases to obtain the race, age, and sex of all 10–18-year-old white, black, and Hispanic children and adolescents admitted statewide in 1988 to inpatient Office of Mental Health facilities and to residential Division for Youth facilities. We did not include more than one admission of the same individual during the 1988 period; therefore, we have an unduplicated count.

To control for the distribution of ethnic categories in the general population, we obtained the distribution of ethnic categories by age and sex for New York State documented in the 1980 U.S. Census. The 1988 admission numbers for the Office of Mental Health and the Division for Youth were divided by the 1980 New York State population numbers for the respective ethnic category, age, and sex; the quotient was multiplied by 100,000.

## RESULTS

Before correcting for population rates, we found that 910 (62%) of the 1,474 Office of Mental Health admissions of children and adolescents 10–18 years old were white and only 341 (23%) were black; in contrast, 780 (56%) of the 1,405 Division for Youth admissions were black and only 389 (28%) were white. These ethnic proportions are in agreement with those of the earlier studies cited.

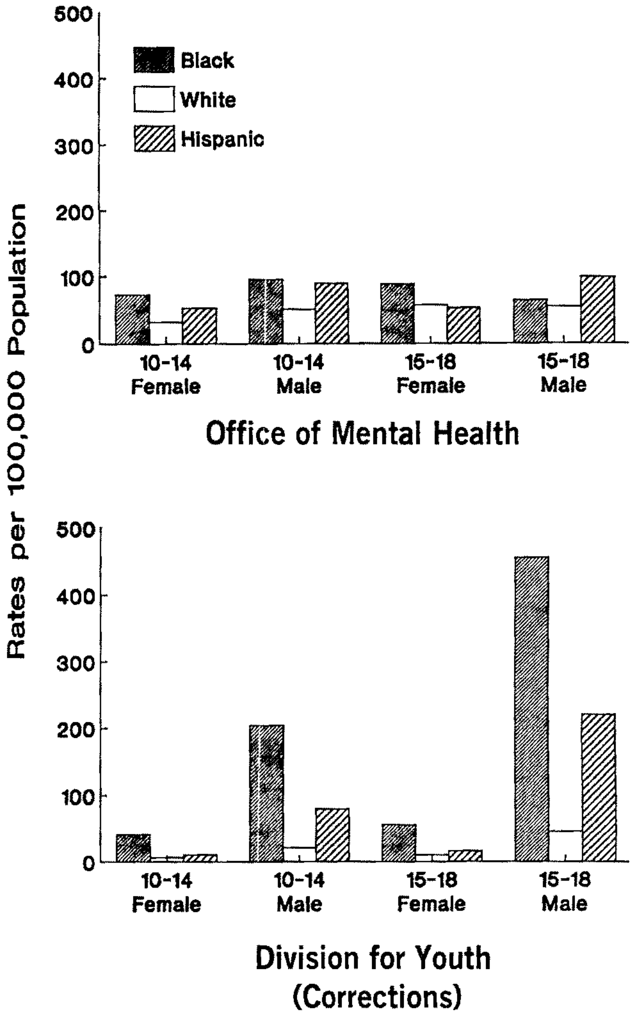
Figure 1 presents the data in rates per 100,000 population for each ethnic group, age, and sex. As shown, when corrected for population rates, there are large racial differences in Division for Youth facilities and only modest differences in Office of Mental Health facilities.

Twofold or greater differences in population-corrected admission rates are considered meaningful. As shown, when corrected for population distribution for age and sex, only the proportion of black to white 10–14-year-old girls admitted to Office of Mental Health facilities was greater than twofold. In contrast, for Division for Youth facilities, there were large ethnic differences at every age and sex category: there were seven times more black than white 10–14-year-old girls, over nine times more black than white 10–14-year-old boys, over five times more black than white 15–18-year-old girls, and over nine times more black than white 15–18-year-old boys.

When ethnic distribution in Office of Mental Health facilities was compared statistically with ethnic distribution in the general population by using goodness-of-fit chi-square analyses, there was a significant difference at each age and sex category: black children and adolescents were proportionately overrepresented compared with white children and adolescents. The same was true when ethnic distribution in Division for Youth facilities was compared with ethnic distribution in the general population (for 10–14-year-old girls, 10–14-year-old boys, 15–18-year-old girls, and 15–18-year-old boys, $\chi^2=39.0$, $\chi^2=41.6$, $\chi^2=14.6$, and $\chi^2=19.6$ for Office of Mental Health facilities and $\chi^2=99.2$, $\chi^2=553.2$, $\chi^2=98.3$, and $\chi^2=1156.8$ for Division for Youth facilities, respectively, df=2, $p<0.0001$ for all). Source of admission to the two agencies was examined. In 1988, all 1,405 of the black, white, and Hispanic 10–18-year-olds admitted to Division for Youth facilities came from the courts. In 1988, 246 (17%) of the 1,474 black, white, and Hispanic 10–18-year-olds admitted to Office of Mental Health facilities came from the courts. When we examined the ethnic distribution of the court admissions to Office of Mental Health facilities we found that 54 (22%) of the children were black, 163 (66%) were white, and 29 (12%) were Hispanic. This was significantly different from the ethnic distribution in the general population: there was a higher than expected proportion of black children and adolescents ($\chi^2=6.9$, df=2, $p<0.05$).

We also examined patient movement between agencies. In 1988 only 12 (0.8%) of the 1,474 children and adolescents admitted to Office of Mental Health facilities came from Division for Youth facilities. The racial breakdown of these youngsters (three [25%] were white, three [25%] were black, and six [50%] were Hispanic) significantly differs from that in the general population: white children and adolescents were significantly underrepresented ($\chi^2=19.3$, df=2, $p<0.0001$). None of the 1,405 youngsters admitted to Division for Youth facilities came from Office of Mental Health facilities.

FIGURE 1. Population-Corrected Comparisons of Ethnicity, Age, and Sex of Children and Adolescents Admitted to New York State Office of Mental Health and New York State Division for Youth Facilities in 1988



## DISCUSSION

That there were few meaningful differences between white and other ethnic categories in population-corrected admission rates in the New York State Office of Mental Health system for children and adolescents does not seem to support an allegation of racial bias for admission to this system. The conclusion that there is an apparent absence of racial bias in this mental health system depends on our understanding of the Office of Mental Health and the Division for Youth as independent. The excess of black children and adolescents in Division for Youth facilities compared with Office of Mental Health facilities is consistent with the findings of Lewis et al. (1, 2), although Westendorp et al. (4) found fewer black than white adolescents in correctional facilities. Had we analyzed our data as these authors did, our results would have been similar to theirs. Both Lewis et al. and Westendorp et al. compared ethnic categories between mental health and correctional facilities and concluded that black children and adolescents were overrepresented in correctional facilities and underrepresented in mental health facilities. In our data set, if we had considered the Division for Youth and Office of Mental Health systems as interrelated and had assumed that both systems provide care for similarly disordered children, we too would have concluded that black children were discriminated against by incarceration in Division for Youth facilities rather than admission to Office of Mental Health facilities. Our decision to examine data within each system rather than comparing data between the systems was based on our understanding that the two systems are largely independent.

For the most part, the juvenile correctional system and the mental health system in New York State have different points of entry. Children and adolescents enter the juvenile justice system exclusively through the courts. In contrast, children and adolescents enter the state mental health system from a variety of referral sources: private hospitals, school systems, and parental referral. Only in a modest percentage of cases (17%)

are youngsters referred by the courts to the mental health system. No children or adolescents were referred to the juvenile correctional system from the mental health system in 1988, and 0.8% were referred from the juvenile correctional system to the mental health system in 1988.

Because the two systems are largely independent, it seems appropriate to look for evidence of racial bias in mental health by examining the racial distribution within the mental health system. We found no statistical evidence of overrepresentation of white children and adolescents in the Office of Mental Health system. On the contrary, the results of the chi-square tests we computed suggest that black and Hispanic children and adolescents are admitted to Office of Mental Health facilities in excess of their distribution in the population. Because there are different points of entry to the mental health and juvenile justice systems, the entry of a disproportionate number of black children and adolescents to the juvenile justice system does not imply racial bias on the part of the mental health system.

To demonstrate an absence of racial bias in admissions to the Office of Mental Health system, many issues would have to be studied beyond the corrected rates of ethnic categories of individuals admitted to its facilities. Snowden and Cheung (5), in a discussion of the admission of adult ethnic minority groups to inpatient psychiatric care, discussed several variables related to the admission of adult psychiatric patients to psychiatric hospitals. These variables include the prevalence of psychiatric disorders in minority groups, the intensity of psychiatric symptoms in minority groups, help-seeking behaviors in minority groups, and gatekeepers' behavior. There is little knowledge of these matters with regard to child mental health.

In contrast to the Office of Mental Health, there was a dramatic preponderance of admissions of black compared with white children and adolescents in the Division for Youth population far beyond the distribution of black children and adolescents in the general population. The population-corrected ratio for black to white admissions to this system was almost 7:1. Reviewing the literature of official delinquency statistics indicates an approximate ratio of almost three black adolescents to one white adolescent (6, 7). The excess of blacks to whites in official delinquency statistics is the subject of considerable controversy in the sociology and penology literature as well as considerable sensitivity among the general public. There is no agreed upon explanation for these figures (8–12).

Our finding that there were more than twice as many incarcerations in the 15–18-year age range than in the 10–14-year age range corresponds roughly to the findings of many other studies on the prevalence of delinquency and age. In general, the studies support the idea that children who are delinquents at age 13 remain delinquent through age 18 and that the number of delinquents increases with age during adolescence. After age 18 or in early adulthood there is a decline in the number of delinquents or antisocial young adults (13–15). In addition, the disproportionate number of boys compared with girls admitted to Division for Youth facilities is consistent with the universal finding that male delinquents outnumber female delinquents. Although the ratio of male-to-female incarcerations in our data was 6.5:1, more sophisticated studies have found the ratio of male-to-female delinquents to range from 5:1 to 2:1 depending on the type of offense (16–18).

A separate but related issue to bias in admission to juvenile correctional institutions compared with mental health institutions is the prevalence of psychopathology in correctional facilities. Several studies have attempted to study the prevalence, severity, and type of pathology in juvenile correctional facilities (19–22). It seems clear that psychopathology is prevalent in such institutions, but, in New York State at least, because the two systems of care have different points of entry, this does not mean that the mental health system per se is racially biased.

Controlling for ethnic, age, and sex distribution in the general population and considering the degree of independence of the mental health and correctional systems allowed us to more adequately describe racial patterns of service utilization in the two systems of care.

*Objective: Vitamin E (α-tocopherol), a free-radical scavenger, has been reported to improve symptoms of tardive dyskinesia. The authors attempted to replicate this finding under more controlled conditions in a larger study group. Method: Fifteen inpatients and six outpatients with tardive dyskinesia received up to 1600 IU/day of vitamin E for 6 weeks in a double-blind, placebo-controlled crossover study. Abnormal Involuntary Movement Scale (AIMS) examinations of these patients were videotaped and rated independently by two trained raters. Levels of neuroleptic medication and vitamin E were measured during both treatment periods. Eighteen patients who demonstrated high blood levels of vitamin E were included in the data analysis. Results: Vitamin E levels were significantly higher while the patients were receiving vitamin E than while they were receiving placebo. For all 18 patients, there were no significant differences between AIMS scores after receiving vitamin E and AIMS scores after receiving placebo. In agreement with previous studies, however, the nine patients who had had tardive dyskinesia for 5 years or less had significantly lower AIMS scores after receiving vitamin E than after receiving placebo. There were no changes in neuroleptic levels during vitamin E treatment. Conclusions: Vitamin E had a minor beneficial effect on tardive dyskinesia ratings in a selected group of patients who had had tardive dyskinesia for 5 years or less. This effect was not due to an increase in blood levels of neuroleptic medications.*

(Am J Psychiatry 1992; 149:773–777)

Tardive dyskinesia is a movement disorder affecting up to 20% of patients treated chronically with neuroleptic agents (1, 2). A number of medications have been tried as therapies for tardive dyskinesia, but results have been mostly disappointing (3). Thus, tardive dyskinesia continues to be an important complication in the treatment of psychosis.

It has been proposed that tardive dyskinesia is due to neuroleptic-induced increases in free-radical production and the subsequent adverse effects of these free radicals on neuronal function (4). Long-term treatment with neuroleptic medication may result in a prolonged increase in dopamine turnover (5) and release (6). Dopamine is cytotoxic to some cell lines (7), an effect that may be mediated by free radicals (8–10). These highly reactive agents can produce membrane destabilization and protein oxidation (11). If the free-radical hypothesis is correct, antioxidants such as α-tocopherol (vitamin E) could inactivate these compounds (12) and exert therapeutic effects on tardive dyskinesia.

Two previous studies (13, 14) used high doses of vitamin E to treat patients with tardive dyskinesia and found improvement in up to 62% of patients. These patients had had tardive dyskinesia, on average, for relatively short periods of time (2.6 and 3.8 years, respectively). The larger study (13) found that the patients who improved had had tardive dyskinesia for a significantly shorter period of time than patients who did not improve. This effect of duration of tardive dyskinesia is consistent with a free-radical mechanism of cellular damage (15).

Although these reports are encouraging, replication studies are needed. Initial trials of a variety of other agents (e.g., choline and lecithin) demonstrated therapeutic effects that could not be replicated. The variable results of such trials may be due to methodological problems inherent in studies of tardive dyskinesia (16), including changes in neuroleptic blood levels, poor interrater reliability over time, stress-induced changes in severity of tardive dyskinesia, and natural fluctuations in the severity of tardive dyskinesia.

In this study, we attempted to control for some of these methodological problems. We administered up to 1600 IU of vitamin E to 21 patients using a double-blind, placebo-controlled, crossover design. Most of the

subjects in the study (N=15) were inpatients for whom medication compliance was assured and extraneous stressors were relatively limited. All examinations of severity of tardive dyskinesia were videotaped and rated blindly at the conclusion of the study. To exclude the possibility that vitamin E reduces tardive dyskinesia simply by increasing neuroleptic levels, these levels were also monitored.

## METHOD

### *Patients*

Subjects were recruited from the inpatient wards and the outpatient clinic of an NIMH hospital and from a brief admissions program at a Veterans Administration (VA) hospital. The inclusion criteria were a diagnosis of tardive dyskinesia (17) for at least 6 months, age between 18 and 75 years, and the absence of serious medical or neurological illnesses. Candidates were excluded if there was evidence of substance or alcohol abuse within the previous 6 months. Patients were screened with a physical and neurological examination, routine blood and urine tests, electroencephalograms, and magnetic resonance imaging or computerized tomographic brain scans. Those with a family history of Huntington's disease were excluded.

Twenty-one candidates met these criteria and gave written informed consent. Their ratings of tardive dyskinesia severity (on the Abnormal Involuntary Movement Scale [AIMS] [18]) had been stable for at least 4 weeks before they entered the study. Psychiatric diagnoses were determined by Board-certified psychiatrists using *DSM-III-R* criteria. Demographic data, including duration of tardive dyskinesia, were gathered through personal interviews and chart reviews.

Patients were maintained on a constant, fixed oral dose of medication for at least 6 weeks before and during the study. One patient had received a long-acting injectable neuroleptic 6 weeks before entering the study and a second patient 10 weeks before entering the study; the remaining 19 patients had not received depot neuroleptics for at least 6 months.

### *Study Design*

Patients were assigned randomly to receive either vitamin E (10 patients) or placebo (11 patients) for the first 6 weeks of the 12-week, double-blind, crossover study. All patients took one 400-mg capsule four times daily. Vitamin E was administered according to the following schedule: 400 IU/day for week 1, 800 IU/day for week 2, 1200 IU/day for week 3, and 1600 IU/day for weeks 4–6. NIMH inpatients were rated weekly, and outpatients were seen at the beginning of the study and twice during each 6-week phase, for a total of 12 and five ratings, respectively.

Blood levels of medications were monitored at baseline and every 3 weeks. Vitamin E levels were measured by using fluorometry (Metpath Laboratories, Rockville, Md.). This method has a coefficient of variation of 10% (19). Levels of other medications were measured either by high-performance liquid chromatography or gas chromatography with ultraviolet electrodes (20, details available on request) when confounding peaks were present. The coefficients of variation for measurements of these medications ranged from 2.5% to 20%. The following tests were also performed every 3 weeks to monitor for adverse effects: prothrombin time, creatinine, creatine phosphokinase, thyroid indexes, cholesterol, and triglycerides.

### *Ratings*

Tardive dyskinesia was assessed by using a modified form of the AIMS rating scale (21). This modified form used separate ratings for choreoathetosis and dystonia. Separate ratings were also made for both left and right upper and lower extremities. Severity of movements was rated on a scale from 0 to 4 on which 0=no abnormal movements, 1=minimal abnormal movements that may be extremes of normal, 2=clearly abnormal movements, and 3 and 4=increasing severity and duration of movements. Seven body regions (described in the standard AIMS [18]) were rated for both choreoathetosis and dystonia. Two scores (right and left side) were given for the regions of upper and lower extremities. Thus, the highest possible total score for each type of movement was 36. The highest possible overall score was 72. Unlike the standard AIMS rating procedure, a point for severity was not subtracted if movements were greater with activation.

The standard AIMS examination (18) was performed during sessions that lasted approximately 5 minutes. All examinations were videotaped in the same room and at the same time of day each week. Most of the patients were also rated repeatedly for at least 4 weeks before entering the study to become familiar with videotaping. Meetings for establishing reliability were held every 1–3 weeks over the entire 3-year study period. All raters were blind to treatment with either placebo or vitamin E. At the completion of the study, videotaped AIMS examinations were reviewed by two blind raters. For these ratings, the intraclass correlation coefficient (ICC) (22) for total AIMS scores, based on 25 randomly selected ratings, was $r=0.82$ ($p=0.002$). Only AIMS scores of videotaped examinations were used for statistical analysis, except for one patient who refused to be videotaped. Live ratings were substituted for videotaped scores for this patient.

The patients' psychiatric status was assessed by using the Psychiatric Symptom Assessment Scale (23) and the Negative Symptom Rating Scale (24). These live ratings were performed the week before the patient entered the study (baseline) and again at the end of each 6-week treatment period by two trained raters. Using the ICC, we found that interrater reliability for the Psychiatric Symptom Assessment Scale was 0.72 ($p=0.002$) and for the Negative Symptom Rating Scale was $r=0.87$ ($p<0.001$).

### *Statistics*

Total AIMS scores from the end of the placebo and vitamin E phases were compared by using a one-tailed paired t test to test the hypothesis that vitamin E produced improvement. Total scores were derived by adding scores from all body areas for both choreoathetosis and dystonia. The patient group was divided in half on the basis of duration of tardive dyskinesia, and a separate comparison was performed on the half with the shorter duration (5 years or less). The duration of tardive dyskinesia of this group was similar to that of groups used in two previous studies of vitamin E (13, 14). A one-tailed paired t test was also used to compare the effect of vitamin E with that of placebo for this group. For these two comparisons, a p value of 0.025 was accepted as the criterion for statistical significance. These two comparisons tested the primary hypothesis of the study and were based on previous findings of improvement in subjects with shorter duration of tardive dyskinesia (15).

The possibility of a carryover or an order effect was tested by using Wilks's lambda. Additional comparisons of other variables were done by using two-tailed paired (unless otherwise stated) t tests. These included AIMS ratings subdivided by type of movement (choreoathetosis versus dystonia) or location (mouth, cheek, tongue, upper extremities, lower extremities, or trunk), Psychiatric Symptom Assessment Scale and Negative Symptom Rating Scale scores, and neuroleptic and other drug levels. Because a number of comparisons were made, a p value of 0.005 was accepted as significant for these additional tests. Pearson's correlation coefficients were used to determine apparent associations between patient variables and improvement with vitamin E. For a measure of improvement with vitamin E, AIMS scores after vitamin E were subtracted from AIMS scores after placebo.

## RESULTS

Fifteen subjects were inpatients and one was an outpatient at the NIMH hospital and clinic. Five were outpatients at the VA hospital. Three patients were not included in the data analysis: one dropped out and two had inconsistent vitamin E blood levels. No adverse effects were noted.

The diagnoses of the 18 subjects included in the final analysis are given in table 1. Six patients had a previous diagnosis of substance or alcohol abuse. The patients' mean age was 43.9 years (SD=2.8), and the mean duration of tardive dyskinesia was 5.9 years (SD=4.8). The mean total dystonia score was 5.5 (SD=0.5) at baseline, and the mean choreoathetosis score was 10.2 (SD=4.1). The mean overall severity score (item 8 on the AIMS) was 2.6 (SD=0.8) out of a possible 4. The 15 patients on neuroleptics were receiving an average dose of 1946 mg/day (chlorpromazine equivalents) (25, 26); three of these patients were receiving molindone (mean dose=4304 mg/day [chlorpromazine equivalents]) and 12 were receiving other agents (mean dose=1120 mg/day [chlorpromazine equivalents]). The mean neuroleptic levels of the 15 patients were 433 ng/ml (SD=822) (chlorpromazine equivalents) at baseline, 388 ng/ml (SD=670) while taking vitamin E, and 246 ng/ml (SD=258) while taking placebo. Other medications are listed in table 1. Doses of all medications were held constant.

There were no significant differences in blood levels of neuroleptics or other medications between the vitamin E and placebo phases. Furthermore, there were no correlations between neuroleptic levels and total AIMS scores or differences in AIMS scores (total AIMS score while receiving placebo minus total AIMS score while receiving vitamin E). Levels of vitamin E were significantly higher after the 6-week treatment period (35.0 mg/liter, SD=9.9) than at baseline (13.2 mg/liter, SD=3.6) or after placebo administration (13.6 mg/liter, SD=3.6) (paired t=–11.7, df=17, p=0.0001).

For all 18 patients, there were no significant differences between total AIMS scores after receiving vitamin E (mean=16.8, SD=6.5) and after receiving placebo (mean=17.3, SD=6.5) (t=–0.64, df=17, p=0.26). Similar results were found when scores were subdivided by type or location of involuntary movements. There was no main effect of the order of administration of vitamin E or placebo on total AIMS scores (F=0.17, df=1, 17, p=0.68). There was no correlation between improvement while receiving vitamin E and age or severity of tardive dyskinesia. Women demonstrated slightly more improvement than men while receiving vitamin E, but this difference was not significant at the 0.005 level (t=–2.68, df=16, p=0.02, unpaired t test).

To examine the effect of duration of tardive dyskinesia on treatment response, patients were divided in half on the basis of how long they had had tardive dyskinesia. One group had had tardive dyskinesia for more than 5 years and the other had had it for 5 years or less (5-year group). When results from the 5-year group were analyzed separately, the total AIMS scores after vitamin E administration (mean=12.8, SD=7) were 18.5% lower than the ratings after placebo administration (mean=15.7, SD=6.2) (t=–2.54, df=8, p<0.02). For the 5-year group, neither choreoathetotic nor dystonic movements showed significant improvement after vitamin E administration when analyzed separately (t=–2.08, df=8, p=0.06; t=–0.98, df=8, p=0.36, respectively). No significant differences were found with vitamin E treatment when subscores were examined by body region (orobuccolingual versus extremities and trunk). As with the total group, there was no carryover effect for the 5-year group (F=0.03, df=1, 8, p=0.87).

The 5-year group had a markedly shorter mean duration of tardive dyskinesia (2.3 years) than patients who had had tardive dyskinesia for more than 5 years (9.6 years). Both groups had similar elevations in vitamin E levels, and neither had significant changes in neuroleptic or other drug levels during either phase of the study.

**TABLE 1. Clinical Characteristics and Modified AIMS Scores of 18 Patients With Tardive Dyskinesia From Videotaped Ratings During 12-Week Crossover Study of Vitamin E and Placebo**

| Patient | Age (years) | Sex | Diagnosis | Duration of Tardive Dyskinesia (years) | Medications | First Treatment | AIMS Score | |
|---|---|---|---|---|---|---|---|---|
| | | | | | | | After Placebo | After Vitamin E |
| 1 | 55 | M | Schizotypal personality | 20 | None | Placebo | 25.5 | 28.0 |
| 2 | 48 | M | Schizophrenia, undifferentiated | 11 | Haloperidol, benztropine | Placebo | 19.0 | 20.0 |
| 3 | 48 | F | Bipolar disorder | 10 | Lithium, haloperidol, benztropine, carbamazepine | Vitamin E | 23.5 | 14.5 |
| 4 | 27 | M | Schizophrenia, undifferentiated | 9 | Mesoridazine, lithium, diphenhydramine, levothyroxine sodium | Vitamin E | 22.0 | 22.5 |
| 5 | 40 | M | Schizophrenia, paranoid | 9 | Lorazepam | Vitamin E | 23.5 | 31.5 |
| 6 | 33 | F | Schizophrenia, undifferentiated | 8 | Haloperidol, benztropine | Placebo | 17.0 | 22.0 |
| 7 | 42 | M | Schizophrenia, undifferentiated | 7 | Molindone, benztropine | Vitamin E | 7.5 | 10.5 |
| 8[a] | 71 | M | Bipolar disorder | 6 | Perphenazine, lithium, lorazepam | Placebo | 12.5 | 19.5 |
| 9[a] | 61 | M | Depression, psychotic | 6 | Lithium, fluoxetine, enalapril, sulfamethazine | Vitamin E | 25.5 | 20.0 |
| 10 | 64 | F | Schizophrenia, residual | 5 | Haloperidol, amantadine, triazolam, tolazamide | Vitamin E | 25.0 | 15.0 |

[a] Outpatient.
[b] Live AIMS ratings.

There were no significant differences between Psychiatric Symptom Assessment Scale or Negative Symptom Rating Scale scores at the end of vitamin E treatment and after placebo treatment (t=0.55, df=13, p=0.59 and t=0.15, df=13, p=0.88, respectively).

## DISCUSSION

Vitamin E treatment was not effective in the group as a whole in lowering ratings of tardive dyskinesia. In contrast, two earlier reports (13, 14), which included patients with a shorter duration of tardive dyskinesia (averaging 2.6 and 3.8 years, respectively), did find improvement with vitamin E. For a similar comparison, we divided our patients into those with short-term (5 years or less) tardive dyskinesia and those with long-term (more than 5 years) tardive dyskinesia. The short-term group had significantly lower scores while receiving vitamin E than while receiving placebo, consistent with the previous studies. These data suggest that vitamin E may be somewhat effective early in the course of tardive dyskinesia.

The difference between vitamin E and placebo treatments was 18.5% in our short-term group. In comparison, the first controlled study (13) found a 45% improvement. The second report (14), similar to ours, found only a 21% improvement. The greater improvement seen in the first study compared with the latter two could be due to several methodological differences. The first study used live ratings and did not include measures of interrater reliability. The second study used ratings of videotaped examinations, as did our study. Ratings of videotapes may have the advantage of improved interrater reliability. The first study might also have been complicated by changes in neuroleptic doses or compliance problems, issues largely avoided in the present study.

The potential role of vitamin E in treating tardive dyskinesia remains unclear. The relatively minor 18.5%

improvement in the short-term group suggests that vitamin E has little clinical efficacy. Nevertheless, several patients appeared to improve markedly while taking vitamin E, a change not always reflected in AIMS ratings. For example, one patient with severe truncal dystonia was able to walk erect for the first time in 2 years during vitamin E treatment but continued to exhibit marked neck dystonia. His rating for truncal dystonia decreased from severe to moderate (from 4 to 3). This improvement was negated on the AIMS score by a less clinically important increase in choreoathetosis of the fingers. This suggests that even though improvement on vitamin E is not usually dramatic, some patients may show substantial clinical improvement.

It is unclear whether vitamin E, if used for prophylaxis, could prevent the development of tardive dyskinesia. It may be relevant that a large, uncontrolled study using high-dose multivitamin treatment (including vitamin E) together with long-term neuroleptic administration (27) reported a remarkably low incidence of tardive dyskinesia. Additional well-controlled studies are needed to clarify the possible efficacy of vitamin E in preventing tardive dyskinesia.

The therapeutic efficacy of vitamin E, although minor, supports the free-radical hypothesis of tardive dyskinesia. Vitamin E is a potent free-radical scavenger, and symptom improvement may be due to a reduced concentration of free radicals. This implies that free radicals are relevant to the pathogenesis of tardive dyskinesia. Alternatively, vitamin E could work in other ways. For example, it could alter neurotransmission in neurons related to movement, such as dopaminergic or $\gamma$-aminobutyric acid-ergic neurons. Although there are no data to support such highly speculative possibilities, they are alternatives to the antioxidant hypothesis. One potential problem with an antioxidant mechanism of action arises when trying to explain how a reduction in free radicals could improve symptoms caused by preexisting neuronal injury. This, however, is not an unreasonable hypothesis because other basal ganglia disorders can improve after neurotoxic agents are removed. In Wilson's disease, for example, chelation of excess copper both prevents progression and often improves preexisting abnormal movements (28).

In conclusion, the data suggest that vitamin E treatment has a mild beneficial effect in patients who have had tardive dyskinesia for a brief time. Vitamin E's effect did not appear to be due to an increase in serum neuroleptic levels. Although larger replication studies are needed, vitamin E is relatively safe and may be a reasonable treatment alternative in patients with early tardive dyskinesia. Finally, although other possibilities need to be examined, these results offer some support for the free-radical hypothesis of tardive dyskinesia.

# A Crossover Study of Focused Cognitive Therapy for Panic Disorder

Aaron T. Beck, M.D., Leslie Sokol, Ph.D., David A. Clark, Ph.D.,
Robert Berchick, Ph.D., and Fred Wright, Ed.D.

*Objective: This study sought to determine the short- and long-term effects of focused cognitive therapy for panic disorder. Method: Thirty-three psychiatric outpatients with the* DSM-III *diagnosis of panic disorder were randomly assigned to either 12 weeks of individual, focused cognitive therapy or 8 weeks of brief supportive psychotherapy based on principles of client-centered therapy. The patients who received supportive psychotherapy were subsequently given the opportunity to cross over to cognitive therapy for 12 weeks. Patients were rated for panic and depression before therapy, after 4 and 8 weeks of therapy, and at 6-month and 1-year follow-up. Results: Clinician ratings and self-ratings of panic frequency and intensity indicated that the focused cognitive therapy group achieved significantly greater reductions in panic symptoms and general anxiety after 8 weeks of treatment than did the group that received brief supportive psychotherapy. At 8 weeks, 71% of the cognitive therapy group were panic free, compared to 25% of the psychotherapy group. Moreover, 94% of the psychotherapy patients elected to cross over to 12 weeks of cognitive therapy. At 1-year follow-up, 87% of the group that received cognitive therapy only and 79% of the group that crossed over into cognitive therapy remained free of panic attacks. Conclusions: Focused cognitive therapy offers a promising nonpharmacological alternative for the treatment of panic disorder.*

(Am J Psychiatry 1992; 149:778–783)

While the immediate effectiveness of benzodiazepines and imipramine in alleviating panic symptoms has been documented, certain problems, such as patients' resistance to medication, intolerance of side effects, withdrawal symptoms, and high relapse rates (71% to 95%) have also been reported (1–6). Consequently, alternative nonpharmacological approaches are worth exploring.

Behavioral interventions have been somewhat effective in the treatment of panic disorder (7–9). In the past few years, a cognitive approach that focuses on the patient's misinterpretation of bodily sensations or psychological experience as catastrophic has been advanced (10, 11). Treatment is designed to demonstrate to patients how they have misconstrued the "dangerousness" of their symptoms. Two controlled studies (8, 9) have indicated the efficacy of behavioral treatment with cognitive components. In addition, controlled outcome studies have supported the effectiveness of focused cognitive therapy aimed at modifying patients' attributions of the cause of panic-related bodily sensations (12, 13, and unpublished 1991 paper by D.M. Clark).

In a prospective trial, Sokol et al. (13) found that focused cognitive therapy was highly effective in reducing the frequency of panic attacks (from a pretreatment mean of 4.5 panic attacks per week to a posttreatment mean of no attacks per week). These results were maintained over a 1-year follow-up period.

The current study was a replication and extension of the study by Sokol et al. (13) with the addition of 8 weeks of brief supportive psychotherapy as a comparison treatment. This comparative therapy condition, based on Rogers's nondirective therapy (14), was selected to take into account the possibility of spontaneous recovery as well as improvements resulting from contact with a therapist and self-monitoring of panic symptoms. The study contained four components: 1) 8 weeks of focused cognitive therapy compared with 8 weeks of supportive therapy, 2) an additional 4 weeks of cognitive therapy for the experimental group, 3) cross-

over of the patients who received supportive therapy to 12 weeks of cognitive therapy, and 4) 6-month and 1-year posttreatment follow-up for both groups.

## METHOD

Thirty-three subjects between the ages of 18 and 65 years were drawn from outpatients successively entered into therapy at our center. Diagnostic assessment was carried out by trained psychologists using the Structured Clinical Interview for DSM-III (SCID) (15). Patients who met the *DSM-III* criteria for panic disorder (N=27) or agoraphobia with panic attacks (N=6) were invited to participate in the study. Twenty-two patients had secondary axis I diagnoses of major depression or dysthymia, 11 had diagnoses of generalized anxiety, and one had a diagnosis of simple phobia. Nine patients (four who received cognitive therapy only and five who received brief supportive psychotherapy) had axis II diagnoses.

The majority of the patients had longstanding histories of panic disorder (for the whole group, mean=7.2 years, SD=6.8; for the cognitive therapy group, mean=6.2 years, SD=6.1; for the brief psychotherapy group, mean=8.4 years, SD=8.7). Twenty-nine of the 33 patients reported previous psychotherapeutic treatment for panic (mean number of years of previous treatment=2.4, SD=3.6). The mean number of panic attacks in the 3 weeks before entry into the study was 6.2 (SD=6.1) for the cognitive therapy patients and 8.4 (SD=8.7) for the brief psychotherapy patients. There were no significant differences between the group that received cognitive therapy only and the group that received brief supportive psychotherapy on any of these demographic and diagnostic variables. Furthermore, 16 (48%) of the patients were currently on a daily regimen of benzodiazepines and still met the *DSM-III* criteria for panic disorder; an additional subject was taking antidepressant medication.

Random assignment resulted in 17 subjects for focused cognitive therapy and 16 subjects for brief supportive psychotherapy. The cognitive therapy condition involved 12 weekly individual sessions with a trained cognitive therapist; the brief supportive psychotherapy condition involved 8 weeks of supportive contact with a trained therapist. Upon completion of 8 weeks of cognitive therapy or brief supportive psychotherapy, patients were given the option of an additional 12 weeks of therapy in the other condition.

Data on panic frequency and intensity and depression were obtained from the subjects' self-reports and the ratings of independent clinicians before treatment and at 6- and 12-month follow-up. In addition, subjects assigned to the cognitive therapy group were evaluated after 4, 8, and 12 weeks of therapy, while the brief supportive psychotherapy subjects were assessed after 4 and 8 weeks. The brief supportive psychotherapy subjects who crossed over into cognitive therapy at the end of 8 weeks (crossover group) were reassessed after 12 weeks of cognitive therapy.

All 17 subjects in the cognitive therapy group completed the full 12 weeks of cognitive therapy, with four patients requiring up to four sessions beyond the 12-week protocol. In addition, 6-month and 1-year follow-up data were available on 15 of the cognitive therapy group. In the brief supportive psychotherapy condition, the 16 patients completed the 8 weeks of supportive therapy, and all chose to cross over into cognitive therapy. However, one patient subsequently completed only two sessions of cognitive therapy and then dropped out of treatment. Follow-up data were available on 14 of the crossover subjects.

Therapists followed a detailed treatment manual for the focused cognitive therapy of panic (16). The treatment is a form of brief, structured psychotherapy based on the hypothesis that panic attacks are the result of a vicious cycle involving fear of imminent physical or psychological disaster (17) arising from the misinterpretation of certain bodily sensations or psychological experiences (10, 11). For example, when heart palpitations or chest pains are misinterpreted as signs of an impending heart attack, this will lead to an escalation of the patient's symptoms of anxiety and panic. Cognitive strategies are designed to break the vicious cycle of panic by providing corrective information and experiences that result in the reattribution of unpleasant physiological or affective phenomena to nonpathological and less threatening sources.

Qualified postdoctoral therapists met weekly for 30-minute sessions with the patients who received brief supportive psychotherapy. Since the patients were requested to self-monitor their panic symptoms, a review of their weekly panic logs was the initial focus of the weekly sessions. The therapists applied Rogers's basic principles of unconditional positive regard, genuineness, and accurate empathy in order to establish a supportive, trusting therapeutic relationship with the patients. The therapists' technique was largely nondirective and included active listening, reflecting, and paraphrasing (14). On occasion, nonpanic issues were addressed if they became pressing. However, by taking a nondirective approach, the therapists did not apply specific interventions focused on alleviating panic symptoms.

At each assessment interval, independent clinical raters reviewed patients' daily logs of panic frequency to determine whether the recorded panic attacks actually met the *DSM-III* criteria for panic. In addition, self-ratings of weekly panic frequency and intensity (on a scale of 1–5) were obtained from subjects' responses on the Mobility Inventory for Agoraphobia (18).

Psychometric data were also collected on each testing occasion. The Beck Depression Inventory (19) and the Beck Anxiety Inventory (20) were administered to assess the intensity of depressive and general anxiety symptoms. A 60-item Specific Fear Inventory (unpublished 1985 paper by A.T. Beck and G. Brown) was given to assess individuals' level of situational distress and avoidance. The upset and avoidance scores of the 13-item Fear of Travel subscale were used for the analy-

[a] Because of missing values for some variables, Ns varied across analyses from 14 to 17 patients in the cognitive therapy group and 15 to 16 patients in the brief supportive psychotherapy group.

[b] Data are based on the intake evaluation.

ses, since a previous study suggested that this subscale showed the best discrimination of panic disorder.

Two-by-three repeated measures multiple analyses of variance (MANOVAs) with group (cognitive therapy only versus brief supportive psychotherapy) as the between-group factor and time (pretreatment, 4 weeks, and 8 weeks) as the within-subjects factor assessed treatment effectiveness over the first 8-week period. Separate MANOVAs were conducted on clinician-rated panic frequency and Beck Depression Inventory and Beck Anxiety Inventory scores. Self-rated panic frequency and severity were analyzed in the same MANOVA, as were the Specific Fear Inventory upset and avoidance scores. Significant multivariate F values were followed up with univariate F tests and polynomial trend analysis on the repeated measure. A second series of MANOVAs analyzed data collected over the pretreatment, posttreatment, and 6- and 12-month follow-up periods for the cognitive therapy group and the 16 brief supportive psychotherapy patients who crossed over into cognitive therapy. Violation of the assumption of normality necessitated that logarithmic transformations be performed on the self- and clinician ratings of panic.

Significant quadratic and cubic trends frequently emerged with trend analysis on the main effect for time or the Time by Group interaction. This suggests some fluctuation in subjects' scoring across the different assessment intervals. Since the main hypotheses of the study were tested with the linear component, only this is reported here. An extended report of the study, including the complete trend analysis, is available from the first author on request.

## RESULTS

Analysis with t tests revealed that before treatment, there were no significant differences between the cognitive therapy patients and the brief supportive psychotherapy patients on any of the measures of panic symptoms, depression, general anxiety, and situational fear and avoidance. Since there were no significant pretreatment between-group differences on these dependent variables, it was not necessary to covary out pretreatment levels in the MANOVAs we report.

### *Cognitive Therapy Versus Brief Supportive Therapy at 8 Weeks*

Table 1 presents data on the dependent measures for the cognitive therapy and brief supportive psychotherapy groups during the pretreatment period and after 4 and 8 weeks of treatment. Analysis of independent clinician ratings of panic frequency revealed a significant Group by Time interaction ($F=6.54$, $df=2, 27$, $p<0.005$) with a significant linear component ($F=12.94$, $df=1, 28$, $p<0.001$). Similarly, analysis of self-rated panic frequency and intensity produced a significant Group by Time interaction ($F=2.70$, $df=4, 27$, $p<0.05$) with significant linear components on both frequency ($F=7.15$, $df=1, 30$, $p<0.01$) and intensity ($F=10.63$, $df=1, 30$, $p<$

0.01). These results indicate that the cognitive therapy subjects obtained significantly greater reductions in clinician-rated and self-rated panic frequency than did the subjects who received brief supportive psychotherapy.

A Group by Time interaction ($F=3.32$, $df=2, 58$, $p<0.05$) with a significant linear trend ($F=5.25$, $df=1, 29$, $p<0.03$) emerged for the Beck Anxiety Inventory scores but not for the Beck Depression Inventory scores. (The Mauchley test of sphericity indicated a violation of the homogeneity of covariance assumption with all of our analyses except those for the anxiety inventory scores. As a result we used the more conservative multivariate approach except in the case of the anxiety scores, in which it was possible to use a repeated measures analysis of variance with a Greenhouse-Geisser correction to the degrees of freedom.) However, the linear component ($F=5.25$, $df=1, 29$, $p<0.03$) for the main effect for time ($F=11.04$, $df=2, 29$, $p<0.0001$) was significant for the Beck depression scores.

These results indicate that although the cognitive therapy patients evidenced significantly greater reductions in general anxiety than the brief supportive psychotherapy patients, both groups experienced a significant decline in depression scores over the first 8 weeks of treatment. Finally, analysis of the upset and avoidance scores on the Fear of Travel subscale of the Specific Fear Inventory revealed a Group by Time interaction ($F=2.87$, $df=4, 27$, $p<0.04$) with a significant linear component for the upset score only ($F=7.51$, $df=1, 30$, $p<0.01$). This indicates that the cognitive therapy group had significantly lower upset scores on the Specific Fear Inventory at 8 weeks than did the brief supportive psychotherapy group. However, no significant between-group differences in the avoidance scores emerged.

In summary, the repeated measures MANOVA produced three F statistics, one for the interaction and two main effects for time and group. The interaction term tests whether the downward trends over treatment sessions are parallel. The partitioning of the interactions into linear components indicated that on all of our dependent measures except the Beck Depression Inventory score and the Specific Fear Inventory avoidance score, the cognitive therapy group had a stronger downward trend in symptoms than the brief supportive psychotherapy group.

Chi-square analysis comparing presence versus absence of weekly panic attacks revealed that on the basis of clinician ratings, a significantly larger number of the cognitive therapy patients than of the brief supportive psychotherapy patients had no panic attacks at 8 weeks (cognitive therapy group, N=12, 71%; brief psychotherapy group, N=4, 25%). This difference in outcome was significant for the clinicians' ratings of panic frequency ($\chi^2=5.20$, $df=1$, $p<0.02$) and the patients' self-reports ($\chi^2=5.37$, $df=1$, $p<0.02$).

### *Posttreatment and Follow-Up*

Table 2 presents data on the dependent variables for the cognitive therapy and crossover groups before treatment, after treatment, and at 6-month and 1-year follow-up.

Analysis of end-state functioning indicated that after 12 weeks of focused cognitive therapy, 16 (94%) of the 17 patients who received cognitive therapy only were free of weekly panic attacks according to the independent clinician ratings. The one patient showing only partial recovery transferred into another treatment program. For the crossover group, 10 (63%) of the patients were panic free at the end of treatment. Of the remaining crossover patients, three showed poor response to treatment, two evidenced partial recovery, and one failed to complete the treatment program. Three of these patients sought additional treatment for their panic symptoms.

A 2×4 MANOVA revealed a significant linear trend ($F=10.77$, $df=1, 17$, $p<0.001$) for the main effect of time ($F=9.42$, $df=3, 15$, $p<0.001$) on the independent clinician ratings of panic frequency. Analysis of self-rated panic frequency and intensity revealed a significant main effect for time ($F=26.74$, $df=6, 16$, $p<0.0001$) with linear trends for panic frequency ($F=9.07$, $df=1, 21$, $p<0.01$) and intensity ($F=10.52$, $df=1, 21$, $p<0.01$). These results indicate that both the cognitive therapy group and the crossover group maintained treatment gains at 1-year follow-up, with significantly fewer panic attacks at posttreatment assessment and follow-up than at pretreatment assessment. Moreover, analysis of end-state functioning indicated that at 1-year follow-up, 87% (N=13) of the cognitive therapy subjects and 79% (N=11) of the brief supportive psychotherapy subjects who crossed over into cognitive therapy were panic free.

MANOVA results on the Beck Depression Inventory and Beck Anxiety Inventory scores over the follow-up period revealed a main effect for time (for depression score, $F=5.39$, $df=3, 16$, $p<0.01$; for anxiety score, $F=13.57$, $df=3, 14$, $p<0.0001$) with a significant linear trend (depression score, $F=9.28$, $df=1, 18$, $p<0.01$; anxiety score, $F=22.98$, $df=1, 16$, $p<0.0001$). In addition, analysis of the Specific Fear Inventory upset and avoidance scores revealed a main effect for time ($F=4.69$, $df=6, 13$, $p<0.01$) with significant linear components for upset ($F=12.83$, $df=1, 18$, $p<0.01$) and avoidance ($F=7.65$, $df=1, 18$, $p<0.05$). Once again, these results indicate that the cognitive therapy and crossover subjects continued to have significantly lower Beck Depression Inventory, Beck Anxiety Inventory, and Specific Fear Inventory upset and avoidance scores at 1-year follow-up compared to their pretreatment levels. The failure to find a significant linear component on the Group by Time interaction indicates that cognitive therapy was equally effective in reducing panic and anxiety in the group that received cognitive therapy only and the crossover group.

## DISCUSSION

These findings represent a replication and extension of the naturalistic study by Sokol et al. (13). In contrast

| Crossover group | 16.6 | 14.1 | 15.3 | 11.2 | 12.1 | 11.6 | 11.5 | 11.0 |

[a] Because of missing values for some variables, Ns varied across analyses from 9 to 12 patients in both groups.

[b] Data are based on the intake evaluation for the cognitive therapy group and the 8-week evaluation after brief supportive psychotherapy for the crossover group.

[c] The cognitive therapy group received 12 weeks of cognitive therapy only. The crossover group received 8 weeks of brief supportive psychotherapy followed by 12 weeks of cognitive therapy.

[d] This unexpectedly high posttreatment mean was due to an extreme outlier. That subject had 14 panic attacks after 12 weeks of cognitive therapy. However, the mean number of posttreatment panic attacks for the remaining 14 subjects was 0.9 (SD=1.6).

to that study, however, the present trial of cognitive therapy was compared with a trial of supportive psychotherapy for the first 8 weeks—the period during which the greatest therapeutic improvement has been shown to occur (13). The cognitive therapy patients improved significantly more on various symptom measures of panic and anxiety than did the comparison group.

By the end of the prescribed 12 weeks of treatment, patients receiving cognitive therapy showed a significant and clinically meaningful reduction in the number of panic attacks. A parallel improvement was evident on self-report measures of depression, anxiety, and situational avoidance. These therapeutic gains were stable up to 1-year follow-up for 13 of the 15 patients enrolled in the follow-up study. One patient showed a complete clinical relapse and another a partial recurrence of panic symptoms.

Fifteen of the 16 patients who crossed over from supportive therapy to cognitive therapy also showed a significant reduction in panic attacks, avoidance, and symptoms of depression and anxiety at the end of treatment. Of the 14 crossover patients on whom follow-up data were available, 11 (79%) were free of panic attacks by 1 year; one patient continued to show only partial improvement, one had a complete clinical relapse, and one had a partial recurrence of panic symptoms.

Sixteen of the subjects who entered the study were regularly taking some form of medication. In fact, all but one of these patients were taking daily doses of a benzodiazepine but continued to meet the *DSM-III-R* criteria for panic disorder. At the end of treatment and at 1-year follow-up, only four (25%) of the 16 medicated patients had completely discontinued their medication, although a further seven (44%) of these patients had reduced their medication levels. Because of the limited sample size, it was not possible to investigate systematically the influence of continued use of medication on the effectiveness of cognitive therapy. We are currently in the process of addressing this question with a larger sample of panic patients.

The drop in depression scores in the brief supportive psychotherapy group may be attributed to the fact that patients in that group viewed their therapists as warm and understanding. Although the therapists may have had doubts about the efficacy of the supportive therapy in relieving panic symptoms, they did make a strong effort to apply the principles of nondirective therapy (14). The fact that depression but not panic or anxiety declined during the 8 weeks of supportive therapy suggests that the therapists' emphasis on the therapeutic relationship had an impact on depression even though panic attacks were not relieved.

In conclusion, this study adds to the growing number of controlled and open trials indicating that panic attacks are particularly sensitive to cognitive or cognitive-behavioral interventions. These cumulative findings provide support for the efficacy of cognitive therapy for panic attacks. In addition, the relatively low rates of relapse and recurrence and the absence of side effects point to special advantages of this form of psychosocial treatment.

# Qualitative Assessment of Brain Morphology in Acute and Chronic Schizophrenia

Jeffrey Lieberman, M.D., Bernhard Bogerts, M.D., Gustav Degreef, M.D.,
Manzar Ashtari, Ph.D., George Lantos, M.D., and Jose Alvir, D.P.H.

Objective: *Neuroimaging studies of brain morphology in schizophrenia have used predominantly morphometric techniques to assess brain scans. However, as currently implemented, such methods are not particularly helpful in the routine assessment of individual patients. The purpose of this study was to evaluate brain morphology seen with magnetic resonance imaging (MRI) by qualitative assessment, the most frequently used method in clinical practice for evaluating brain scans.* Method: *First-episode (N=62) and chronic, multiepisode (N=24) schizophrenic patients and healthy comparison subjects (N=42) underwent MRI of the whole head in a sequence that provided 63 contiguous brain slice images. Each subject received a rating of normal, questionably abnormal, or definitely abnormal for four brain regions (lateral ventricles, third ventricle, medial temporal lobe structures, and frontal/parietal cortex) and a global rating.* Results: *The schizophrenic patients had significantly higher global rates of abnormal morphology (first-episode group, 31%; chronic group, 42%) than the normal subjects (5%). The highest regional rates of abnormalities were seen in the lateral ventricles and the lowest in the frontal/parietal cortex. Although the chronic patients had generally higher abnormal rates than the first-episode patients, these differences were not statistically significant. The qualitative ratings of brain morphology were significantly correlated with quantitative assessments performed in separate studies.* Conclusions: *Despite its limits in sensitivity (and until quantitative morphometric techniques are made practical and more widely available), qualitative evaluation of MRI scans can be a useful technique in research and clinical evaluation of patients with schizophrenia.*

(Am J Psychiatry 1992; 149:784–794)

Post-mortem and in vivo imaging studies of the brain have demonstrated morphologic abnormalities in patients with schizophrenia (1–3). These alterations include enlargement of the lateral and third ventricles, enlargement of the cortical sulci of the frontal, temporal, and parietal regions, and reduction in the volume of the medial temporal lobe structures (2–11). Despite the consistency of these findings, it is apparent that the pathology in schizophrenia is relatively subtle in magnitude compared to that of other neurodegenerative disorders such as Alzheimer's disease and Huntington's disease. Generally speaking, standard neuroradiologic evaluations based on visual inspection regard as abnormal only the extreme examples of the pathomorphology characteristic of schizophrenia. Recent research on brain morphology in schizophrenia has emphasized morphometric statistical studies of post-mortem brains, computed tomography (CT), and magnetic resonance imaging (MRI) (1–11).

MRI has shown a clear advantage over CT by virtue of its multiplanar capability, high tissue contrast and resolution, and absence of ionizing radiation. Medial temporal lobe structures can be well visualized, especially in coronal MRI slices. Several MRI studies of schizophrenic subjects have reported increased ventricle size, altered midline dimensions in the corpus callosum, and reduced frontal and temporal lobe size (4–15). All of these studies, however, used morphometric meth-

ods and described statistical differences between patients and nonpsychiatric control subjects. While they are necessary to establish scientific evidence of group differences, morphometric methods are not very helpful in the routine clinical assessment of an individual scan. One solution to this problem of what is normal or abnormal in an MRI scan of a single schizophrenic subject would be to collect well-defined normative quantitative data for different age groups and to compare individual patients' values with the appropriate age- and sex-defined range of normal anatomic volumes. To date, this principle, which is widely used in all fields of clinical medicine, has not been applied in MRI assessment of the brain, since standardized age- and sex-related morphometric data (e.g., for volumes of ventricular, cortical, and subcortical structures) are not yet available and since standardized mensuration systems are not yet widely used.

For the time being, qualitative assessment remains the most frequently applied method in clinical medicine to determine whether a scan is normal or not (16). Taking this fact into account, this article addresses the following questions. 1) Can brain abnormalities be seen in MRI scans of patients when qualitative assessment, as it is usually performed in clinical practice by psychiatrists or neuroradiologists, is used? 2) How frequently do these abnormalities occur in different brain regions of schizophrenic subjects as compared to normal subjects? 3) How strong is the correlation between qualitative assessment and quantitative measurement of various brain structures?

To investigate these questions, we evaluated brain morphology by using blind qualitative examination of MRI scans of the brain in three groups of subjects: first-episode schizophrenic patients with little or no prior neuroleptic treatment, treatment-refractory chronic schizophrenic patients, and normal volunteers.

## METHOD

Schizophrenic subjects were selected from patients in two research protocols that were being conducted at a hospital. The first was a prospective study of psychobiology in schizophrenia, which ascertained patients who had entered the hospital in their first episode of schizophrenia and had not had previous neuroleptic treatment (this study has been described in detail elsewhere [17]). Diagnoses were determined according to the Research Diagnostic Criteria (RDC) (18) on the basis of information from a structured diagnostic interview, the Schedule for Affective Disorders and Schizophrenia (19), and confirmed by long-term follow-up (1–3 years). The second protocol was a study of clozapine treatment in refractory schizophrenia (20). Patients ascertained for this study were diagnosed by a research psychiatrist as having chronic schizophrenia (according to *DSM-III-R*) on the basis of a comprehensive clinical evaluation and a history of resistance to treatment. This was defined as the persistence of psychotic symptoms at a significant level of severity despite adequate independent trials (6 weeks at 1000 mg/day in chlorpromazine equivalents) of three neuroleptics from two different biochemical classes.

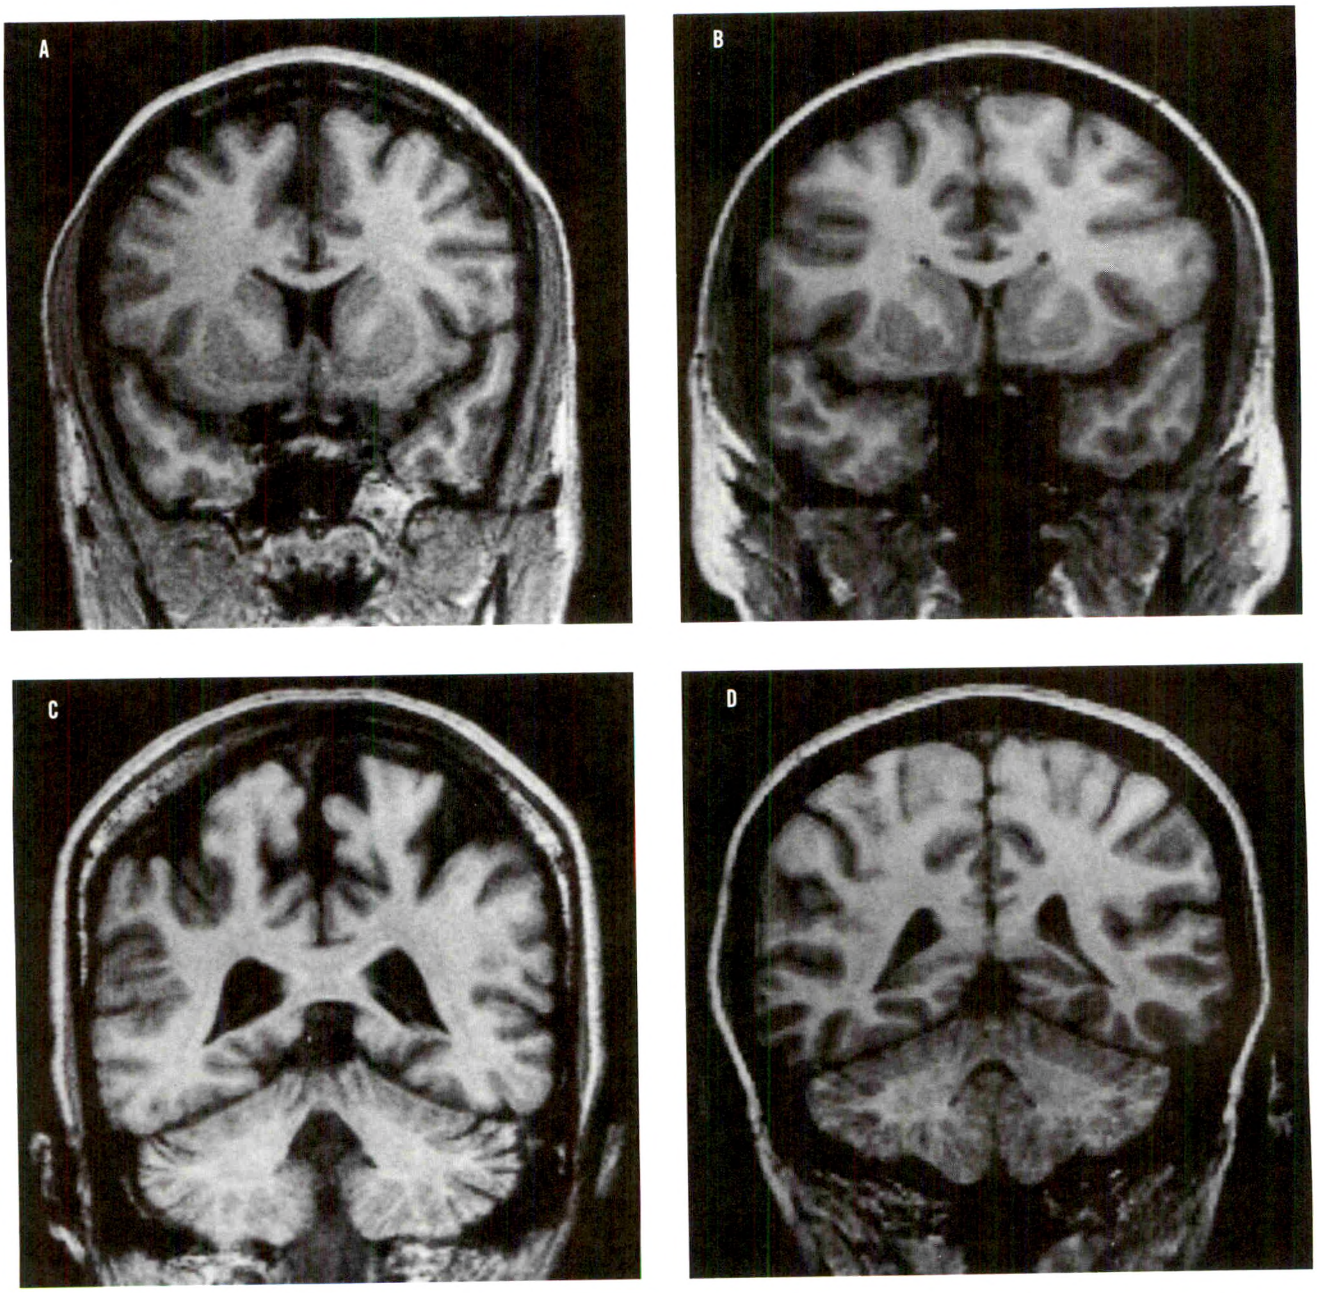
Normal comparison subjects were recruited from the medical center staff and community through advertisements. The volunteers were screened for medical and psychiatric illness and history of substance abuse (unpublished paper of J.A. Walsleben et al.).

None of the patients or comparison subjects had a history of substance dependence or current abuse or a history of chronic neuromedical illness or drug treatment known to affect the brain (e.g., corticosteroids). The normal comparison subjects were selected with regard to matching the demographic characteristics of the patient groups.

The subjects were scanned in a 1.0-tesla whole-body MRI system (Siemens Magnetom) with a dedicated head coil. Brain images were obtained in the coronal plane through the whole head in 3.1-mm contiguous slices by using a 50° FLASH sequence with a repetition time (TR) of 40 msec and an echo time (TE) of 15 msec in one acquisition. This sequence provided 63 contiguous slices in a 256×256-pixel matrix with no zoom factor and a resolution of 1.0×1.0×3.1 mm in 11 minutes (this procedure has been fully described by Ashtari et al. [21]).

For analysis, the imaging data were transferred by means of magnetic tape onto a SUN work station for quantitative assessment (the results of which are described in references 6 and 22 and an unpublished paper by B. Bogerts et al.). Video film hard copies were printed for visual qualitative evaluation. MRI scans of patients and comparison subjects were combined in a randomized order and evaluated independently, under blind conditions, by two research psychiatrists (B.B. and G.D.) trained in neuroanatomy and radiologic assessment. On the coronal spin-lattice relaxation time ($T_1$)-weighted scans, four regions were assessed: lateral ventricles, third ventricle, frontal and parietal cortex, and medial temporal structures. Qualitative evaluations were made on a 3-point scale (normal, questionable, abnormal). The criteria that were developed to classify regions of interest on this scale are described in appendix 1. Their essence can be summarized as follows. An abnormal cortex was defined on the basis of the prominence of the interhemispheric fissure, cortical sulci, and the cortical subarachnoid space in the frontal and/or parietal regions (figure 1, A–D). Abnormality of the lateral ventricles was determined on the basis of increased size of the body or frontal or occipital horns and/or blunting of the lateral angles (figure 2, A–D, and figure 3, A–C). Abnormality of the third ventricle was determined on the basis of its width (figure 3, C–E). Evaluation of the medial temporal structures was based on the size and shape of the hippocampal formation and the size of the temporal horn throughout its anteroposterior extension (shown at the level of the mammillary body in figure 3, E–G). An abnormal rating for the medial temporal structures was given if there was a

**FIGURE 1.** Coronal Magnetic Resonance Images of a 20-Year-Old Man (A and C) and a 30-Year-Old Woman (B and D) at Two Different Levels[a]

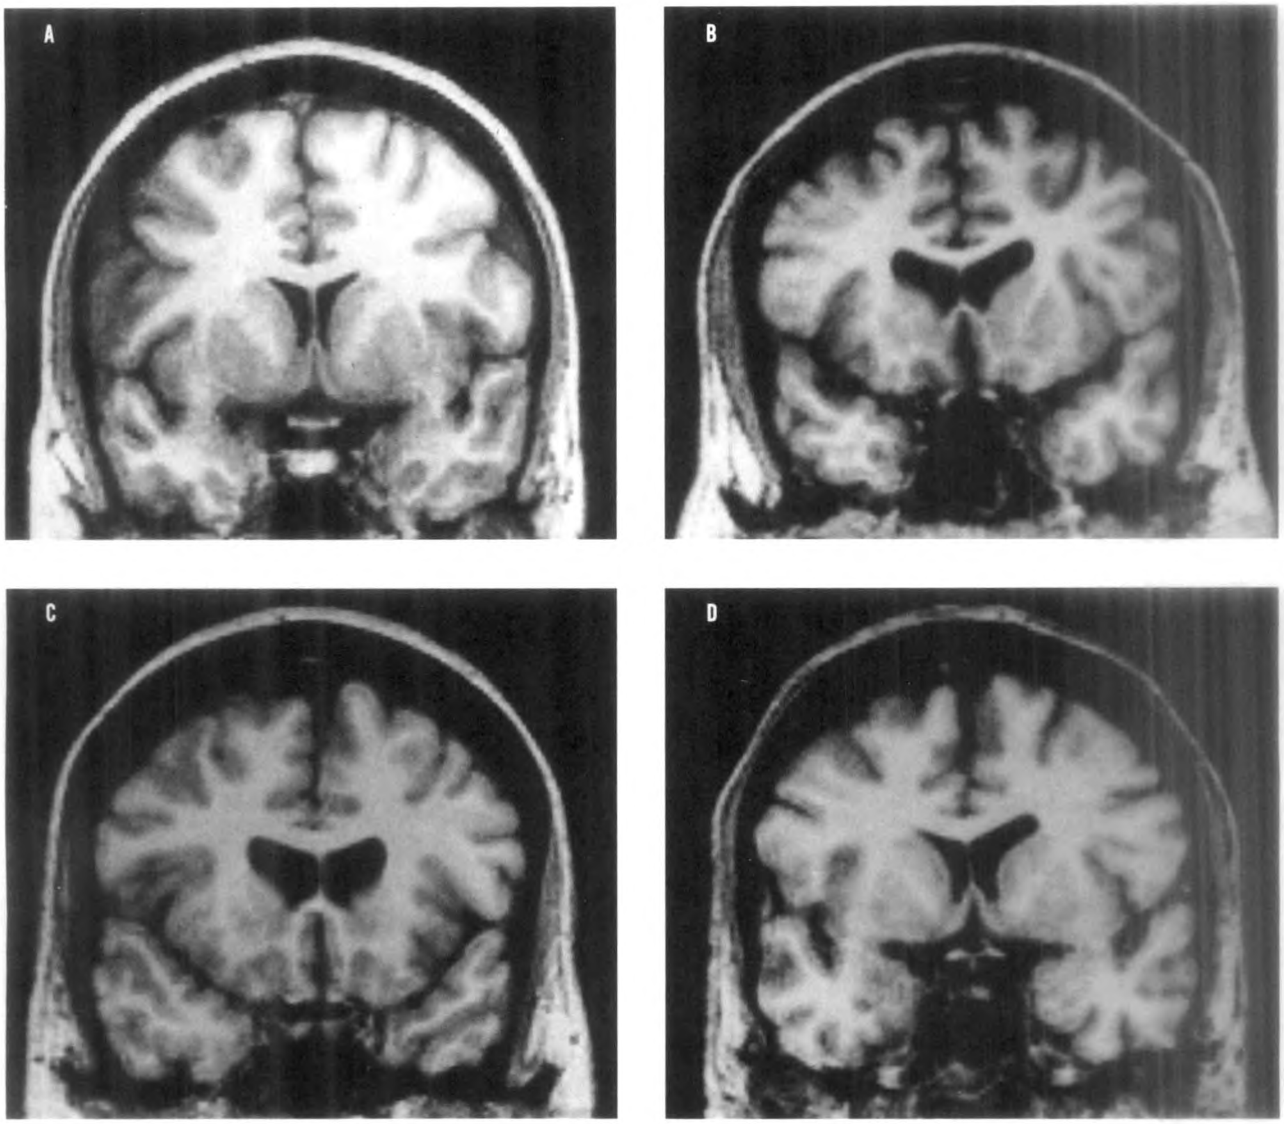


[a] A and B show the frontal cortex just posterior to the genu of the corpus callosum. C and D show the parietal cortex at the splenium of the corpus callosum. A illustrates reduced frontal cortical volume and increased interhemispheric fissure, while B shows normal anatomy at the same level. C illustrates markedly reduced parietal cortical volume and increased subarachnoid space and interhemispheric fissure, while D shows normal anatomy at the same level.

clear reduction in the size or a dysplastic configuration of the hippocampal formation or an increase of the temporal horn size on the right and/or left side of the brain (figure 3, A–G). A subject was classified as having a global abnormality if he or she had a definite abnormal rating in one or more of the four brain regions.

The interrater reliability of the two research psychiatrists was determined by computing the intraclass correlations (kappas) (23) of their ratings. The kappas for the four brain regions (frontal and/or parietal cortex, lateral ventricles, third ventricle, and medial temporal structures) were 0.72, 0.77, 0.77, and 0.60, respectively. Complete agreement was reached on 75% of the ratings in each of the four regions. For only one region (medial temporal structures) and on only one qualitative rating was there disagreement by a factor of 2 (one psychiatrist gave a rating of 0 [normal] and the other, 2 [abnormal]). In approximately 25% of the ratings, the raters disagreed by

FIGURE 2. Coronal Magnetic Resonance Images Showing Normal and Enlarged Lateral Ventricles[a]

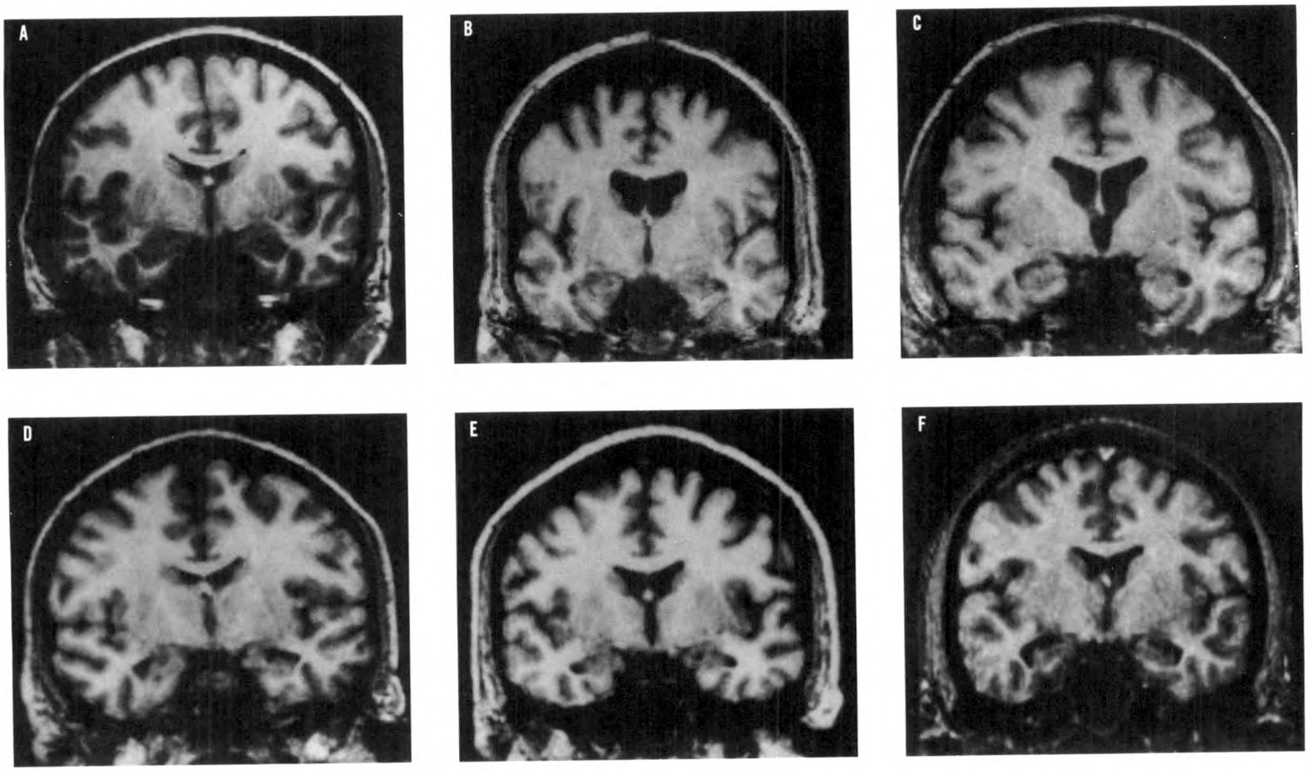


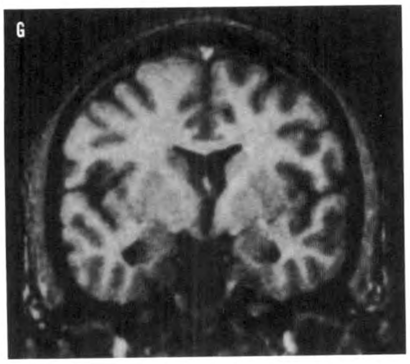
[a] A: Image of a 30-year-old woman at the level of the optic chiasm. The configuration of the lateral ventricles is normal.
B and C: Images of a 25-year-old man and a 36-year-old woman at levels of one and three slices posterior to the genu of the corpus callosum, respectively, showing lateral ventricle enlargement. Note the blunted lateral angle of the ventricles, which can commonly be seen in elderly normal subjects but is rare in younger normal subjects.
D: Image of a 25-year-old man at the level of the optic chiasm, with enlargement of the left frontal horn (the patient's left is on the right in the figure). This asymmetric enlargement is distinct from A, B, and C, which show bilateral involvement of the ventricles.

1 point (either 0 [normal] versus 1 [questionable] or 1 [questionable] versus 2 [abnormal]).

In contrast to morphometric procedures, qualitative assessment of brain structures in CT and MRI depends largely on the observers' experience and orientation and the clinical (or scientific) context in which they view the scan. Relevant factors (e.g., ventricle size is age related, and what might be normal for age 60 may not necessarily be normal for age 20) are frequently overlooked. To establish the validity of the qualitative ratings, they were compared with the volumes of all components of the lateral and third ventricles and the medial temporal structures (amygdala-hippocampus complex) that had been previously determined with a computerized mensuration system (6, 21–24). The qualitative ratings (normal, questionable, abnormal) of the lateral ventricles, third ventricle, and medial temporal structures and the quantitatively determined volumes of the same structures were compared by analysis of variance (ANOVA) and found to be significantly associated in the ANOVAs that had the quantitative measure as the dependent measure and the qualitative rating as the between-groups factor (for the right and left lateral ventricles, respectively, $F=16.6$, $df=2, 31$, $p<0.0001$, and $F=27.9$, $df=2, 31$, $p<0.0001$; for the third ventricle, $F=17.2$, $df=2, 31$, $p<0.0001$; and for the

**FIGURE 3. Coronal Magnetic Resonance Images at the Level of the Mammillary Body and the Level of Monro's Foramen**[a]





[a] A: Image of a 21-year-old man at the level of the mammillary body, showing normal anatomy of the lateral and third ventricles, the anterior hippocampus, and the temporal horn.
B: Image of a 21-year-old man at the level of the mammillary body, with lateral ventricle enlargement and normal-appearing third ventricle and medial temporal structures.
C: Image of a 21-year-old man at the level of the mammillary body, with marked enlargement of the third ventricle, moderate enlargement of the lateral ventricles, questionable enlargement of the temporal horns, and normal-appearing medial temporal structures.
D and E: Images of a 16-year-old girl and a 22-year-old woman at the level of the mammillary body, showing bilateral reduction in hippocampal volumes. D also shows normal third and lateral ventricles, while E shows questionably enlarged third and lateral ventricles.
F and G: Images of a 21-year-old man. F, at the level of Monro's foramen, shows reduced amygdala volume, enlarged temporal horns bilaterally, and a questionably enlarged third ventricle and lateral ventricle. G, at the level of the mammillary body, shows reduced hippocampal volume, enlarged temporal horns bilaterally, and a questionably enlarged lateral ventricle.

right and left medial temporal structures, respectively, F=7.5, df=2, 28, p=0.003, and F=3.4, df=2, 28, p=0.05). The weaker association of the medial temporal structures is explained by the fact that this brain region was assessed as abnormal if the hippocampus looked dysplastic or if the temporal horn was enlarged (the two changes did not always coincide). Therefore, correlations of the qualitative ratings of the medial temporal structures with the volume of one or the other structure were necessarily smaller. In addition, the shape of the medial temporal structures is less homogeneous and more variable than that of the ventricles, making reliable assessment more difficult. Data on cortical volume were not available; hence, no analyses for the cortex were performed.

Categorical data analysis (chi-square test) was used to compare the three groups on the distribution of brain pathomorphology, as well as on the categorical demographic and clinical variables such as race and diagnosis. ANOVA was used to compare the groups on the number of affected regions, as well as on the continuous demographic and clinical variables such as age. Because three groups were being compared in these analyses, significant results were followed up to test which groups actually differed from each other. These comparisons were of special interest in the contrast between the first-episode and the chronic, treatment-refractory groups. These between-group comparisons were done with chi-square and t tests.

## RESULTS

The study groups consisted of 62 patients in their first episode of schizophrenia, 24 treatment-refractory patients with chronic schizophrenia, and 42 normal vol-

[a] Significantly different from the chronic group ($\chi^2$=7.3, df=1, p=0.001).
[b] Significantly different from the chronic group ($\chi^2$=8.7, df=1, p=0.003).
[c] Significantly different from the chronic group ($\chi^2$=16.5, df=3, p<0.001).
[d] Significantly different from the first-episode group ($\chi^2$=10.1, df=3, p=0.02).

unteers. As would be expected, the first-episode patients were younger (mean age=24.1 years, SD=5.8) than the chronic schizophrenic patients (mean=29.1 years, SD=5.7) and the comparison subjects (mean=28.8 years, SD=7.5) (F=8.9, df=2, 125, p=0.001). The sex ratio, racial/ethnic composition, and diagnoses of the three groups are shown in table 1. There was a higher proportion of male patients in the chronic schizophrenic group than in the first-episode and normal groups. There was also variation in the racial/ethnic distribution of the groups, with the chronic schizophrenia group having the highest proportion of white subjects. The normal comparison subjects had a higher education level (1=graduate school, 2=college graduate, 3=some college, 4=high school graduate) than the patient groups (normal subjects, mean=2.0, SD=0.9; first-episode patients, mean=3.4, SD=1.1; chronic patients, mean=3.5, SD=0.9). The patient groups were predominantly schizophrenic; the balance had schizoaffective disorder. The chronic, multiepisode group obviously had a longer duration of illness (mean=478 weeks, SD=291) than the first-episode group (51 weeks, SD=85) (t for unequal variance=6.9, df=25, p<0.001).

The prevalence rates of brain pathomorphology by region are shown in table 2. The schizophrenic patients had higher abnormal rates (questionable and definite) than the comparison subjects in all four regions. With the global criterion of defining a patient as abnormal if at least one of the four brain regions assessed was abnormal (or questionable if at least one of the four brain regions assessed was questionable), 57% of the comparison group were rated normal, 33% of the first-episode patient group were rated normal, and 25% of the chronic patient group were rated normal ($\chi^2$=15.8, df=4, p=0.003). The highest prevalence of abnormal morphology in any specific region was in the lateral ventricles, where the normal rate was 29% for the chronic patients, 56% for the first-episode patients, and 79% for the normal subjects ($\chi^2$=18.2, df=4, p=0.001). On visual inspection, the most noticeable feature of lateral ventricle enlargement was the blunting of the lateral corner between the caudate nucleus and corpus callosum (figure 2, B and C). This was seen particularly in the left lateral ventricle, which in the quantitative and qualitative assessments was frequently preferentially affected (figure 2, D). (For additional information on the quantitative differences in left and right ventricle volume, see reference 22.) The lowest rates of pathomorphology were seen in the frontal/parietal cortical regions, where the rates of normalcy for the first-episode, chronic, and normal groups were 76%, 75%, and 93%, respectively ($\chi^2$=8.8, df=4, p=0.07). The low rates of pathomorphology in this region could be due to the fact that cortical sulci are less easily visualized in the coronal plane than in the axial plane. In addition, the substantial variability of size, shape, and configuration of cortical sulci and gyri make qualitative assessment of pathomorphology of this region more difficult than for simpler structures like the ventricles.

Although the chronic schizophrenic patients appeared to be more severely affected than the first-episode schizophrenic patients, comparisons between the first-episode and chronic groups revealed only one region, in the lateral ventricles, where marginally significant differences were exhibited ($\chi^2$=5.4, df=2, p=0.07).

Abnormal morphology ratings in all four regions for the entire study group were significantly intercorrelated (table 3). The highest correlations were between the lateral ventricles and the medial temporal structures, between the lateral ventricles and the third ventricle, and between the third ventricle and the medial temporal structures. The lowest correlations were between the frontal/parietal cortex and the other structures.

To examine the distribution of abnormal morphology in the study group in another way, we classified subjects by the number of regions that were rated as definitely abnormal (table 4). Comparisons of the three subject groups on the number of regions affected within each subject revealed that the chronic schizophrenic group was most severely affected, with a mean of 0.71 regions (SD=1.08) definitely abnormal, followed by the first-episode schizophrenic group, with a mean of 0.47 abnormalities (SD=0.78), and the normal group, with a mean of 0.05 abnormalities (SD=0.22). The three groups differed in the mean number of pathomorphologic regions when the abnormal rating was used as the criterion level (F=7.3, df=2, 125, p=0.001) and when the questionable rating was used as the criterion level (F=7.5, df=2, 125, p=0.0009). Although each of the patient groups differed significantly from the normal comparison group, they did not differ from each other by either the abnormal or the questionable criterion level (t=1.1, df=84, p=0.26, and t=1.2, df=84, p=0.25, respectively).

To examine the effect of gender, we compared the rates of brain pathomorphology for men and women in the combined patient group (N=86). The male patients

had consistently higher rates of pathomorphology, but the only difference that reached statistical significance was for the lateral ventricles (for male patients, 37% normal, 37% questionable, and 26% abnormal; for the female patients, 69% normal, 15% questionable, and 16% abnormal ($\chi^2$=8.3, df=2, p=0.02).

## DISCUSSION

Using blind qualitative assessment of MRIs, we detected rates of abnormal brain morphology that were comparable to rates reported in the literature for similar populations (3–15). The substantial number of questionable ratings indicates the difficulty in distinguishing subtle abnormalities in brain morphology from what may be extremes in normal human neuroanatomic variation. Almost all morphometric postmortem CT and MRI studies have found a considerable overlap between patients and control subjects, with the majority of patients having values within the control range. The percentage of patients having values outside the range of the control subjects varies from 5% to 40% and depends on the selection criteria used to ascertain patients and control subjects, the assessment methods, and the specific brain region evaluated.

Although there are arguments derived from statistical considerations of ventricular measure distributions which suggest that a subgroup of schizophrenic patients have abnormal values and also that the whole Gaussian distribution of VBR values is shifted toward higher values (5), there is no doubt that the brain structure of the majority of schizophrenic patients looks normal, or at least not definitely abnormal, whereas some patients clearly have enlarged ventricles. This qualitative study came to the same conclusion. Moreover, the very high correlations of our qualitative ratings with the actual volumes show that qualitative ratings, which are much less time consuming and easier to perform than morphometric procedures, can be a valuable tool in psychiatric evaluation if performed by trained physicians.

The most problematic structure to assess was the cerebral cortex. As in the medial temporal lobe, the configuration of cortical sulci and gyri in the normal human brain has enormous variability. Therefore, we were quite conservative (possibly overly cautious) in defining cortical structures as abnormal. Indeed, only three of the 86 schizophrenic patients were rated as having definitely abnormal cortices. Our experience and that of others reported in the literature derived from CT scan studies of schizophrenic subjects suggests that the percentage of schizophrenic subjects with definite enlargement of cortical sulci and fissures (including the Sylvian and interhemispheric fissures) is considerably higher (2). While coronal MRI scans are superior to CT in assessing the ventricles and various soft tissue structures, including medial temporal structures, axial CT or MRI scans might be more appropriate than the coronal slices that we used to rate cortical sulcal and fissure enlargement by qualitative visual inspection.

We found significant correlations in abnormal morphology between the lateral and third ventricles and the medial temporal structures. The lower correlations between the frontal/parietal cortex and the other regions could be seen as consistent with the hypothesis of independent pathological processes affecting different brain regions (cortical and subcortical), as suggested by Cannon et al. (25). In our schizophrenic groups there were many patients who had selective enlargement of the lateral and/or third ventricle or had abnormalities of the medial temporal structures or cortex, indicating the lack of neuropathological homogeneity of the disease (figure 1, C, and figure 3, B–D). However, any such interpretation is limited by the intercorrelation among brain regions and the low rates of abnormality in the cortical regions that we found in this study.

The fact that both schizophrenic groups had greater rates of abnormal morphology than the normal subjects but did not significantly differ from each other is interesting and has several implications. First, these results confirm previous findings of abnormal brain morphology in young schizophrenic patients at the onset and early stages of their illness (26–33) as well as in chronic patients (2, 3). The 31% prevalence of global abnormal morphology in the first-episode patients is less than the rates described in more chronic populations in the literature but is comparable to that of other first-episode samples. However, only one-third of the first-episode patients were rated normal and 36% were rated questionable. This raises the possibility that a larger proportion of schizophrenic patients at the onset of illness may exhibit pathological changes of the brain and that these may not only be seen in a subgroup of schizophrenic individuals but are more widely distributed, as has been suggested by Suddath et al. (5). The limiting factors in the latter case are the standards for comparison and methods of assessment.

Second, the fact that the rates of abnormal morphology were not substantially greater in the chronic patients than in the first-episode patients suggests that there is not substantial progression in the neuropathology of schizophrenia, at least of a magnitude that visual inspection can detect. This interpretation is further supported by the fact that the chronic patients were treatment refractory, so they not only were older and had been ill longer but also had a severe form of the illness. The greater proportion of male subjects in the chronic group is significant, because there are suggestions from our data and the data of others that male patients may have higher rates of abnormal morphology than female patients (6, 8, 9, 22, 34). On the other hand, it should also be pointed out that the chronic patients had generally higher rates of abnormal morphology and a greater frequency of multiple areas of involvement than the first-episode patients. However, the degree to which the chronic schizophrenic patients exhibited greater abnormal morphology, though noteworthy, does not seem to be sufficiently great to be explained as reflecting progressive neuropathological change during the illness. Rather, it would seem to be due to the concentration of predominantly male patients with more severe forms of schizophrenia in the chronic group. This is consistent with prospective studies of brain morphology conducted with CT (35–38) and MRI (39, 40), the majority of which found no consistent pattern of change. We also cannot rule out the possibility that chronic exposure to treatment may be a factor in the differences in morphology between the patient groups. It is also possible that if neuropathological changes do occur in the course of the illness, they may be of a magnitude which was not detectable by visual inspection. Thus, both to answer the question of whether neuropathological change is progressive during the illness and to define more clearly the population exhibiting pathomorphology, valid and reliable methods of quantitative assessment are required (41–43).

**TABLE 4. Number of Abnormal and/or Questionable Ratings for Brain Regions Within Individual Schizophrenic Patients and Normal Comparison Subjects**

| | Schizophrenic Patients | | | | Normal Comparison Subjects (N=42) | |
|---|---|---|---|---|---|---|
| | First-Episode (N=62) | | Chronic (N=24) | | | |
| Number of Brain Regions/ Rating | N | % | N | % | N | % |
| No region | | | | | | |
| Abnormal | 43 | 69 | 14 | 58 | 40 | 95 |
| Abnormal/ questionable | 21 | 34 | 6 | 25 | 24 | 57 |
| One region | | | | | | |
| Abnormal | 10 | 16 | 6 | 25 | 2 | 5 |
| Abnormal/ questionable | 14 | 23 | 5 | 21 | 10 | 24 |
| Two regions | | | | | | |
| Abnormal | 8 | 13 | 2 | 8 | 0 | 0 |
| Abnormal/ questionable | 14 | 23 | 3 | 13 | 7 | 17 |
| Three regions | | | | | | |
| Abnormal | 1 | 2 | 1 | 4 | 0 | 0 |
| Abnormal/ questionable | 8 | 13 | 9 | 38 | 0 | 0 |
| Four regions | | | | | | |
| Abnormal | 0 | 0 | 1 | 4 | 0 | 0 |
| Abnormal/ questionable | 5 | 8 | 1 | 4 | 1 | 2 |

It seems clear that given the substantial overlap between patients and comparison subjects on measures of brain morphology, and until the diagnostic specificity of the characteristic forms of pathomorphology is established, brain MRI will not be useful in determining the diagnosis of schizophrenia apart from ruling out the occurrence of other neurological conditions (e.g., obstructive hydrocephalus, tumor, cerebrovascular infarction). However, evidence is emerging which associates abnormal brain morphology with forms of schizophrenia that have poorer prognoses (44, 45, and unpublished paper by J. Lieberman et al.). The most consistent finding has been that patients with abnormal morphology respond less well to antipsychotic drug treatment and have a poorer outcome (29, 45, 46–49). The increased rate of abnormal morphology in the chronic patients in our study (though not statistically significant) is consistent with this. Thus, brain MRIs may provide useful information to clinicians for evaluating the prognosis and determining treatment strategies for patients. For example, if patients with abnormal morphology take longer to respond to antipsychotic drugs and have a greater likelihood of ultimately being unresponsive, clinicians may want to allow a longer trial for a given dose or type of medication before changing the regimen. This could be particularly useful in limiting the potential for drug toxicity that can occur when drug dosage is increased too rapidly and unnecessarily. It could be particularly useful with younger patients who are earlier in their course of illness or with patients whose prior histories are not well known to the clinician.

In summary, qualitative evaluations of brain morphology on MRI scans by trained observers under blind conditions were able to identify abnormal morphology in first-episode and chronic schizophrenic patients as compared to normal subjects at rates that were comparable to those reported in the literature for these populations. The fact that only moderately higher rates of pathomorphology were seen in chronic multiepisode than in first-episode schizophrenic patients suggests that preexisting brain pathology may predispose to more severe forms of the illness rather than reflect a progressive or degenerative process.

Despite its limits in sensitivity, and until quantitative morphometric techniques are more practical and more widely available, qualitative assessment of brain morphology appears to be a useful technique in research and clinical evaluation of patients with schizophrenia.

## APPENDIX 1. Criteria for Qualitative Assessment of Brain Morphology

### LATERAL VENTRICLES

*Abnormal*

1. Extreme blunting of the lateral angles of the lateral ventricles at the central part or frontal horns, or
2. Extreme size of the lateral ventricles in two of three sections (frontal, body, and occipital), or
3. Any three of the following:
   Moderate blunting of the lateral angles of the lateral ventricles at the central part and frontal horns
   Moderate size of the lateral ventricles in at least two of three sections (frontal, body, and occipital)
   Marked asymmetry in size of the right and left lateral ventricles
   Markedly abnormal shape of the lateral ventricles

*Questionable*

1. Any two of the following:
   Moderate blunting of the lateral angles of the lateral ventricles at the central part and frontal horns
   Moderate size of the lateral ventricles in two of three sections (frontal, body, and occipital)
   Moderate asymmetry in size of the right and left lateral ventricles
   Moderately abnormal shape of the lateral ventricles

### THIRD VENTRICLE

*Abnormal*

1. Marked widening of the third ventricle, particularly in the anterior portion

*Questionable*

1. Moderate widening of the third ventricle throughout its anteroposterior extent

### CORTEX

*Abnormal*

1. Marked enlargement of the cortical sulci in the anterior, parietal, or occipital lobe, or
2. Any two of the following:
   Marked enlargement of the interhemispheric fissure

Marked enlargement of the cortical subarachnoid space
Marked enlargement of the subarachnoid cisterns

*Questionable*

1. Diffuse and moderate enlargement of cortical sulci in the anterior, parietal, or occipital lobe
2. Any two of the following:
   Moderate enlargement of the interhemispheric fissure
   Moderate enlargement of the cortical subarachnoid space
   Moderate enlargement of the subarachnoid cisterns

MEDIAL TEMPORAL LOBE

*Abnormal*

1. Marked abnormality in the shape of the hippocampus (loss of the gyral pattern, reduction in size, abnormal shape), or
2. Marked enlargement of the temporal horn plus at least a moderate abnormality in the shape or size of the hippocampus, or
3. At least a moderate rating on 1 or 2 plus the following:
   Marked reduction in the size of the hippocampus
   Extreme asymmetry of the shape or size of the hippocampus or temporal horn

*Questionable*

1. Any two of the following:
   Moderate reduction in the size of the hippocampus
   Moderate enlargement of the temporal horn plus at least a moderate abnormality in the shape or size of the hippocampus
   Moderate asymmetry of the shape or size of the hippocampus or temporal horn

# Pattern of Recurrence of Illness After Recovery From an Episode of Major Depression: A Prospective Study

Mario Maj, M.D., Ph.D., Franco Veltro, M.D., Raffaele Pirozzi, M.D., Silvana Lobrace, M.D., and Lorenza Magliano, M.D.

*Objective: This study assessed prospectively the pattern of recurrence of illness after recovery from an episode of major depression. Method: Seventy-two patients who had recovered from an episode of primary, nonbipolar, nonpsychotic major depression were evaluated bimonthly with the Comprehensive Psychopathological Rating Scale for a period ranging from 20 to 108 months (median=66 months). New ("prospective") episodes were ascertained with a structured diagnostic interview. The probabilities of remaining well after the index episode and after the first prospective episode were assessed by the life-table method. The severity and duration of prospective episodes and the index episode were compared by linear regression analysis. Results: The probability of remaining well after recovery from the index episode was 76% at 6 months, 63% at 1 year, and 25% at 5 years. The risk of recurrence was lower among patients receiving prophylactic treatment with antidepressants and/or lithium and among those with histories of fewer than three previous episodes. The probability of remaining well was significantly lower 2 years after the first prospective episode than 2 years after the index episode. A pattern of increasing severity from the index episode to the first, second, and third prospective episodes was observed and was not affected by treatment. Conclusions: Major depression has a high rate of recurrence, even when bipolar and psychotic cases are excluded. The highest rate is observed during the first months after recovery from an episode. Prophylactic drug treatment reduces the risk of recurrence but apparently does not affect the trend toward increasing severity of subsequent episodes.*

(Am J Psychiatry 1992; 149:795–800)

The pattern of recurrence of illness after recovery from an episode of major depression has been repeatedly investigated during the last decade with the use of quantitative survival analysis techniques (1–6). Most studies have focused on the time between recovery and the first prospectively observed new episode ("prospective" episode), showing that the longer individual patients stay well after the index episode, the less likely they are to experience a recurrence. Only a few papers have reported on the time to the second prospective episode, showing that it tends to be shorter than the time to the first prospective episode (2).

The above-mentioned data have been obtained by longitudinal follow-up of groups of patients whose treatment was not under the researchers' control. In most investigations, however, the assessment of the course of illness was actually done retrospectively, by reviewing, on the basis of information provided by the patients, periods as long as 6 months. The validity of the findings obtained by this procedure has been questioned (7).

Other shortcomings of some of the currently available studies include 1) imprecise definition of "recovery" (in order to be complete, a definition should specify a threshold for the number and severity of symptoms and indicate the period for which the symptoms must remain at a subthreshold level); 2) confusion between the concepts of recurrence (a new episode that occurs after recovery from the index one) and relapse (a return of symptoms, satisfying the full criteria for an episode, that occurs during a period of remission but before actual recovery); 3) inclusion of patients with bipolar illness in the patient groups studied (this may confuse the picture, since patients with bipolar disorder have been reported to be at higher risk for recurrence than patients with unipolar disorder); and 4) failure to stratify patients according to the treatment received during the observation period (prophylactic medication with antidepressants or lithium is likely to affect the course of

illness, although it must be acknowledged that the choice of treatment is itself in part determined by the clinical situation).

These methodological drawbacks may help explain the divergent findings reported in the literature concerning factors that affect the risk of recurrence. A predictive value of the number of previous episodes has been detected by some authors (1, 5) but not confirmed by others (6), and the same applies to the predictive significance of an underlying minor depression (2, 5) and of the persistence of nonsuppression of cortisol on the dexamethasone suppression test (DST) after recovery from the index episode (8).

In this article we report on a study in which patients who had recovered from an episode of primary, nonpsychotic major depression, and who had no previous history of mania or hypomania, were followed up for a period of 20–108 months by means of bimonthly personal interviews. We evaluated 1) the time to the first and second prospective recurrences, 2) the factors affecting the risk of recurrence at 2, 3, and 5 years after recovery from the index episode, 3) the stability of diagnosis during the observation period, 4) the severity and duration of prospective episodes as compared to the index episode, and 5) the pattern and prognostic significance of symptoms between episodes.

## METHOD

Subjects were recruited from a center for affective disorders at the University of Naples. All patients who recovered from an episode of primary, nonpsychotic major depressive disorder, defined according to the Research Diagnostic Criteria (RDC) (9), between Jan. 1, 1982, and Dec. 31, 1983, and who had no history of mania or hypomania were admitted to the study. Recovery was defined as 1) the absence, for at least 8 consecutive weeks, of the prominent dysphoric mood required by RDC criterion A for major depressive disorder and 2) the presence, during the same period, of no more than two symptoms listed in criterion B for major depressive disorder, each with a rating of no more than 1 on the Hamilton Rating Scale for Depression (10). The RDC diagnosis was made after the patient had been interviewed with the Schedule for Affective Disorders and Schizophrenia—Lifetime Version (SADS-L) (11). All interviews were conducted and all diagnoses were made by the same senior psychiatrist (M.M.), who had received formal training in the use of the RDC and the SADS within the framework of his collaboration with the World Health Organization and had had long experience in the application of these instruments in research settings.

The study group included 72 patients (30 male and 42 female) whose age at entry ranged from 27 to 55 years (mean=42.3 years, SD=6.6) and whose education level ranged from 2 to 17 years (mean=9.6 years, SD=3.6). Forty-seven patients (65.3%) were married, 17 (23.6%) had never been married, six (8.3%) were separated or divorced, and two (2.8%) were widowed. The mean age at onset of the first RDC major depressive episode was 32.6 years (SD=5.6). The index episode was the first RDC major depressive episode for six patients (8.3%), whereas 23 patients (31.9%) had had one or two previous episodes, and 43 (59.7%) had had three or more previous episodes. Eighteen patients (25.0%) had family histories of RDC major affective disorders (determined by using the Family History Research Diagnostic Criteria) (12). Forty-five patients (62.5%) were hospitalized for the index episode, and 27 (37.5%) were not. The mean duration of the index episode was 2.8 months (SD=1.9). The mean score on the Hamilton depression scale at the height of the episode was 21.8 (SD=3.3). According to the RDC, the index episode was of the endogenous type in 21 patients (29.2%); the episode was superimposed on a chronic and intermittent minor depressive disorder in 19 patients (26.4%) and on a cyclothymic personality in seven (9.7%). For 69 patients, the DST could be performed after recovery from the index episode (for methods, see reference 13). Nonsuppression was detected in 11 patients (15.3%).

All patients were instructed to visit the center bimonthly for clinical assessment. Treatment was decided by the psychiatrist in charge of each patient and was not under the control of the investigators. On each visit, patients were evaluated with the Comprehensive Psychopathological Rating Scale (14). The occurrence of RDC-defined major depressive, manic, schizoaffective, or schizophrenic episodes was ascertained by using the relevant sections of the SADS, and this information was recorded. If the patient was hospitalized, assessments were performed on the hospital ward. Recovery from the prospective episodes was defined by the same criteria that were used for recovery from the index episode. All interviews were conducted and all diagnoses were made by the same senior psychiatrist (R.P.), who was blind to the baseline information. He had received formal training in the use of the RDC, the SADS, and the Comprehensive Psychopathological Rating Scale, and his consistency with the initial rater (M.M.) in the application of each of these instruments had been formally assessed and found to be satisfactory (90% agreement or greater).

The duration of the observation period ranged from 20 to 108 months (median=66 months); it was 3 years or more for 64 patients (88.9%) and 4 years or more for 55 (76.4%). During this period, 53 patients (73.6%) received prophylactic medication with tricyclic antidepressants (at least 75 mg/day) or lithium carbonate (at least 600 mg/day) or both, whereas 19 patients (26.4%) received lower doses of these drugs or were not given prophylactic treatment. These two subgroups of patients did not differ significantly with respect to duration and severity of the index episode and number of previous episodes.

The probability of remaining well after recovery from the index episode was estimated at 2-month intervals up to 5 years by the life-table standardized method (15). The same method was used to obtain survival curves for patient subgroups defined by treatment received (no prophylactic treatment versus prophylactic treatment with tricyclic antidepressants, lithium, or both), number of previous episodes (three or more versus fewer than three), and whether or not the index episode was superimposed on a chronic and intermittent minor depressive disorder. Curves were compared by the Mantel-Haenszel test (15). An additional estimate obtained for the entire patient group, as well as for the subgroups, was the monthly rate of episodes (number of episodes per number of person-months observed) for the whole observation period and for each year of follow-up.

Stepwise multivariate logistic regression was used to analyze the effect of several variables on the risk of recurrence at 2, 3, and 5 years after the index episode. Variables included sex, age, education level, marital status, age at onset of illness, number of previous episodes, family history of major affective disorders, inpatient or outpatient status during the index episode, duration of the index episode, score on the Hamilton depression scale at the height of the index episode, RDC subtype of the index episode, presence or absence of an underlying chronic and intermittent minor depressive disorder or cyclothymic personality, and response on the DST at entry.

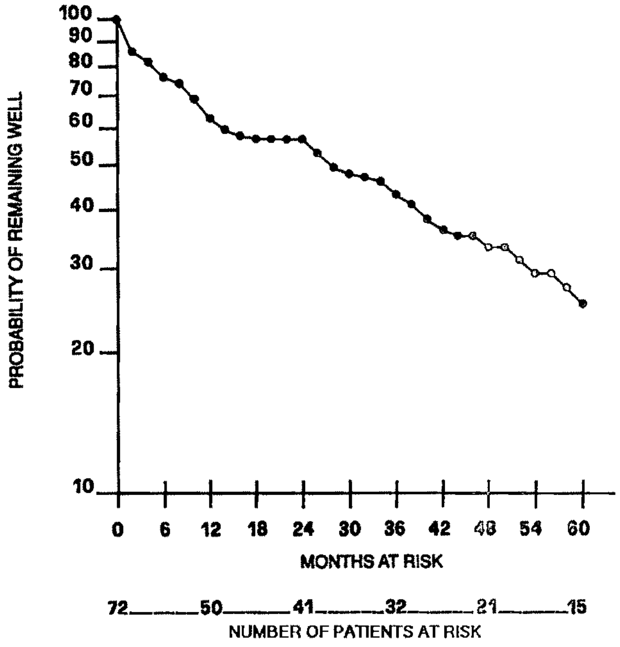
For the 51 patients who experienced a recurrence, the probability of remaining well after the first prospective episode (at 2-month intervals up to 3 years) was assessed by the life-table standardized method. For these patients, the cumulative probability of remaining well after recovery from the first prospective episode was compared with that after recovery from the index episode by using the Mantel-Haenszel test. Linear regression analysis was used to compare the severity and duration of the first, second, and third prospective episodes with that of the index episode. The same analysis was performed for the patient subgroups defined by treatment received.

Finally, the relation between the occurrence of each symptom on the Comprehensive Psychopathological Rating Scale during intervals between episodes and the risk of a recurrence in the subsequent year was evaluated by stepwise multivariate logistic regression.

## RESULTS

During the observation period, we recorded 120 episodes in the 51 patients with recurrences. The RDC diagnosis was nonpsychotic major depression in 97 episodes (80.8%), psychotic major depression in 13 (10.8%), mania in six (5.0%), schizoaffective disorder in three (2.5%), and schizophrenia in one (0.8%). Twenty-one (29.2%) of the 72 subjects did not have any episode during the observation period (which, for them, ranged from 38 to 96 months, with a median 64 months). Thirty-four patients (47.2%) had only episodes of nonpsychotic major depression, six (8.3%) had episodes of both nonpsychotic and psychotic major depression, five (6.9%) had episodes of both nonpsychotic major depression and mania, and three (4.2%) had only episodes of psychotic major depression. One patient had episodes of both nonpsychotic major depression and schizoaffective disorder, one had episodes of both psychotic major depression and schizoaffective disorder, and one had both schizoaffective and schizophrenic episodes.

**FIGURE 1. Cumulative Probability of Remaining Well for 72 Patients After Recovery From the Index Episode of Major Depression**



The cumulative probability of remaining well after recovery from the index episode was 86% at 2 months, 76% at 6 months, 63% at 1 year, 57% at 2 years, 43% at 3 years, and 25% at 5 years. A 50% probability was detected at 2 years and 4 months after recovery (figure 1). A significant difference in the probability of remaining well after recovery from the index episode was observed between patients who received prophylactic treatment and those who did not ($\chi^2=12.70$, df=1, $p<0.001$, Mantel-Haenszel summary) (figure 2) and between patients with three or more previous episodes and those with fewer than three episodes ($\chi^2=3.84$, df=1, $p<0.05$, Mantel-Haenszel summary) (figure 3). The difference between the survival curves of the patients with and the patients without an underlying chronic and intermittent minor depressive disorder was not significant ($\chi^2=1.99$, df=1, $p>0.10$, Mantel-Haenszel summary).

The monthly rate of episodes was 5% (declining from 7% in the first year of observation to 3% in the fifth year) in the entire patient group, 4% in treated patients, 9% in untreated patients, 3% in those with fewer than three previous episodes, and 7% in those with three or more previous episodes.

On stepwise multivariate logistic regression, the risk

FIGURE 2. Cumulative Probability of Remaining Well After Recovery From the Index Episode of Major Depression for 53 Patients Receiving and 19 Patients Not Receiving Prophylactic Drug Treatment

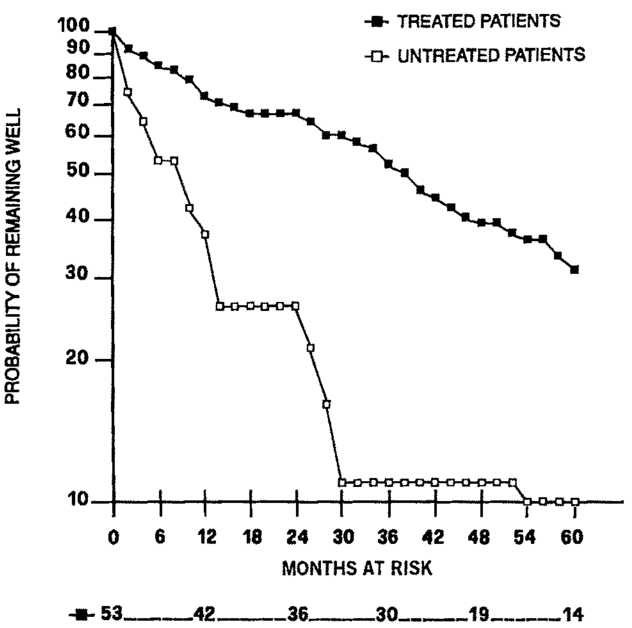


FIGURE 3. Cumulative Probability of Remaining Well After Recovery From the Index Episode of Major Depression for 29 Patients With Fewer Than Three and 43 Patients With Three or More Previous Episodes

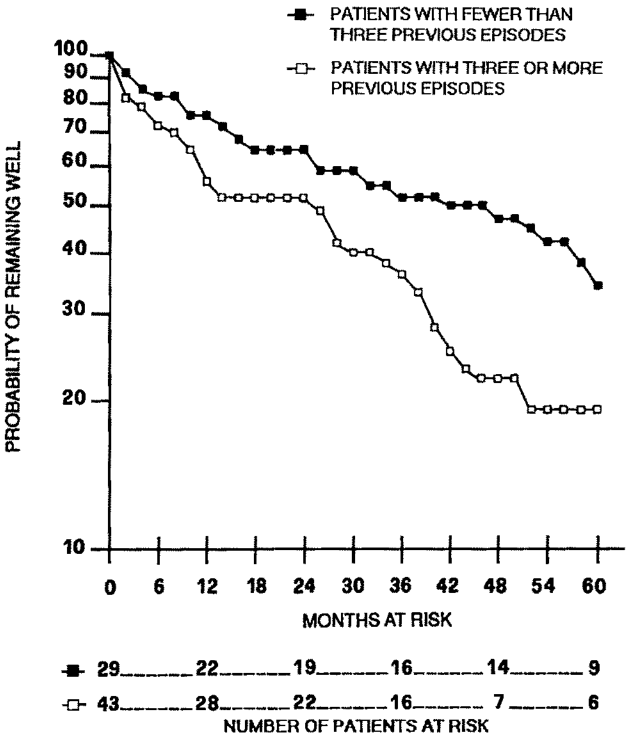

of recurrence at 2 and 3 years after recovery from the index episode was found to be affected only by the number of previous episodes (at 2 years, F=11.82, df=1, 64, $p<0.0001$; at 3 years, F=21.14, df=1, 58, $p<0.0001$), whereas the risk of recurrence at 5 years was affected by the number of previous episodes (F=15.01, df=1, 41, $p<0.0001$), by the presence of an underlying chronic and intermittent minor depressive disorder (F=12.24, df=2, 40, $p<0.0001$), and by a family history of major affective disorders (F=11.84, df=3, 39, $p<0.0001$).

For the 51 patients who experienced a recurrence, a 50% probability of remaining well after recovery from the first prospective episode was detected at 22 months. For these patients, the probability of being well was significantly lower 2 years after the first prospective episode than 2 years after the index episode ($\chi^2=4.23$, df=1, $p<0.05$, Mantel-Haenszel summary), whereas differences were not significant with respect to probabilities at 1 and 3 years.

On linear regression analysis, a pattern of increasing severity from the index episode to the first, second, and third prospective episodes was observed (F=13.74, df=1, 67, $p<0.0004$). The same pattern was found in the subgroup of patients who received prophylactic treatment (F=6.14, df=1, 56, $p<0.01$). No significant pattern in duration of the episodes was found.

During the observation period, we recorded at least one between-episodes symptom on the Comprehensive Psychopathological Rating Scale in 818 (38.0%) of 2,153 follow-up visits. The most frequently rated symptoms during the first 5 years of observation were lassitude (58.3% of patients and 8.7% of visits), sadness (50.0% of patients and 5.5% of visits), and reduced sleep (34.7% of patients and 4.3% of visits). Only four patients (5.5%) did not have any between-episodes symptom on the Comprehensive Psychopathological Rating Scale during the entire observation period (ranging, for them, from 42 to 60 months); all four of them were also free of prospective episodes. On stepwise multivariate logistic regression, the only between-episodes symptom on the Comprehensive Psychopathological Rating Scale whose occurrence was significantly associated with the risk of recurrence during the subsequent year was pessimistic thoughts (F=6.00, df=1, 110, $p<0.01$).

## DISCUSSION

The main strengths of this study are the following. 1) All patients were evaluated bimonthly by means of personal interviews throughout the follow-up period, so that the course of illness was directly observed rather than retrospectively reviewed on the basis of information provided by the patients (in particular, the assessment of the nature, duration, and severity of prospective episodes was as direct and accurate as that of the index episode). 2) Clear definitions of episode and recovery, based on the RDC and perfectly corresponding to those recently proposed by Frank et al. (16), were used, and attention was focused on recurrences (new episodes occurring after recovery) as opposed to relapses (returns of symptoms before recovery). 3) In the follow-up period, all of the interviews were done and all of the diagnoses were made by the same psychiatrist (thus eliminating the bias involved in changing the assessor from one patient to another or in changing the assessor for the same patient through a period which in some cases was as long as 9 years). 4) The psychiatrist who conducted all interviews and made all diagnoses during follow-up was blind to the baseline information on the patients, so that the expectations of the investigators did not affect the research findings.

The main limitation of the study is that it was carried out in a specialized university center, to which the most severe cases are especially likely to be referred. A reflection of this fact can be found in the percentage of first-episode patients, which was much lower even than that reported in studies conducted in similar university settings in the United States (2), suggesting that selection bias may be more pronounced in geographic areas (such as southern Italy) where very few specialized research centers are available. Because of this bias, the results of the study cannot be generalized to the entire population of patients with major depressive disorder.

Overall, this investigation confirmed that major depression has a high rate of recurrence, even when bipolar and psychotic cases are excluded. Within a period of 5 years, three of four patients who have recovered from a major depressive episode can be expected to undergo a recurrence. This figure is consistent with the estimate of the NIMH/NIH Consensus Development Conference Statement (17), according to which "between 50% and 85% of patients with a major depressive episode who seek treatment at university medical centers will have at least one subsequent episode of depression in their lifetime." It was also confirmed that the risk of recurrence is highest during the first months after an episode and decreases the longer the patient continues to stay well. This calls for careful monitoring and continuous treatment of patients who have just recovered from an episode of major depression. On the other hand, the tendency toward a decrease in the probability of remaining well after the first prospective episode was only partially verified; in particular, the probability was reduced at 2 years but not reduced at 1 year and 3 years.

A history of three or more major depressive episodes was found to be the most powerful predictor of an early recurrence after recovery from the index episode, whereas the evidence concerning the predictive value of the presence of an underlying minor depressive disorder was equivocal (the comparison between the survival curves of patients with and without this underlying disorder showed no significant difference, but the presence of the disorder was associated with a high risk of recurrence at 5 years after recovery from the index episode). The finding of a prognostic value of persisting nonsuppression of cortisol on the DST was not replicated. In this connection, it is important to emphasize that previous studies which reported this finding did not adequately define "recovery" from the index episode, so that persisting nonsuppression may have been related to incomplete remission of symptoms.

The impact of prophylactic treatment on the risk of recurrence in patients who have recovered from an episode of major depression is evident from our data. We recognize that in a naturalistic study, "treatment itself becomes an outcome, because the patient's state [is] likely to help determine the choice of treatment" (18). Nevertheless, since our patients who received prophylactic treatment did not differ significantly from those who did not receive it with respect to the duration and severity of the index episode and the number of previous episodes, we assume that the therapeutic habits of the psychiatrists in charge of the patients, and the patients' own attitudes toward treatment, were the main determinants of medication status in our study group, so that stratification of patients by treatment received is correct and useful.

If prophylactic treatment affects the risk of recurrence, it does not seem, however, to influence the severity of prospective episodes. In fact, a trend of increasing severity from the index episode to the first, second, and third prospective episodes was observed in both treated and untreated patients. This finding suggests that the prognosis of nonpsychotic major depression is worse than currently believed, even when adequate drug treatment is provided, and may call for more comprehensive, multimodal therapeutic strategies. The occurrence of psychotic and schizoaffective episodes during the observation period points in the same direction and suggests an overlap between nonpsychotic major depression on the one hand and psychotic major depression and schizoaffective disorder on the other. Moreover, the appearance of a schizophrenic episode in one of our patients confirms that "sequential schizoaffective disorder" (19), i.e., a disorder marked by the independent occurrence of affective and schizophrenic episodes in the same individual, is a possible, although rare, phenomenon.

This study confirmed that symptoms between episodes are frequent in patients who have recovered from an episode of major depression. We suggest that these symptoms, when they do not reflect an underlying personality disorder, may have at least three different meanings: they may be the prodrome of a new episode, they may be residual symptoms after an episode, or they may represent a "micro-episode" in themselves. In individual patients, specific symptoms may be more often prodromic, residual, or part of a micro-episode, but no generalization is possible. Apparently, there are symptoms whose occurrence is associated with an increased risk of recurrence during the subsequent year. This was true in this investigation for the Comprehensive Psychopathological Rating Scale symptom of pessimistic thoughts (defined as fluctuating or persistent thoughts of guilt, inferiority, self-reproach, sinfulness, remorse, and ruin). To relate this finding to cognitive models of depression is tempting but too speculative at this stage.

In conclusion, we believe that the investigation of the long-term course of nonpsychotic major depression can benefit greatly from the prospective follow-up of patients consecutively recruited and interviewed personally at short intervals and from the application of quantitative survival analysis techniques. Further research should, in our opinion, more thoroughly explore the influence of stressful events and social support on the course of illness, complementing the assessment of psychopathological status with the evaluation of psychosocial adjustment.

# Lithium, Benzodiazepines, and Sexual Function in Bipolar Patients

A.-Missagh Ghadirian, M.D., M.Sc., Lawrence Annable, B.Sc., Dip.Stat., and Marie-Claire Bélanger, R.N.

*Objective: Lithium and benzodiazepines are widely used in the treatment of bipolar patients. Yet studies of the effect of these drugs on sexual function are scarce. This study surveyed sexual function in bipolar patients treated with lithium, either alone or in combination with other drugs. Method: Sexual function was assessed by self-rating scale in 104 outpatients (45 men and 59 women) with a* DSM-III *diagnosis of bipolar disorder who were attending an affective disorders clinic. All patients were under treatment with lithium, either alone (35%) or in combination with benzodiazepines (49%), tricyclic antidepressants (17%), neuroleptics (17%), tryptophan (10%), or carbamazepine (1%). The patients were in a stable and euthyroid state at the time of the assessment. Serum lithium and plasma prolactin concentrations were measured at the same time. Results: Multiple regression analysis revealed an association between concomitant benzodiazepine administration and sexual dysfunction scores. Difficulties in sexual functioning were significantly more common in patients treated with a combination of lithium and benzodiazepines (49%) than in those treated with either lithium alone (14%) or lithium in combination with other drugs (17%). No relationship was found between serum lithium or plasma prolactin levels and sexual dysfunction scores. Conclusions: Lithium, when given alone, did not appear to have a major effect on sexual function, whereas its combination with benzodiazepines was associated with sexual dysfunction in about half of the patients. More attention should be given to drug-induced sexual dysfunction, since its presence can have important consequences for clinical management and compliance.*

(Am J Psychiatry 1992; 149:801–805)

Although a large number of manic-depressive patients are treated with lithium, reports in the literature concerning the effects of lithium on sexual function are scarce (1), conflicting, and primarily anecdotal. Whereas in one study (2), decreased libido was reported in 50% of patients receiving long-term lithium treatment, other investigators have found this effect to occur in less than 5% of patients (3, 4). Impairment in sexual functioning during long-term lithium treatment has been reported in a small percentage of patients (3, 4) or has been reported to be absent (2). In two case reports of sexual dysfunction associated with lithium treatment in male patients with bipolar I disorder, the effect disappeared with placebo substitution in one patient, while in the other there was a spontaneous remission during continued treatment (5). A comparison of sexual functioning in 24 patients with major affective disorder treated with lithium and in a control group of surgical outpatients failed to reveal any significant differences between the groups in the prevalence of sexual dysfunction (6). Little information is available from these studies on the effect of medications given with lithium on sexual function. The inhibiting effect of benzodiazepines on sexual function has previously been reported (7–9). Most of these reports, however, are either anecdotal or based on animal studies. Literature on the effect of benzodiazepines on large samples of bipolar patients is rare.

The mechanism of action of psychotropic medications on sexual function is not well understood. Three different mechanisms may be involved: 1) central: the drug effect at the CNS level may cause sedation and subsequent inhibition of sexual activity, 2) peripheral: this effect may lead to blockade of cholinergic and α-adrenergic receptors of the autonomic nervous system, which will interfere with sexual function, and 3) hormonal: this effect may appear in the form of hyper-

prolactinemia or reduced androgen action and elevated estrogen levels in men. None of these possible mechanisms has been clearly identified as being associated with the effect of lithium on sexuality.

In view of the scarcity and inconclusive nature of the data with respect to lithium and sexual functioning, we carried out a survey of sexual functioning in manic-depressive outpatients treated with lithium, either alone or in combination with other psychotherapeutic drugs, of which the most frequent were the benzodiazepines. The data collected allowed us to explore the relationships among lithium dose, serum lithium levels, plasma prolactin levels, concomitant medications, and self-assessments of sexual dysfunction.

## METHOD

Patients were recruited for this study from an affective disorders clinic. All patients attending the clinic were asked to participate in the study, and those who agreed gave written informed consent. The group studied consisted of 104 outpatients (45 men and 59 women) who had a *DSM-III* diagnosis of bipolar disorder and were under treatment with lithium. The patients ranged in age from 20 to 68 years (mean=45).

Thirty-six patients (35%) were being treated with lithium alone, and the remainder with a combination of lithium and one or more other drugs: 51 (49%) with benzodiazepines (43 of these with clonazepam at doses ranging from 0.5 to 12.0 mg/day [mean=2.2 mg/day]), 18 (17%) with tricyclic antidepressants, 18 with neuroleptics, 10 (10%) with tryptophan, one (1%) with carbamazepine, and one with a combination of estrogen and methyltestosterone. Of the 68 patients being treated with a combination of lithium and other medications, 43 were receiving one concomitant drug, 20 were receiving two concomitant drugs, and five were receiving three concomitant drugs. The duration of treatment with lithium varied from 1 month to 25 years (mean=6.7 years, median=6.0). Ninety percent (N=94) of the patients had been treated with lithium for 6 months or longer. Any comorbid medical condition that was noted was considered mild and stabilized or in remission at the time of the survey. Only 16 of the 104 patients were receiving nonpsychiatric medications, most of which were at low doses.

The patients were interviewed by the same psychiatrist, who completed Clinical Global Impression Scales of Depression and Mania (9-point scales), the Hamilton Rating Scale for Depression, and a rating scale for mania that consisted of five items assessing mania taken from the Inpatient Multidimensional Psychiatric Scale and four from the Brief Psychiatric Rating Scale. The ratings suggest that at the time of the interview, 96 patients (92%) had normal mood or nearly so, six (6%) were mildly depressed, two (2%) were moderately depressed, and none was manic.

At the same visit, the patients completed the self-rating scale for sexual dysfunction, in separate versions for men and women (10). The men's version of the scale includes nine items and a global assessment of sexual functioning, and the women's version includes six items, a global assessment of sexual functioning, and two items concerning menstrual changes. Each item was rated on a 4-point scale relative to a period of normal mood while the patient was not treated with lithium (0=no change, 1=mild change, 2=moderate change, 3=great change). The scale used was a revised version of a self-rating scale that we have shown to be valid and sensitive for the detection of changes in sexual function induced by neuroleptics (10).

Blood samples for the assay of serum lithium and plasma prolactin levels (11) were taken at the time the patient completed the rating scale for sexual dysfunction.

## RESULTS

The lithium doses and serum lithium and plasma prolactin levels in the patients who completed the rating scale for sexual dysfunction are summarized in table 1.

The distribution of scores for each item of the self-rating scale for sexual dysfunction is shown for male patients in table 2. To summarize, 58% of male patients reported no change in sexual functioning while taking medication, 23% mild changes, 9% moderate changes, and 9% great changes (item 10). Responses to individual items of the questionnaire revealed that the changes consisted of decreased sexual desire (43%), difficulty in getting or maintaining an erection (40%), decreased quality of orgasm (36%), and decreased quantity of ejaculate (32%). The majority of these changes were mild. Few men reported any increase in sexual desire (7%) or improvement in sexual functioning (11%).

The distribution of the sexual dysfunction and menstrual change scores for female patients is shown in table 3. On the global assessment item (item 9), 75% of women reported no change in sexual functioning, 5% mild changes, 5% moderate changes, and 15% great changes. Specific difficulties noted were decreased sexual desire (40%), decreased quality of orgasm (24%),

[a] Percents are based on number of patients for whom data were available.

decreased ability to have orgasm (26%), and pain during orgasm (4%). In women who were still menstruating, 35% reported disturbances in menstruation. In contrast to the results for men, 24% of women reported increased sexual desire while taking medication, and 22% reported improved orgasms.

Table 4 shows the overall assessment of changes in sexual function (item 10 for men and item 9 for women) classified by treatment combination. The results for men and women were pooled, since they did not show any statistically significant ($p<0.05$) differences in this respect. When given alone, lithium was associated with sexual dysfunction in 14% of patients. In contrast, 60% of patients receiving the lithium-benzodiazepine combination reported some degree of sexual dysfunction.

Stepwise multiple linear regression analyses were carried out for each sex separately to see whether lithium dose, serum lithium level, plasma prolactin level, age, or any of the classes of concomitant psychoactive medications being taken (benzodiazepines, tricyclic antidepressants, neuroleptics, tryptophan, and carbamazepine) were related to the global scores for the assessment of sexual dysfunction (item 10 for men and item 9 for women). For this purpose the stepwise inclusion method was used, with a significance level of $p<0.15$ for entry and retention in the model. Each of the classes of psychoactive medication was entered as a dichotomous dummy variable coded 1 or 0 according to whether or not the medication was being taken at the time of the survey. Only benzodiazepine intake was found to be related ($p<0.15$) to the global sexual dysfunction scores, and this relationship was stronger in women than in men (men: $F=2.68$, $df=1, 37$, $p=0.11$, $R^2=0.07$; women: $F=12.50$, $df=1, 55$, $p<0.001$, $R^2=0.19$). No relationship ($p<0.15$) was found between the global scores for sexual dysfunction and age, lithium dose, serum lithium concentration, or plasma prolactin concentration in either sex. When the patients were classified according to concomitant benzodiazepine intake, 49% of those taking benzodiazepines reported some degree of sexual dysfunction on the global assessment item, compared to 17% of those not taking benzodiazepines ($p<0.001$, Fisher's exact probability test, two-tailed). Clonazepam was the most frequent (86%) benzodiazepine taken.

Following this finding of an association between combined lithium and benzodiazepine intake and the global assessment of sexual dysfunction, we carried out exploratory stepwise multiple linear regression analyses in each sex on the individual items of the self-rating scale for sexual dysfunction to identify which aspects of sexual functioning were affected. Because this involved carrying out 17 separate multiple regression analyses, we used a stricter criterion of $p<0.05$ for entry and re-

[a] Percents are based on number of patients for whom data were available.

tention of terms in the model. Age, lithium dose, serum lithium level, plasma prolactin concentration, and concomitant medication type were included as explanatory variables. These analyses revealed that in men, concomitant benzodiazepine intake was associated with difficulty in getting an erection ($F=6.51$, $df=1, 39$, $p=0.01$, $R^2=0.14$), decreased quality of orgasm in some patients ($F=5.32$, $df=1, 39$, $p=0.03$, $R^2=0.12$), but improved quality of orgasm in others ($F=5.33$, $df=1, 38$, $p=0.03$, $R^2=0.12$). The only other significant ($p<0.05$) relationship detected among the specific symptoms in men was an association between increased libido and a high serum lithium level ($F=17.82$, $df=1, 38$, $p<0.001$) but a low lithium dose (negative relationship, $F=4.26$, $df=1, 38$, $p=0.05$, $R^2=0.33$); however, this finding should be balanced against the fact that only three of 44 men who responded to this question reported an increase in libido since beginning medication.

In women, benzodiazepine intake was associated significantly ($p<0.05$) with absence of change in quantity of menstrual blood loss ($F=4.12$, $df=1, 39$, $p=0.05$, $R^2=0.10$). The only other significant ($p<0.05$) relationship detected among the specific symptoms in women was an association between increased libido and low lithium dose ($F=5.16$, $df=1, 55$, $p=0.03$, $R^2=0.12$).

Age was not significantly ($p<0.05$) related to any of the sexual dysfunction items in either men or women.

## DISCUSSION

Mania and depression have different effects on human libido and sexual behavior. In view of the fact that hypersexuality is a common finding in manic episodes (and even paradoxically in some depressive states), it may be difficult for a bipolar patient to make an objective judgment of his or her sexual function while treated with lithium. Often these patients perceive their sexual excitement during the manic phase as a pattern of sexual function to be expected after improvement. On the other hand, patients with underlying depression and decreased libido may assume that it is the medication which perpetuates their sexual impairment. Indeed, many of these patients become noncompliant as a result of this misconception.

The results of the present study suggest that it is unlikely that lithium, when given alone, has a major effect on the sexual functioning of bipolar patients receiving long-term prophylactic therapy. Only 14% of 36 patients treated with lithium alone reported any sexual difficulties, and there was no significant relationship between serum lithium level or lithium dose and the scores for global sexual functioning. The majority of the changes in sexual function reported during treatment with lithium alone were of a mild nature. This is in conflict with some of the previous findings, particularly from studies of the effect of lithium on normal control subjects (12, 13), which concluded that lithium has an inhibitory effect on male sexual desire or behavior. However, the effect of lithium on healthy volunteers may not be the same as that on manic-depressive patients.

The most important finding from this study was that the majority of cases of sexual dysfunction reported were associated with concomitant benzodiazepine, largely clonazepam, intake. About 50% of the patients treated with a combination of lithium and benzodiazepines complained of some degree of sexual difficulty regardless of whether a third medication was present or not. The inhibition of sexual response with benzodiazepines has previously been reported (7–9, 14). Because all of the patients included in this study were receiving lithium, it is impossible to say from these results whether benzodiazepines alone or the lithium-benzodiazepine combination was the causal factor. There is also the possibility that lithium may potentiate the effect of benzodiazepines on sexual function. In men, reduced libido occurred in 43% of all those surveyed, and the multiple regression analyses revealed that concomitant benzodiazepine intake was specifically associated with difficulties in getting an erection and diminished quality of the orgasm. In women, no specific form of impairment in sexual functioning associated with benzodiazepines could be identified despite the fact that the relationship between concomitant benzodiazepine intake and the global assessment of sexual dysfunction was of greater statistical significance than in men. However, this failure to identify specific problems associated with concomitant benzodiazepines in women may be a limitation of the group size, and it should be noted that among all women surveyed, reduced libido was reported in 40%, decreased ability to have an orgasm in 26%, and decreased quality of orgasm in 24%. Furthermore, the sexual dysfunction associated with the lithium-benzodiazepine combination could not, in either sex, be linked to any unique pathological traits that distinguished patients who were receiving concomitant benzodiazepines from those who were not. Insomnia could have been a factor in benzodiazepine administration, but in the absence of other symptoms of importance, it did not constitute a significant psychopathological development.

Most research studies of drug effects on human sexual behavior involve men and rarely women. In our previous study of schizophrenic patients (10), we found that women were as vulnerable to the adverse effects of antipsychotic drugs as men. The results from the present study suggest that women with bipolar affective disorder treated with lithium and other drugs were slightly less at risk for sexual dysfunction than men. Menstrual changes since beginning medication were reported in approximately 35% of all women surveyed but could not be linked to any specific drug. On the other hand, concomitant benzodiazepine administration appeared to be associated with less change in quantity of menstrual blood loss since beginning medications.

There are a number of methodological issues that have an important bearing on the study of drug effects on sexual function. Among them, age, current state of mood, and the use of concomitant psychotropic medications are but a few variables that can have an important effect on the interpretation of the results. Many reports tend particularly to ignore the effects of concomitant medications on sexual function. Moreover, hypothyroidism caused by lithium can also affect sexual drive and behavior. In the present study, the patients were stable and in a euthyroid state at the time of their evaluation, with the exception of a few mild mood changes. In addition, no relationship was found between age and sexual dysfunction. Other factors that impede efforts to reconcile the conflicting results of different research studies are the lack of a standard nomenclature of sexual dysfunction and standard measurement instruments.

More research is warranted to explore the effects of psychotherapeutic drugs on human sexual function. One way to study further the apparent relationship between concomitant lithium-benzodiazepine treatment and sexual dysfunction observed here would be temporary withdrawal and subsequent readministration of each drug in turn. Changes in sexual functioning could thus be ascribed with some degree of certainty to one or other of the drugs or to their combination. Such a procedure would, however, need to be carried out in stable, euthymic patients with particular attention to ethical considerations.

# Learned Helplessness and Urinary MHPG Levels in Unipolar Depression

Jacqueline A. Samson, Ph.D., Steven M. Mirin, M.D., Stuart T. Hauser, M.D., Ph.D., Brenda T. Fenton, and Joseph J. Schildkraut, M.D.

*Objective: Studies of the learned helplessness paradigm in laboratory animals show increased central noradrenergic activity following exposure to uncontrollable stressors. In clinical studies, depressed patients as a group report higher perceptions of helplessness and powerlessness. The authors examined the relationship between perceptions of powerlessness and noradrenergic activity in depressed patients. Method: Twenty drug-free patients (12 women and 8 men) meeting* DSM-III *criteria for major depressive disorder were given the Kobasa Hardiness Questionnaire, which contains subscales measuring feelings of powerlessness, security, and alienation. Concurrently, 24-hour urine samples were collected for measurement of urinary MHPG. Results: Significant correlations were found between MHPG levels and total hardiness scores as well as between MHPG levels and total powerlessness scores but not between MHPG levels and total security or total alienation scores. Conclusions: These results suggest that depressed patients with high urinary output of MHPG are more likely to show the cognitive features of learned helplessness.*

(Am J Psychiatry 1992; 149:806–809)

Since the initial report of Overmier and Seligman (1), numerous studies have confirmed and refined the learned helplessness phenomenon in laboratory animals. The standard laboratory paradigm exposes animals to uncontrollable and unpredictable stressors such as foot shock or noise in a pretest session. This is followed by a test session in which animals must learn to perform a response such as shuttle avoidance or lever press to terminate a stressor. In general, animals exposed to uncontrollable stressors show persistent deficits in performing the avoidance response. Seligman (2) has proposed that through exposure to the initial uncontrollable and unpredictable stressor, the animals learn that outcome is independent of response. This learning may then become generalized so that subjects respond with inactive behaviors or "helplessness" in the presence of future stressors.

The majority of laboratory studies support the notion suggested by Garber et al. (3) that exposure to uncontrollable and unpredictable stressors results in decrements in the spheres of motivation, cognition, and emotion that parallel certain symptoms associated with depressive disorders in clinical populations (3–5). Of importance, motivational decrements in animals exposed to uncontrollable stressors have been shown to be prevented by pretreatment with antidepressants (6–8) and reversed following treatment with imipramine (9) or nortriptyline (10). Hence, the learned helplessness paradigm has been suggested as an animal model for certain types of depressive disorders.

In animals, learned helplessness is associated with a higher rate of release of norepinephrine in the brain, as reflected by higher levels of the norepinephrine metabolite 3-methoxy-4-hydroxyphenylglycol (MHPG) in whole brain (11, 12) and lower norepinephrine levels in a variety of brain regions (13, 14). These findings correspond to clinical observations that the onset of major depressive illness is often associated with exposure to stressors (15) and that certain subtypes of depressive disorders are associated with alterations in catecholaminergic neurotransmitter functioning (16–20). Of relevance, patients with depressive illnesses show heterogeneity with regard to urinary MHPG output, leading our group to suggest that patients with high MHPG output may have a distinct subtype of depressive illness (21).

In clinical studies, there is evidence that depressed patients, as a group, report perceptions of helplessness or powerlessness (22) and that these beliefs tend to decrease as the depressive illness improves. In this study, we ex-

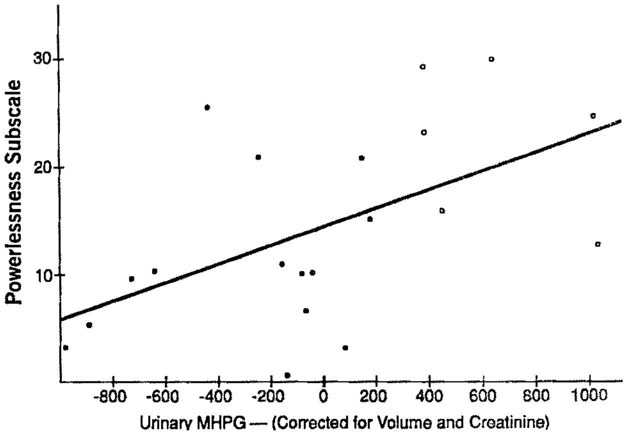
**TABLE 1. Correlations Between Scores on the Kobasa Hardiness Questionnaire and Urinary MHPG Levels in 20 Depressed Patients**

| | Correlation With MHPG | |
|---|---|---|
| Measure | r | p[a] |
| Total hardiness | –0.43 | 0.05 |
| Total alienation | 0.26 | n.s. |
| Total security | 0.38 | 0.09 |
| Total powerlessness | 0.46 | 0.04 |
| Powerlessness subscale derived from the Maddi Alienation Test | 0.51 | 0.02 |
| Rotter Internal-External Locus of Control Scale score | 0.28 | n.s. |

[a] Probability levels are two-tailed, df=18.

**FIGURE 1. Urinary MHPG Levels and Scores on the Kobasa Hardiness Questionnaire Powerlessness Subscale Derived From the Maddi Alienation Test in 20 Depressed Patients[a]**



[a] Urinary MHPG values were statistically adjusted for total volume and creatinine levels. The line running through the scattergram represents the line of best fit for the two variables (r=0.51, p=0.02).

amine the relationship between noradrenergic neuronal activity (as reflected by urinary MHPG levels) and perceptions of powerlessness in a group of hospitalized clinically depressed patients. Based on previous work from our laboratory and others, we hypothesized that higher levels of urinary MHPG would be associated with higher scores on measures of perceived powerlessness.

## METHOD

The patient sample consisted of 20 clinically depressed inpatients seen in two private psychiatric settings. For this study, we considered only those patients who were free from major medical disease and who showed no history of drug or alcohol abuse or addiction. A clinical *DSM-III* diagnosis of unipolar major depressive disorder and a minimum score of 18 on the Hamilton Rating Scale for Depression (21-item version) were required. The resulting sample consisted of eight men and 12 women who ranged in age from 17 to 57 years, with a mean of 31 years (SD=11). The mean Hamilton Depression Rating Scale score for the sample was 30 (SD=5).

On admission to the study, patients were asked to complete the Kobasa Hardiness Questionnaire (23), which includes the Rotter Internal-External Locus of Control Scale (24). One to three consecutive 24-hour urine samples were collected for determination of urinary MHPG and creatinine levels. MHPG levels were subsequently determined by using a modification of the method of Dekirmenjian and Maas (25), and creatinine levels were determined by using a modification of the Jaffe reaction. Biochemical determinations were performed by laboratory staff who were blind to the clinical data, and clinical information was obtained by staff blind to biochemical data. All patients had been free of psychoactive medication for at least 10 days before urine collections. Information on drug use for periods other than immediately prior to admission was not available and was not used in sample selection. Informed consent was obtained before all data collection procedures.

Pearson correlational analyses (two-tailed) were performed by using SPSS-X software. Perceptions were quantified first by using the total score from the Kobasa Hardiness Questionnaire calculated by summing z score equivalents from each of the components (26) and changing the sign so that a positive score indicated hardiness. Second, the total scores on each of the three scales making up the Kobasa Hardiness Questionnaire (i.e., alienation, security, and powerlessness) were examined separately by using the summed z scores of the scale components. Finally, the components making up the total powerlessness score were examined separately. As described by Kobasa et al. (26), these component scales included the powerlessness subscale derived from the Maddi Alienation Test and the Rotter Internal-External Locus of Control Scale. To correct for the effects of urine volume and creatinine on measures of urinary MHPG, urine volume and creatinine levels were statistically partialled from MHPG measures by using regression analysis, as recommended by Maes et al. (27).

## RESULTS

As shown in table 1, significant correlations were found between urinary MHPG levels and total hardiness scores as well as between urinary MHPG levels and total powerlessness scores but not between urinary MHPG levels and total alienation or total security scores. Examination of the components of the total powerlessness score showed a significant correlation between MHPG levels and scores on the powerlessness subscale derived from the Maddi Alienation Test but not between MHPG levels and scores on the Rotter Internal-External Locus of Control Scale. Figure 1 depicts the correlation between the powerlessness subscale derived from the Maddi Alienation Test and MHPG levels.

To control for the possibility that correlations were affected by age, sex, or severity of the depressive disorder, the data were analyzed statistically partialling for the effects of age, sex, and Hamilton Rating Scale for Depression score. Since one depressed subject refused to be scored on the baseline Hamilton Rating Scale for Depression, these analyses included only 19 of the 20 subjects. After statistical adjustments, the correlation between MHPG levels and total hardiness scores decreased in magnitude below significance levels (r=0.39, df=14, p=0.13) but significant correlations remained for the total powerlessness subscale (r=0.53, df=14, p=0.03) and for the powerlessness subscale derived from the Maddi Alienation Test (r=0.55, df=14, p= 0.03). As in the previous analyses, the subscale scores for total alienation and total security showed no significant correlation with MHPG levels.

## DISCUSSION

The results of the present study showed that the significant correlation between total hardiness scores and urinary MHPG levels was primarily influenced by a correlation between powerlessness scores on the Kobasa Hardiness Questionnaire and urinary MHPG levels. Further analyses showed that the association between MHPG levels and powerlessness was primarily influenced by the scores on the powerlessness subscale derived from the Maddi Alienation Test rather than the scores on the Rotter Internal-External Locus of Control Scale. The association found between perceptions of powerlessness and 24-hour urinary MHPG levels supports our initial hypothesis and provides a parallel for previous findings from our group showing an association between learned helplessness and higher brain levels of MHPG in animals (11, 12).

Although both the powerlessness subscale from the Maddi Alienation Test and the Rotter Internal-External Locus of Control Scale scale tap into perceptions of powerlessness, there are subtle differences between the two scales. The powerlessness subscale from the Maddi Alienation Test contains 15 items, seven of which concern the degree to which society in general or specific others control one's actions. In contrast, the Rotter Internal-External Locus of Control Scale contains 23 items, virtually all of which measure the degree to which an individual feels a lack of control due to chance, fate, luck, or forces he or she does not understand. Our results indicate that it is powerlessness defined as the belief that others are actively controlling one's life which correlates with urinary MHPG levels.

The present findings suggest that there is a link between cognitive processes associated with coping responses and noradrenergic neuronal activity as reflected by urinary MHPG levels. Of interest, in a 17-month follow-up of subjects residing in the area of Three Mile Island, Schaeffer and Baum (28) found an association between the use of positive cognitive reappraisal coping behaviors and lower levels of urinary norepinephrine. Taken together with the results in our current report, these findings suggest the possibility that noradrenergic neuronal activity is related to the cognitive interpretation constructed by the individual to explain environmental events—higher norepinephrine output is associated with perceptions of powerlessness, and lower norepinephrine output is associated with perceptions of mastery. Whether norepinephrine output per se represents a heightened stress response in individuals who construct negative appraisals or whether elevated norepinephrine output detrimentally affects the ability to formulate positive appraisals is not clear and will require further research.

Previous animal studies from our group (12) have demonstrated that the motivational decrements of helplessness as well as a higher rate of release of norepinephrine in the brain may be elicited by neutral environmental stimuli if the neutral stimuli have been paired previously with an uncontrollable stressor. These findings suggest the additional possibility that elevated norepinephrine output may reflect conditioned physiological responses to conditioned environmental stimuli. Recent studies (29) showing higher rates of perceptions of helplessness in depressed women who had experienced the loss of their mothers in childhood support the notion of helplessness as a conditioned response in clinical populations.

Although there is a lack of consensus as to the exact proportion of urinary MHPG that is derived from the CNS as opposed to the periphery (30–32), the evidence remains that urinary measures of catecholamines and their metabolites appear to be useful predictors of both diagnosis and treatment response in depressed patients (16–21, 33–42). Finally, treatment response studies from our group (35–39) and others (40–42) suggest that depressed patients with high urinary MHPG levels are less likely to respond to standard noradrenergically active tricyclic antidepressants such as imipramine, desipramine, and maprotiline than are depressed patients with low urinary MHPG levels. Given our current findings of an association between high urinary MHPG levels and perceptions of powerlessness in patients with unipolar depression, it may be that cognitive-behavioral interventions such as those developed by Beck (43) will prove to be beneficial for these patients.

# Crack/Cocaine Abusers in the General Hospital: Assessment and Initiation of Care

Charles Rohrs, M.D., and Hugo Franco, M.D.

*Objective:* Cocaine, either smoked (as "crack") or taken intranasally, is now a common cause of psychiatric illness. This study was designed to assess the impact of cocaine abuse on a general psychiatric service and an obstetrics service in an urban general hospital and to evaluate a program for engaging affected patients in addiction treatment. *Method:* The charts of 300 general psychiatric patients (not admitted for addiction treatment) and 60 cocaine-abusing prenatal or postpartum patients were reviewed. A treatment referral program based on professionally directed peer leadership was established for patients with cocaine abuse. Results of evaluation and referral of 100 other cocaine-abusing psychiatric patients and the 60 prenatal or postpartum patients were then determined. *Results:* Fully 64% (N=191) of the 300 psychiatric patients were diagnosed as substance abusers; 38% (N=113) of them abused cocaine. Almost one-third of these cocaine abusers had no axis I diagnosis other than substance abuse/dependence, and the majority were homeless. Urine samples were positive for cocaine in a majority of the obstetric patients studied. A majority of the psychiatric patients who were referred through the peer-led program enrolled in outpatient cocaine treatment—three times as many as in the chart review group. Most of the obstetric patients suitable for referral enrolled for treatment as well. *Conclusions:* Cocaine abuse may be responsible for a large portion of psychiatric admissions in urban public general hospitals. Cocaine abusers in psychiatric and obstetrics services are apparently responsive to a peer-oriented mode of referral into treatment.

(Am J Psychiatry 1992; 149:810–815)

Abuse of cocaine, whether smoked (as "crack") or taken intranasally, is arguably the most serious psychiatric problem to emerge in the United States in the last decade. Two groups of patients in particular are important to this problem: those admitted to a hospital because of psychiatric sequelae of cocaine addiction and women addicted in the perinatal period. Generally, however, only issues that are immediately related to the hospitalization, such as acute depression or agitation in the former group (1, 2) and delivery and perinatal morbidity in the latter (3, 4), are addressed during a hospital stay. If cocaine-abusing patients are to be drawn into effective outpatient rehabilitation, however, it is necessary to ascertain the nature of this problem in the general hospital and to reorient some parts of the treatment system accordingly. To address this need, we examined an addicted population and developed a model of professionally directed, peer-led intervention for introducing cocaine-abusing patients into long-term treatment. This model drew on both the psychiatric consultation-liaison approach and the drug-free therapeutic community modality for addiction.

## METHOD

The study was carried out at a center-city municipal general hospital in New York that has 1,171 beds, of which 269 are designated for adult general psychiatry and 30 for obstetrics.

On the psychiatry unit, charts of 300 sequentially admitted patients were reviewed with a structured format adapted from the *DSM-III-R* diagnostic criteria for substance abuse and dependence and the Addiction Severity Index (5). Patients admitted to a designated substance abuse treatment service were not included in this

assessment, as the evaluation was directed only at patients hospitalized for psychiatric indications not having to do with addiction, namely, harmfulness to self or others. A diagnosis of substance abuse or dependence was made from the general psychiatric charts by using the discharge diagnosis assigned by the attending physician or, in the absence of such a diagnosis, the patient's fulfillment of specific *DSM-III-R* criteria on the basis of chart notes indicating relevant signs, symptoms, and history. Characteristics of the following subgroups were then examined in detail: 1) patients who could be diagnosed as abusers of or dependent on either alcohol or any illicit drugs (among these we examined patients who abused cocaine, with or without other drugs) and 2) patients for whom no diagnosis of substance abuse or dependence could be made.

On the obstetrics unit, the clinical staff routinely screened newborns for apparent addiction because of the acknowledged high rate of cocaine abuse among women who gave birth to babies at the hospital. Hospital regulations allow testing of the urine of a newborn for drugs of abuse if addiction is suspected in the mother, and this was generally done when clinically indicated. Using the *DSM-III-R* criteria for abuse or dependence, the obstetrics staff designated a series of 40 postpartum patients for consultation for cocaine problems. Clinical and toxicology findings were assessed as a means of determining the impact of cocaine on patients in the perinatal period. An additional 20 perinatal patients were referred from prenatal and pediatric services for cocaine evaluation.

In the referral program, cocaine-abusing inpatients were approached on both the general psychiatry service and the obstetrics service by a liaison team from the hospital's cocaine treatment clinic to encourage them to accept referral to the clinic after discharge. These patients had been admitted to the hospital after the original chart review. The team, designed to emphasize the peer leadership model in the clinic, consisted of a recovering addict and an addiction counselor who had achieved recovery from drug dependence, supervised by a social worker.

For psychiatric patients, a 27-bed general psychiatric ward was used as the site of the referral program for this study. Staff on this ward were sensitized to the needs of patients with both psychiatric and substance abuse diagnoses through a series of discussion meetings that served to alert them to the benefits of the aftercare program and the role of a peer leadership model in liaison. A twice-weekly discussion group focusing on self-help and addiction aftercare was conducted for cocaine-abusing patients. Patients in the referral program were also brought to visit the cocaine clinic while they were still in their index hospitalization, so as to expose them to their peers and introduce them into the peer-led milieu at the clinic. Records of the hospital's ambulatory psychiatric (and addiction) services were then examined to ascertain which of the patients who had been in the referral program and which of those studied in the chart review had appeared for treatment within 3 months of discharge from the inpatient service.

On the obstetrics service and in the prenatal clinic, patients were contacted by team members and evaluated individually. Postpartum patients were typically referred to the team by the obstetrics social workers if they were suspected of cocaine abuse on clinical assessment or if their newborns' urine was positive for cocaine. The social workers on the obstetrics service generally indicated to these patients that clinic attendance was an alternative to possible placement of the newborn in foster care.

This referral approach was modeled on techniques of peer-led addiction treatment in the general hospital that we had studied previously (6, 7). Patient peers from the cocaine treatment clinic were introduced into both clinical settings, obstetric and psychiatric, with considerable preparation of on-site staff, so as to develop a cooperative working relationship with those responsible for inpatient care. Conferences were held with medical and ancillary staff members to explain the role of cocaine dependence in the presenting pathology, options in effecting referral, and the nature of peer-led treatment. In addition to receiving counseling by the cocaine clinic team, patients were invited to a weekly peer-led meeting at the cocaine clinic, and contact was maintained with patients designated for referral while they were in the hospital.

## RESULTS

The review of charts of 300 patients from the general psychiatric service, all admitted on general psychiatric indications, revealed a high prevalence of addictive disorders, which were associated with severe social disadvantage. Information on the charts showed that 191 (64%) of the patients met criteria for a *DSM-III-R* diagnosis of substance abuse or dependence, most commonly involving alcohol (N=145, 48% of the entire 300), cocaine (N=113, 38%), marijuana (N=50, 17%), and heroin (N=32, 11%). Immediately before hospitalization, more than half of the substance-abusing patients were homeless; that is to say, they were either living in the streets (N=68, 36%) or in municipal shelters (N=32, 17%). The psychiatric illness of these substance abusers also represented a major burden on the health care system, as their mean length of hospital stay was 26.4 days (SD=21.2), and the large majority (N=159, 83%) had previously undergone psychiatric hospitalization. The charts indicated that almost all of these patients had been referred to the hospital's ambulatory psychiatric clinics, but despite this, only 12 (6%) of the patients actually appeared there within 3 months of discharge.

The nature of the cocaine-abusing patients (N=113) within the sample of 300 admissions is illustrated by contrasting them with the patients whose charts revealed no substance abuse whatever (N=109). The cocaine-abusing patients were different on a number of variables, revealing their particular clinical needs beyond their drug use per se. They were significantly younger (mean age=

32.9 years, SD=7.9, compared to 41.6 years, SD=7.9; t=5.54, df=168, p<0.001). They were also more likely to be male, black, and homeless, and much more likely to have only a substance abuse diagnosis on axis I (table 1). Furthermore, their average length of stay was somewhat shorter (mean=24.4 days, SD=20.9, compared to 37.7 days, SD=28.6; t=3.94, df=197, p< 0.001). The large majority (N=87, 77%) of the cocaine patients had been given a diagnosis of dependence or abuse by their attending physician; that is, they were generally not undiagnosed. Despite this, only seven (6%) of these patients were referred to the ambulatory psychiatric clinics after discharge and then enrolled.

The clinical staff on the obstetrics ward designate certain postpartum patients as apparent cocaine abusers on the basis of history and clinical findings. A series of 40 women designated in this fashion were evaluated by the liaison team. Urine toxicology screening was done on these mothers and their newborns, and in 24 (60%) of these cases, the urine of one or the other was positive for cocaine. The mean birth weight of the 40 infants was 2810 g (SD=735), and eight (20%) were of low birth weight or "premature" ($\le$2500 g). The majority of these women (N=29, 73%) had previously had children placed in the custody of others, and the majority (N=26, 65%) currently had an open custody case with the city's Child Welfare Administration. Another 20 women were also referred to the cocaine clinic from other hospital sites, primarily from the prenatal clinic (N=12).

In a comparison of the 60 patients from the obstetrics and prenatal clinics and the first 100 psychiatric patients evaluated in the cocaine referral program, the women in the perinatal period were significantly younger (mean age=27.3 years, SD=4.7, compared to 31.3 years, SD=8.5; t=3.73, df=168, p<0.001). The large majority of both groups abused crack cocaine, but the psychiatric patients were more likely than the patients in the perinatal group to have also abused cocaine by the intranasal route and abused other drugs as well (table 2). Although the patients referred from the psychiatric ward were more likely to be homeless, it is notable that very few patients in the perinatal group (N=7, 12%) actually lived in their own homes.

The outcome of the referral program is illustrated in table 2. The majority of the patients referred from both the perinatal group and the psychiatric group to the cocaine clinic enrolled in the cocaine clinic, and five additional patients from the psychiatric group enrolled in the general psychiatric clinics. The mean amount of time between these patients' discharge and their appearance at the clinics was 10.6 days (SD=14). The psychiatric patients were less likely to be referred, however—most commonly because they left the hospital early, against medical advice; others required transfer to long-term facilities or were from remote counties. Altogether, however, more than three times as many cocaine patients in the psychiatric group exposed to the referral program as in the chart-review group eventually enrolled in the ambulatory clinic (22 of 100 versus seven of 113; $\chi^2$=11.3, df=1, p<0.001).

## DISCUSSION

By its very nature, the prevalence of crack/cocaine abuse is hard to measure, particularly among the homeless and indigent. In the Epidemiologic Catchment Area study, for example, a 1-month prevalence of cocaine use of 0% (rounded) was reported (8), but this survey

was carried out in 1980, before the current "crack epidemic" emerged. The National Household Survey on Drug Abuse reported a 1-month prevalence of cocaine use during 1988 of 1.5% (9), but the White House Office of National Drug Control Policy later estimated that the number of heavy cocaine users was more than twice that reported by this survey (10). Furthermore, the federal Drug Abuse Warning Network tabulates emergency room "mentions" of drugs but cannot describe the full impact of these drugs on patients' health or the cost of attendant pathology in added health services.

Even these figures do little to convey the impact of the cocaine epidemic on the highly disadvantaged and often homeless patients served by public general hospitals, and they do not convey the magnitude of the task that confronts psychiatry in such hospitals in meeting the treatment needs of this population. Reports on drug abuse diagnoses among hospitalized psychiatric patients also often underestimate the problem, since drug abuse may be considered a secondary problem or often go unmentioned, even when it is actually instrumental in the admission. This was first pointed out by Crowley et al. with respect to emergency room admissions (11) and was underlined most recently by Haugland et al. (12), who surveyed directors of general hospital psychiatric services (not addiction services) in New York State on the "dual diagnosis" problem in their facilities. On average, the directors of psychiatric services reported that 31% of their patients were substance abusers, considerably higher than the 15% reported by the state's official database (13).

Our own finding of a prevalence of 38% for cocaine abuse among patients admitted for general psychiatric indications to a center-city public hospital may be more representative of such facilities than is generally appreciated. We found that fully 32% of these cocaine abusers had no other axis I diagnosis, in contrast to the nondrug-abusing psychiatric patients, almost all of whom had axis I diagnoses not associated with substance use. It is unlikely that most of this 32% of cocaine-abusing patients who were admitted (i.e., 12% of all psychiatric admissions) would have required hospitalization in the absence of cocaine use. Furthermore, given the exacerbation of existing psychopathology produced by cocaine (1, 2, 11), it may well be that the current crack/cocaine epidemic precipitated as many as 20% of the general psychiatric admissions to this facility, even though the length of stay was somewhat shorter than that of patients without cocaine abuse. These findings merit replication in a larger, national sample to ascertain true prevalence rates of cocaine-related psychopathology among psychiatric admissions.

Adding further to the burden of the crack/cocaine epidemic on general hospital facilities is the fact that the large majority of the cocaine patients were recidivists and had protracted hospital stays. They were also more likely to be black and homeless than were the patients with single diagnoses and were therefore disadvantaged in terms of available community resources. Furthermore, over one-half of the 20% who were tested for HIV were seropositive, portending a serious risk for transmission, given the reported prevalence of high-risk behavior among these patients (14).

Any assessment of the impact of cocaine in general hospitals must inevitably attend to the issue of perinatal morbidity as well. As Chavkin (3) pointed out, in New

York City 11%–20% of toxicology screens on women in labor in inner-city hospitals are positive for illicit drugs, mostly crack/cocaine; nonetheless, a survey she conducted revealed that the majority of drug treatment programs did not accept pregnant addicts (3). In our hospital as well, urinalyses for a group of 125 women selected at random from those admitted to the obstetrics ward showed 15 (12%) to be positive for cocaine (personal communication from M. Allen). Furthermore, as indicated in our results, the mean birth weight for the babies of the 40 apparent cocaine abusers in our perinatal study group was quite low, a standard deviation below the mean birth weight (3300 g, SD=519) of all live births at the hospital. The rehabilitation problems confronting this population are grave as well, since few of the patients in the perinatal group we evaluated lived in their own homes, and the majority had low-birth-weight babies and were involved in child custody cases.

The task of engaging crack/cocaine patients in addiction rehabilitation is a difficult one, given the very high dropout rates expected from these patients even before treatment is initiated (15). Except for noting dropout as an artifact, however, there has been little attention to this problem in the literature on general hospitals. In our hospital, as in many others, charts generally indicate that a referral was made to the hospital's psychiatric outpatient service, without reflecting the social and communication supports necessary to ensure that patients will appear for treatment. Patients with dual diagnoses, who are likely to be influenced strongly by denial of their addiction, typically ignore the suggested follow-up option unless considerable effort is invested in ensuring an effective referral. Furthermore, 22% of our cocaine abusers were diagnosed in accordance with the *DSM-III-R* criteria upon chart review by the research staff, but they were not given formal diagnoses in the clinical charts by the attending physician. This reflects a further bias against proper referral.

Central to the problem of engagement of these cocaine abusers in aftercare is the absence of a meaningful interpersonal context in which motivation for treatment can be generated while they are in the hospital. Public psychiatric facilities rely heavily on medication for manifest psychiatric symptoms and on the maintenance of a stable, "quiet" milieu. The introduction of enthusiastic support for follow-up care is not common. Addiction problems, because they generally precede and follow hospitalization and are dormant in between, can easily be ignored. The introduction of a peer-led culture infused with the commitment of recovering addicts, on the other hand, can address the issue of the drug problem while patients are in the hospital. It also provides an interpersonal bridge to aftercare, encouraging patients and staff alike to work toward a proper follow-up, which is central to recovery. In order to do this, however, such a program must be sanctioned by clinical leadership and cooperate closely with clinical staff.

In addressing this alternative, we introduced the option of a peer-leadership self-help model into general hospital services. This approach is inherent in Alcoholics Anonymous and related 12-step programs for the addicted. Findings relevant to peer-oriented engagement of patients for treatment of substance abuse have been reported previously. Group treatment modalities have been found useful for patients with dual diagnoses by Kofoed et al. (16) and Hellerstein and Meehan (17); they demonstrate the value of the use of peer support in the treatment process. Galanter et al. (6, 7) found that inpatient alcoholics can be better engaged in ambulatory care by using peer-based self-help from the ambulatory program, and De Leon and Zeigenfuss (18) documented the efficacy of peer leadership in the long-term rehabilitation of drug addicts in therapeutic communities. On this basis we felt that professionally supervised, recovered peer addicts might be a useful device for engaging the crack/cocaine patients on general hospital services.

In evaluating our format for engaging these patients, we considered the appearance of a patient for psychiatric aftercare, at either the cocaine clinic or the general psychiatric clinics, as sufficient. Either setting could provide follow-up after discharge from the hospital. As reported here, our findings therefore evaluated the potential for bringing these seemingly refractory cocaine patients into any appropriate aftercare treatment. They point out the value of using a peer-led referral format as well.

On the psychiatry service, the referral program addressed a majority of the eligible patients and succeeded in increasing threefold the number of patients enrolling in the clinics. This was done by altering the culture on the experimental unit in two ways. The staff was educated to the need for addressing their patients' crack/cocaine problems as well as the acute psychiatric problems that precipitated admission. Furthermore, both patients and staff were exposed to the peer-led culture of the cocaine clinic by introducing recovering addicts into the milieu treatment; the viability of using patient peers as instruments for engagement in aftercare was established, and its favorable outcome was demonstrated.

For the obstetric patients, too, the large majority of those proposed by the ward staff for evaluation were found suitable for referral to the cocaine clinic, and most of them appeared and enrolled in the clinic. Given the high toll of perinatal morbidity associated with cocaine use (4), and the fact that most of these patients were multiparous and likely to become pregnant again, the importance of rehabilitating them cannot be underestimated. This issue is particularly compelling from a medicolegal standpoint, because questions are currently being raised about the imposition of quasi-punitive measures, even criminal charges, on pregnant and postpartum addicts (19).

Crack/cocaine abuse is apparently most common among a highly disadvantaged, often homeless population of predominantly black patients; it certainly is in our hospital. This population is quite different demographically and diagnostically from non-substance-abusing patients. The difference raises the importance of cross-cultural issues in treatment, but these issues often gain limited attention in the mainstream of psychiatric management (20). Nonetheless, these issues go to the core of our conceptions of pathology and treatment. As Rogler (21) pointed out, psychiatric illness cannot be conceived of as a distinct entity concealed by culture but must be understood to be in active interaction with it. Crack/cocaine abuse therefore cannot be viewed as pathology independent of the affected subculture. For example, communication patterns, attitudes toward relating, and networks of acquaintance among our patients were important bases on which the recovering peers were able to engage them for follow-up. These served as a vehicle for establishing supportive ties, one that was not available to the professional staff. Research sensitive to this subculture and its needs must therefore underlie our approach to drug abuse and dependence and the best options for treatment.

## Commentary

# Homeless Mentally Ill or Mentally Ill Homeless?

Carl I. Cohen, M.D., and Kenneth S. Thompson, M.D.

*Mainstream psychiatry conceptualizes people who are homeless and mentally ill as distinct from other homeless persons because it is thought that their status stems from their mental disorder and the poor implementation of deinstitutionalization. The authors believe this dichotomy is illusory. They present data indicating that recent socioeconomic and political shifts contributed greatly to homelessness among all groups, regardless of mental illness; that those with and without mental illness have similar biographical and demographic profiles; that high levels of mental distress are common to all homeless persons; and that few mentally ill homeless persons require involuntary hospitalization. This perspective suggests novel responses that de-emphasize clinical solutions and focus on empowerment, consumerism, entitlement, community-level interventions, and closer alliances with other advocates for the homeless.*

(Am J Psychiatry 1992; 149:816–823)

> What I wish to do, is to go down into the East End and see things myself. I wish to know how those people are living there, and why they are living there, and what they are living for.
>
> —Jack London (1)

Within psychiatric circles, a debate has emerged between those who use "homeless" as an adjective and "mentally ill" as a noun and those who reverse the order (2, 3). This is not merely a grammatical issue. Rather, as we move into the second decade of mass homelessness, psychiatry faces a critical juncture in its conceptualization of the interplay of homelessness and mental illness.

The most prominent viewpoint within psychiatry has been that the fundamental problem of homeless mentally ill persons is their mental illness. From this perspective, their homelessness is important because it reflects the severity and consequences of their disease. This viewpoint rests on the notions that 1) the occurrence of homelessness among the mentally ill stems primarily from the disabling functional deficits of their disorder (4, 5), and 2) the recent increase in homelessness among the mentally ill is a product of the poor implementation of deinstitutionalization (6, 7). Comments by leaders of the major psychiatric organizations in this country illustrate this viewpoint. In outlining "the perspective of the American Psychiatric Association," Lamb and Talbott (8) wrote, "How do the chronically mentally ill become homeless? . . . The chronically and severely mentally ill are not proficient at coping with the stresses of this world." Similarly, Richard Wyatt (6), chief of the Neuropsychiatry Branch of the National Institute of Mental Health (NIMH), declared, "America's homeless crisis began in 1963 when deinstitutionalization became law through enactment of the Mental Retardation Facilities and Community Mental Health Centers Act. . . . By law, the former residents of structured institutions became the homeless."

On the basis of these perceptions, the problems and service needs of persons who are homeless and mentally ill are conceptualized as being qualitatively different from those of "not mentally ill" homeless persons (9). Like the domiciled severely mentally ill population, the

homeless mentally ill are viewed as requiring services from an assertive mental health care system capable of satisfying their multiple needs (8). Often, involuntary psychiatric hospitalization is included as a key element of such a system (5, 10, 11). The focus on these specialized needs and services leads to the view that advocacy and program planning for the homeless mentally ill population is best done separately from that for other homeless groups (9).

Our objective is to address this perspective by arguing that, although well-meaning, it is tenuous on empirical and strategic grounds. Underpinning our argument is the notion that the conceptual dichotomy between homeless persons with and without mental illness is largely illusory. On closer examination, "not mentally ill" homeless people have many mental health problems; similarly, the "mentally ill" homeless have numerous nonpsychiatric problems that arise from the sociopolitical elements affecting all homeless people. This alternative perspective, although appearing to be a difference in emphasis, is a conceptual shift. Whereas the mainstream perspective acknowledges that nonpsychiatric factors foster homelessness among the mentally ill, it is believed that mental illness is the "basic, underlying problem" (7) and that other forces impinge on this core deficit. Our model views homelessness as the core element of the broader socioeconomic and political context, which in turn becomes intertwined with personal biography and illness. This alternative perspective perforce spawns novel responses to homelessness and mental illness.

## CAUSES OF HOMELESSNESS AMONG THE MENTALLY ILL

The belief that homelessness is a problem of severe mental illness arose during the early 1980s, when the initial reports about the new homeless appeared in the psychiatric literature (3, 12). Biases were created by methodological weaknesses in the research (13, 14), particularly with respect to the settings in which observations were made (e.g., psychiatric emergency rooms, clinical referrals), and these biases led to inflated estimates—as high as 97%—of the percentage of homeless who were seriously mentally ill (15). In recent years, however, more scientifically rigorous studies sponsored by NIMH have found between one-fourth and one-third of homeless persons to be severely mentally ill (16). Despite the earlier methodological flaws, it is evident that a disproportionate number of homeless persons have severe mental illness.

By dint of their training, psychiatrists have been especially prone to concentrate on individual traits (17). Hence, there has been a tendency to assume that the cognitive and behavioral styles of the mentally ill are the primary causes of their homelessness. Theorists who have focused on these individual characteristics of mentally ill homeless persons point to their propensity to "drift," to "wander," to "outrun problems," to be "disorganized," to have "poor problem-solving abilities," and to be unable to "deal with even ordinary landlord-tenant situations" (4, 5, 8, 10). Nevertheless, none of these reports has been able to demonstrate how mental illness alone causes homelessness (18).

A corollary of the belief that the disabilities of severe mental illness lead to homelessness is the conviction that mental health services should enable patients to overcome their disabilities and thereby allow them to be domiciled in the community. From this perspective, the increase in the occurrence of homelessness among the mentally ill is taken as evidence of the failure of community-based services and the policy of deinstitutionalization (6, 7, 9, 15, 19). However, it is unlikely that the current practice of deinstitutionalization and community-based care is the primary reason for homelessness among the severely mentally ill. First, it should be underscored that of the 2 million schizophrenic persons in the country, fewer than 8% are living in public shelters or on the streets (20). Nearly one-half live with their families. Moreover, given the high volume of discharges from psychiatric institutions and the increased restrictions in hospital admission policies during the 1960s and early 1970s, it might have been anticipated that large numbers of mentally ill persons would have become homeless during this period if the primary cause of homelessness was the shift in patient care from institutions to inadequate community-based mental health services. Yet evidence points to a significant temporal gap: the dramatic increase in homelessness among the mentally ill occurred only at the very end of the 1970s.

Several writers have noted that the policy of deinstitutionalization also affects increasing numbers of "new" chronic mentally ill individuals, who in years past would have been long-term residents of state hospitals and who are now further expanding the homeless mentally ill population (3, 12). Implied in this framework is the assumption that many of the new chronic mentally ill homeless require institutionalization (21); however, as we will discuss, the data suggest otherwise. Fisher and Breakey (22) concluded after a comprehensive review of the literature that, although deinstitutionalization is often blamed for the increase in homelessness, "empirical data to support this view are sparse" (p. 20), a view shared by Tessler and Dennis in their review of NIMH-sponsored research on homeless mentally ill persons (23). Even if deinstitutionalization had been better implemented, other, more dominant social forces would have likely continued to spawn more homelessness among the mentally ill.

The past 15 years have been characterized by marked social, political, and economic changes, which are much more likely to have contributed to the dramatic increase in homelessness in general, as well as among those with mental illness. For example, there has been a rapid decline in the availability of low-cost housing. Wright and Lam (24) observed that at this stage of American history there is simply not sufficient low-income housing to accommodate the poor population; consequently, "the new homeless are largely victims of a housing market that is assuredly not of their own making." Data suggest that most homeless mentally ill persons lost their rooms in single-room-occupancy hotels or low-priced apartments not because of psychoticism but because they 1) were evicted because of renewal projects and fires, 2) were victimized by unscrupulous landlords or by other residents, or 3) could no longer afford the rent (25). For example, in New York City, during 1975–1981 more than 30,000 rooms in single-room-occupancy residences were lost; 10,000 such rooms were lost in San Francisco during the 1970s (26). The experience of one of us (C.I.C.) as a community psychiatrist working in midtown Manhattan is similar to the experiences of others in the field. During the mid-1970s, it was unusual to encounter difficulty placing discharged patients in single-room-occupancy hotels. By the early 1980s, however, hotel managers not only refused to accept new tenants with psychiatric histories but often refused to reaccept old tenants who had been hospitalized. Ironically, in these instances, institutionalization, rather than deinstitutionalization, contributed to homelessness.

Other major socioeconomic dislocations that have occurred in the last 15 years include the loss of many manufacturing jobs, which have been replaced, if at all, by low-wage service positions (27), and the Reagan administration's targeting of social welfare programs, which led to the elimination or reduction (actual or secondary to inflation) of social welfare benefits (26). It is important to note that these dislocations and their effects were not randomly distributed throughout the population. Rather, during the 1980s poor and marginal populations suffered further deprivation (28). As a result, the nature, form, and distribution of poverty in the United States has shifted substantially in the last 20 years (18, 26, 27, 29–35). The upsurge in homelessness is one example of these changes and may be best seen as the most extreme form of this new destitution (18, 26, 33, 36, 37). As might be expected, people of color have been differentially affected by these socioeconomic processes. For example, the percentage of poor African-Americans living in extremely poor neighborhoods increased from 25% to 40% during the 1980s (38). Changes of this kind account for the disproportionately high numbers of African-Americans and Latinos among the homeless, a finding that has been documented in numerous studies (23, 33).

Persons with severe and persistent mental illness have been excessively burdened by these dislocations because of their symptoms, disabilities, lack of resources, dependence on others, and susceptibility to stigma, neglect, and victimization (39). This vulnerability has been compounded as the historical safety net for at-risk individuals provided by families and community supports has been torn asunder by the weight of poverty and its associated pathologies, such as drug use, crime, violence, and disease. Consequently, the population of severely mentally ill living in the community has been swept along with other relatively powerless and vulnerable populations, such as poor African-Americans, into increasing poverty, resourcelessness, and homelessness, to become a part of a destitute population referred to by some as the "underclass" (27, 40).

These processes recall longstanding historical forces in industrial society. For example, Foucault noted that in seventeenth-century France such forces "seemed to assign the same homeland to the poor, to the unemployed prisoners, and to the insane" (41). Thus, along with other homeless groups, the homeless mentally ill must first be seen as impoverished and disenfranchised, rather than diseased. From this perspective, the policy of deinstitutionalization is important because once mentally ill persons are released into the community, they are exposed to these detrimental forces. Many homeless persons with mental illness also see things this way. In a study conducted in Ohio (42), homeless mentally ill people identified their economic and social problems, rather than symptoms of mental illness, as the principal reasons for their homelessness.

## COMMONALITIES WITH OTHER HOMELESS PERSONS

In light of the findings just described, the position that persons who are homeless and mentally ill are a unique subgroup becomes more questionable. Just as the principal causes of homelessness do not differentiate the mentally ill homeless from the homeless who are not mentally ill, research comparing them has shown little difference in their demographic profiles, geographic origins, work skills, and levels of substance abuse; the extent to which family or economic problems contributed to their homelessness; and the size of their social networks (23, 43, 44). For example, in a study by one of us (C.I.C.) (44), according to relatively sophisticated network measures, only one-seventh of each group reported two or fewer network links and no subject was a total isolate. Thus, the stereotype in the psychiatric literature of the lone psychotic person huddling in a doorway may be the exception rather than the norm.

Noteworthy in this regard are the findings of Foulks et al. (45) for homeless chronic mentally ill veterans, who did not differ from the general population in their performance on neuropsychological tests and exhibited particular cognitive strengths in planning and foresight. Furthermore, work by Anthony et al. (46) has debunked the notion that there is a strong correlation between a person's psychiatric symptoms and a person's skills. Indeed, the fact that many homeless persons with chronic mental illness successfully survive on the streets and in shelters belies the notion that these individuals are unable to cope with life stresses. Psychiatrists serving the homeless mentally ill may be susceptible to the "clinician's illusion" (47), i.e., the belief that persons with more longstanding and more pronounced disorders are more likely to show up in clinical caseloads. As a consequence, psychiatrists are prone to view the "mentally ill" homeless as more numerous and markedly disabled and to underestimate or ignore mental distress among the rest of the homeless population.

The severely mentally ill and "not mentally ill" share the extreme stress of the experience of homelessness. The initiation into homelessness is a crisis (48) that results from a concatenation of many life crises and stressors. Once a person has become homeless, the stressors escalate. One homeless man lamented, "I can't relax my body, lay down, and sleep. It's no joke sitting up in a hard bench sleepin'. Every time somebody passes and scrapes their feet, you jump up. My nerves is on edge 'cause I've seen people attacked in the park. I was sitting in Central Park, day was just breaking, and a guy picked up a wire basket and beat another man to death" (44, p. 94).

A psychiatry resident at the Uniformed Services College of Medicine related that he was granted permission to do an elective in the Washington, D.C., shelters on the grounds that it was the closest approximation to combat conditions that existed in peacetime (R. Koshes, personal communication).

It is axiomatic that homelessness is accompanied by feelings of disconnectedness, self-blame, demoralization, and powerlessness, regardless of the presence or absence of a severe and persistent mental illness. In fact, unless the term "mental illness" is limited to the major psychotic and affective disorders on axis I of *DSM-III-R*, it is difficult to segregate a subpopulation of the homeless mentally ill from the general homeless population. Several studies have shown high rates of substantial depressive symptoms among the homeless (33, 48, 49, 50). For example, in Rossi's study in Chicago (33), demoralization was rampant and nearly one-half of the subjects had depressive symptoms felt to be severe enough to warrant treatment. In a study of older homeless men (44) conducted by one of us (C.I.C.), one-fourth of the subjects said they wished they were dead. In a similar vein, the prevalence of alcohol and substance abuse and dependency among the homeless is also known to be extremely high (23, 51). It is clear from these studies that emotional distress and behavioral problems are essentially ubiquitous among the homeless. Finally, it would be disingenuous to contend that no differences exist between the mentally disabled and not mentally disabled homeless populations. For example, in a review of NIMH-funded studies, Tessler and Dennis observed that "compared to non-impaired homeless individuals, mentally disabled homeless persons were more likely to be homeless for longer periods of time, to have less contact with families and friends, to have more barriers to employment, poorer physical health, and more contact with the legal system" (23, p. 36). Nevertheless, although these differences are not unimportant, the cumulative evidence we have outlined weighs heavily in favor of the commonalities, rather than differences, as the primary determinants of homelessness.

## SERVICE APPROACHES

Mainstream psychiatry's relatively recent recognition that homeless persons with psychiatric problems may benefit from assertive, comprehensive, and coordinated psychiatric and social welfare services is commendable. Nevertheless, it is frequently reported that the mentally ill homeless refuse these services. Before we conclude that their resistance to these services arises from their disordered thinking, we must first examine the manner in which services are offered. Although well-intentioned, psychiatry has tended to focus primarily on the psychiatric deficits of homeless people to the relative exclusion of their shared social environments, their individual and collective strengths, and their essential rights and privileges as citizens. As a result, the strategy used has been paternalistic (or maternalistic) rather than focused on context, entitlement, and empowerment (52). The former approach frequently engenders feelings of humiliation, although this is not fully appreciated by most service providers. As Orwell observed nearly 60 years ago, "A man receiving charity practically always hates his benefactor—it is a fixed characteristic of human nature" (53). Because psychiatry has focused almost exclusively on pathology, there is a lack of understanding of the living conditions and life attitudes of people occupying the margins of society, leading to substantial miscommunication and misunderstandings between service providers and the served (54).

The problems of disempowerment and stigma are also exacerbated by psychiatry's concentration on disease and its subsequent emphasis on directing mental health services to those whose conditions meet certain criteria for chronic mental illness. This creates problems because many homeless emotionally distressed or disabled people, chronically mentally ill or not, do not view themselves as mentally ill (3), and some have had previous negative experiences with mental health care systems. For example, a consumer-oriented survey by Goering et al. (55) indicated that part of the reason for the presumed resistance to accepting services was an incongruence between the client's priorities and the mental health services offered. Many of the homeless mentally ill persons surveyed felt disenfranchised and exhibited considerable antipathy toward any formal system. Like most people, the homeless mentally ill generally desired a safe, comfortable home and did not wish to be segregated in residences for the mentally ill, which they perceived as dangerous and stigmatizing. Hence, the form and content of disease-focused services as presently constituted often reflect insensitivity to the desires, experiences, and social world of homeless people in psychiatric distress—a point that has sometimes been missed by those (e.g., the APA Task Force on the Homeless Mentally Ill) who have viewed these individuals as primarily a subgroup of the chronic mentally ill.

The failure of current approaches to engage the homeless mentally ill in services and get them off the streets has led to a mounting call by some for their involuntary hospitalization (4, 10). Embedded in this demand is a belief that civil libertarians have created a situation in which the homeless mentally ill have become too entitled and are protected by stringent commitment laws that allow them to follow their own wishes and, as a result, permit them to perish in the streets with "their rights on" (56, 57).

Although we concur with the notion that mentally ill homeless persons who are incompetent to make decisions about accepting treatment, who are dangerous to themselves or others, or who are gravely disabled should be hospitalized against their wills (4, 5, 10), in actuality few mentally ill homeless persons meet these criteria unless the criteria are stretched beyond their intended meanings and thereby threaten the protection of human rights. In fact, an examination of data from Project Help in New York City—which is often cited as a model program for involuntary hospitalization (4) because of its broader definitions of dangerousness to self or others—reveals that roughly two-thirds of the homeless persons targeted for hospitalization by Project Help were ultimately deemed unqualified for involuntary hospitalization (58). Comments by staff of Project Help are revealing: "Many of the homeless are overtly psychotic, yet have adapted to the life in the streets and are not at significant risk" (59, p. 924). Similarly, Snow et al. found that "efforts of the homeless mentally ill to survive on the streets are not as chaotic or as irrational as they appear from a distance" (60, p. 418). Several well-designed studies (61–63) have supported these observations, showing that only 5%–7% of single adult homeless persons are in need of acute inpatient care.

Yet there is a grain of truth in the observation that being entitled to stay out of institutions is a real problem for the homeless mentally ill and society. However, unlike those who focus first on mental illness and believe that the homeless mentally ill have too many rights, our focus on homelessness reveals that the mentally ill homeless, like the rest of the homeless, do not have enough rights. Their right to be truly in the community is merely theoretical until they have procured the legal, political, therapeutic, and economic means necessary to construct and maintain a secure niche within the community.

Emphasizing homelessness challenges the current scope and nature of psychiatric concern and practice with homeless populations. It calls for the profession, along with others, to cast a wider net so as to recognize and address the broad social and psychiatric causes and effects of homelessness and destitution, helping the homeless to solve their problems and to build a new, more humane niche for themselves in society. Among other things, this necessitates a restructuring of clinical encounters with patients so that they are less paternalistic and disease oriented and are more focused on empowering individuals and groups to solve their problems by eliciting sources of health and strength (64–67). This perspective recognizes that individual-oriented clinical and social services are not sufficient in themselves. Rather, they must be integrated with a range of social psychiatric interventions that are akin to the strategies used with refugees, displaced persons, and persons experiencing extreme life stressors, such as combat veterans, cancer survivors, and disaster victims. Thus, in addition to clinical attention on the individual level, this entails the kinds of systems-level interventions advocated by mental health professionals in communities that have endured major catastrophes (68) or other forms of social instability (69). Examples of this work are 1) the establishment of settings that provide permanent independent living with ongoing social supports and 2) an effort by one of us (K.S.T.) and others to establish a therapeutic community in a men's shelter. On a much larger scale, an example of this kind of approach can be found in the report "To Build a Community," produced by the Los Angeles Citizens' Task Force on Central City East, an area of Los Angeles where the homeless congregate (70). In addition to traditional community mental health services, the report called for large-scale preventive projects to identify at-risk individuals, community development programs including conflict management and consensus building, and close collaboration with universities to develop model service programs.

## ADVOCACY

It is doubtful whether separately advocating on behalf of the mentally ill homeless, as opposed to the homeless and destitute in general, makes sense from either a pragmatic or moral perspective. In recent years psychiatrists have become more biomedically focused and have been circumspect about addressing broader sociopolitical issues, which are thought to be outside their purview (71). Although social and political contexts have been recognized, they have not been well integrated into etiological theory. However, several analysts (31, 72–74) have noted how "medicalizing" social conditions such as homelessness tends to deflect solutions away from the social arena and onto individuals. Similarly, we have seen in other disciplines that theorizing which is not based on context can have pernicious consequences (e.g., explanations of lower IQs among African-Americans) (75). It is noteworthy that the 320-page APA task force report on homelessness (12) devoted merely two sentences and no analysis to the disparity between the numbers of homeless people of color and homeless whites. It has remained for other social scientists to examine the links between racism, poverty, and homelessness.

We have shown why psychiatry must extend its theoretical and clinical gaze beyond the chronic mentally ill homeless population, not to forget them but to include them with others in the community and to make certain that it does not neglect persons suffering from nonchronic forms of mental distress (18). Psychiatrists must collaborate with other social scientists and human service workers in confronting social problems, particularly poverty and destitution, and their effects on individuals, families, and communities. This means that psychiatry must give greater priority to examining the connections between public issues and private troubles, a part of the process aptly named "the sociological imagination" by C. Wright Mills (76). This is particularly important for public psychiatry, which, by concentrating on deinstitutionalization, chronicity, and the disease paradigm, has minimized its obligation to provide a full range of psychiatric services to the poor in need, regardless of chronicity (77).

The separation of the homeless mentally ill from the homeless in general creates a false division, pitting what many might see as the morally deserving homeless who are mentally ill, not at fault, and therefore worthy of public largesse against the unworthy, nondeserving homeless underclass who are destitute by choice, not illness. Besides being unscientific, such a morally tinged subdivision of the homeless may backfire on both the severely mentally ill and the objectives of the profession. Are the homeless mentally ill any more deserving than the children, women, elderly, veterans, or unemployed men who are homeless? In addition, historically it has been difficult to persuade legislatures to fund large-scale programs for chronic mentally ill individuals, even when the mentally ill are domiciled and successful models exist (78). How likely are legislatures to support the development of what amounts to a special (and extremely expensive) social welfare and treatment system for the chronic mentally ill alone? Scull (79) described this dilemma as it occurred historically in Britain:

> To improve the living conditions of lunatics living in the community would have entailed supplying relatively generous pension or welfare benefits to provide for their support, implying that the living standards of families with an insane member would have been raised above those of the working class generally . . . something approximating a modern social welfare system, while their brethren were subject to the rigours of a poor law based on principles of less eligibility.

Finally, mental health workers must recognize the primacy of homelessness in order to ally themselves with other advocates for the homeless and destitute, including the homeless themselves. In this way, the overriding social and political etiological factors may begin to be addressed. By working in concert to develop meaningful social solutions (including better mental health services), all vulnerable subgroups, including the chronically mentally ill, will benefit. Prospects for social change are made more likely by increasing discontent, particularly among the one-third of the nation's families who are now "shelter poor" (i.e., unable to pay for nonhousing necessities and still cover housing costs) and among urban dwellers, such as those in New York, where one in nine persons live in imminent danger of homelessness or at high risk for future homelessness, by the homeless themselves as they begin to organize politically, and by the rising tide of concern for social responsibility with the end of the Cold War and the Reagan era (80–82). Thus, one can envision a future alliance between the homeless, the working class, and other socially concerned persons, including professionals, in support of new initiatives that would include governmental housing programs, improved health services, rejuvenated antipoverty programs, and community development projects.

Although empirical evidence and the limited progress made in the past decade in addressing the problems of mental illness among the homeless bespeak a revision of prevailing theory and strategies along the lines outlined in this paper, American psychiatry has not appreciably altered its position since the original APA report in 1984. In 1990 the APA Task Force on the Homeless Mentally Ill issued an interim report (83) that stated, "The comprehensive [sic] view of the initial APA recommendations remains an excellent embodiment of principle." Ironically, the original decision to separate the chronic mentally ill from other homeless populations was never made on empirical grounds; rather, it was based on an a priori belief that the task force's credibility would be enhanced (8). More encouraging has been the task force's recent report on homeless families and children (84), which, in contradistinction to its position on single homeless persons, is more encompassing and less clinical in that it includes all families, regardless of degree of mental illness. Such broad-based approaches are necessary because past experience has amply demonstrated that major advances in services for the mentally ill—notably following World War II and in the 1960s—have come primarily through alliances in which mental health services are conceptualized as one component of a wide-ranging social agenda (85, 86).

# Are Panic Attacks Traumatic Stressors?

Richard J. McNally, Ph.D., and Brian M. Lukach, M.S.

*Like typical stressors that produce posttraumatic stress disorder (PTSD), panic attacks are sudden, unpredictable, and often perceived as life-threatening. Structured interviews with 30 subjects with panic disorder revealed that five (17%) and two (7%) met lifetime and current* DSM-III-R *PTSD criteria, respectively, following their most terrifying panic attack. PTSD produced by panic is less severe than PTSD produced by either rape or combat.*

(Am J Psychiatry 1992; 149:824–826)

A characteristic cause of posttraumatic stress disorder (PTSD) is exposure to a sudden, unpredictable, life-threatening event, such as gunfire or violent rape. Although the individual may emerge physically unscathed from the trauma, the perception of a close brush with death is often sufficient to trigger the syndrome (1). Indeed, most studies have uncovered a dose-response effect whereby the severity of PTSD symptoms varies as a function of perceived threat (2, 3). Although perceived threat is usually highly correlated with actual threat, theorists have speculated whether perceived threat alone may suffice to produce PTSD (unpublished 1989 paper of J.S. March).

Spontaneous panic attacks are sudden, unpredictable events that are commonly perceived as life-threatening. Indeed, according to some cognitive theorists (4), panic cannot occur unless the individual believes he or she is in imminent danger (e.g., of dying from a heart attack). If the perception of danger is necessary for panic to occur, and if such perceptions are sufficient to produce PTSD, persons with panic disorder should ordinarily develop PTSD.

To test whether panic constitutes a traumatic stressor, we assessed the occurrence of PTSD symptoms in subjects with panic disorder and compared their pattern of symptom endorsement with that of a comparison group of subjects with PTSD.

## METHOD

The group of subjects with panic disorder comprised 25 women and five men with the disorder. We used the Structured Clinical Interview for DSM-III-R (SCID) (5) to establish the diagnosis. Subjects ranged in age from 17 to 47 years (mean=33.5), and their number of years of education ranged from 10 to 19 (mean=13.3). They were recruited from the anxiety disorders clinic of an urban medical school, an agoraphobia treatment center in a suburban area, and a support group in a suburban area. All were unpaid, and all volunteered when asked to participate in an interview study concerning panic. Clinic patients were consecutively referred patients who sought behavioral treatment for panic disorder; the remaining subjects with panic disorder were randomly selected from among active support group members.

The group of comparison subjects comprised 17 male Vietnam veterans with combat-related PTSD who were inpatients on a Veterans Administration stress disorder treatment unit and one male and 12 female community volunteers with rape-related PTSD. The diagnosis of PTSD was established by SCID interviews in two unrelated studies in which these subjects participated. The comparison subjects ranged in age from 22 to 53 years (mean=37.6), and their number of years of education ranged from 9 to 18 (mean=14).

To assess the occurrence of PTSD symptoms in the subjects with panic disorder, we used the SCID PTSD module developed by Kulka et al., in collaboration with Spitzer et al., for the Vietnam Veterans Readjustment Study (6). After ruling out a history of *DSM-III-R* traumatic stressors that might produce PTSD symptoms, we asked subjects with panic disorder to identify "the most frightening panic attack you ever experienced, perhaps one in which you thought you were about to die." Once they specified an attack, we asked them to estimate, in percents (1%–100%), the likelihood that they thought they were about to die during the attack. Using the SCID, we assessed the occurrence of PTSD symptoms in reference to this attack. Subjects then completed the Impact of Event Scale—Revised (7) in reference to their most frightening panic attack. Their scores were compared with those of the 12 subjects with rape-related PTSD for whom we had Impact of Event Scale—Revised data.

## RESULTS

According to their scores on the SCID, five (17%) of the 30 subjects with panic disorder qualified for a lifetime diagnosis of PTSD, and two (7%) qualified for a current diagnosis of PTSD. The mean subjective rating of the likelihood of impending death during the worst panic attack by the five subjects with panic disorder who also had PTSD was 72% (range=0%–100%); the rating by the 25 subjects with panic disorder who did not have PTSD was 56% (range=0%–100%) ($t<1$, df=28, n.s.).

Chi-square tests (Yates-corrected) indicated that a higher percentage of the 30 subjects with PTSD than of the five subjects with panic disorder and a lifetime diagnosis of PTSD endorsed each of the 17 PTSD symptoms on the SCID except for the startle response. A significantly higher percentage of subjects with PTSD than of subjects with panic disorder and PTSD endorsed nightmares, flashbacks, psychogenic amnesia, loss of interest, concentration problems, and physiological reactivity to reminders of the trauma (table 1).

Two-tailed t tests indicated that the 12 subjects with rape-related PTSD for whom Impact of Event Scale—Revised scores were available had a significantly higher mean total score on this scale than the 30 subjects with panic disorder (46.3, SD=7.1, versus 33.0, SD=15.4) ($t=3.81$, df=39, $p<0.001$), as well as a higher mean avoidance subscale score (21.9, SD=3.0, versus 17.9, SD=9.0) ($t=2.15$, df=39, $p<0.05$) and higher mean intrusion subscale score (24.2, SD=7.2, versus 14.9, SD=8.2) ($t=3.43$, df=40, $p<0.001$). Two-tailed t tests indicated that the 12 subjects with rape-related PTSD did not have a significantly higher (p values greater than 0.10) mean total score (41.8, SD=6.6), avoidance subscale score (21.8, SD=4.6), or intrusion subscale score (20.0, SD=4.0) on the Impact of Event Scale—Revised than the five subjects with panic disorder and PTSD. Thus, the Impact of Event Scale—Revised was sensitive to the presence of PTSD as diagnosed by the SCID.

**TABLE 1. *DSM-III-R* PTSD Symptoms Endorsed by Subjects With PTSD, Panic Disorder, and Panic Disorder With PTSD**

| | Subjects With PTSD (N=30) | | Subjects With Panic Disorder (N=30)[a] | | Subjects With Panic Disorder and PTSD (N=5) | |
|---|---|---|---|---|---|---|
| Symptom | N | % | N | % | N | % |
| Intrusive thoughts | 30 | 100 | 10 | 33 | 4 | 80 |
| Nightmares[b] | 28 | 93 | 3 | 10 | 1 | 20 |

| Numbness | 26 | 87 | 2 | 7 | 2 | 40 |
| Foreshortened future | 27 | 90 | 10 | 33 | 5 | 100 |
| Sleep problems | 29 | 97 | 8 | 27 | 3 | 60 |
| Irritability | 25 | 83 | 12 | 40 | 3 | 60 |
| Concentration problems[b] | 26 | 87 | 7 | 23 | 1 | 20 |
| Hypervigilance | 29 | 97 | 17 | 57 | 4 | 80 |
| Startle response | 29 | 97 | 15 | 50 | 5 | 100 |
| Physiological reactivity to reminders of the trauma[b] | 28 | 93 | 6 | 20 | 2 | 40 |

[a] The panic disorder group includes the five subjects who qualified for a lifetime PTSD diagnosis.

[b] These PTSD symptoms were endorsed more frequently by the PTSD group than by subjects with panic disorder who also qualified for a lifetime diagnosis of PTSD ($p<0.05$).

## DISCUSSION

Although panic attacks are sudden, unpredictable events that are often perceived as life-threatening, they produce PTSD far less often than prototypical traumatic stressors (e.g., exposure to gunfire) (2). Certain characteristics of panic may diminish its traumatogenic potential. For example, panic attacks are often misperceived as heart attacks, and heart attacks are more common and more in the range of everyday experience than prototypical traumatic stressors. On the other hand, heart attacks rarely strike young people, and young people are those most at risk for panic disorder. For them, heart attacks are outside the range of everyday experience.

Perhaps the "internal" locus of panic renders it less traumatogenic than prototypical "external" traumatic stressors. The findings of two studies (8, 9), however, suggest that internal stressors may produce PTSD. As many as 25% of patients who survived a myocardial infarction (8) and as many as 46% of those who recovered from a psychotic episode (9) experienced PTSD. However, in neither study did the investigators use structured diagnostic interviews or rule out a history of exposure to prototypical external trauma. Moreover, in the latter study (9), the phenomena that postpsychotic patients reported reexperiencing primarily concerned "external" events surrounding involuntary hospitalization (e.g., forced sedation) rather than "internal" psychotic symptoms per se (e.g., frightening hallucinations). Nevertheless, these findings suggest that structured interviews to assess the occurrence of PTSD are warranted, especially in heart attack survivors.

Most plausibly, subjects with panic disorder may entertain multiple, shifting interpretations of their symptoms during a panic attack. That is, they may fear that they are having a heart attack without being convinced of it. In contrast, most external traumatic stressors (e.g., exposure to gunfire) do not leave room for such varied and potentially noncatastrophic interpretations. Thus, the inherent ambiguity of panic may attenuate its traumatogenic potential.

In summary, this study has etiological implications for both PTSD and panic disorder. Our findings are consistent with the view that an objective definition of what constitutes a traumatic stressor ought to be retained in the *DSM-IV* criteria for PTSD. That is, threats may need to be actual as well as perceived for PTSD to occur. On the other hand, our findings also suggest that catastrophic thoughts may not necessarily precede even the worst panic attacks of those with panic disorder (10). That is, even during their most frightening attack, patients may not be wholly convinced that danger is truly imminent.

# Onset of Panic Disorder

**Carlo Faravelli, M.D., Stefano Pallanti, M.D., Francesco Biondi, M.D., Sabrina Paterniti, M.D., and M. Alessandra Scarpato, M.D.**

*The situations in which the first panic attack occurred were investigated in 44 patients affected by panic disorder. Although the first panic attack was reported to be unexpected and no avoidance was present before it, 75.8% of patients (N=22) with panic disorder with agoraphobia had their first panic attack in phobogenic situations, compared with 20% of patients (N=3) with panic disorder without agoraphobia.*

(Am J Psychiatry 1992; 149:827–828)

Since the introduction of panic disorder as a separate nosological category there has been considerable debate on this subject. On one hand, a position, which is usually referred to as the "American view," maintains that spontaneous panic attacks constitute the core of the disorder, phobic avoidance being secondary to the recurrences of panic attacks. On the other hand, the so-called "European view" contends that phobic attitudes may exist before the occurrence of panic and that this peculiar cognitive style is the primary aspect of the illness. Although the issue can be solved only by prospective studies, the observation of the context in which the first panic attack occurs may offer a different angle for exploring the problem. Lelliott et al. (1) reported that 92% of their agoraphobic patients with panic experienced their first panic attack in public places rather than at home.

Because these findings merit further consideration and, to our knowledge, no other study has replicated them, we decided to explore in detail the circumstances of the onset of panic disorder. Since we had the opportunity of being referred a certain number of subjects during the initial stages of their illness, we explored only those cases in which the first panic attack had occurred shortly before the interview (within 6 months) in order to improve the reliability of recall. Using an approach different from that of Lelliott et al. (1), who studied only agoraphobic patients with panic disorder, we investigated patients with panic disorder, whether with agoraphobia or not.

## METHOD

Of the patients referred to our outpatient facility during 1988–1989, 98 satisfied *DSM-III-R* criteria for panic disorder, and in 44 of these the onset of the illness was precisely datable to within 6 months of the interview. Of these, 15 patients had no sign of phobic avoidance and 29 were agoraphobic (five at a mild level, 10 at a moderate level, and 14 to a severe degree). Patients with panic disorder with and without agoraphobia did not differ in sex (female:male ratio=18:11 for phobic and 9:6 for nonphobic patients), age (mean=25.1 years, SD=5.8, versus mean=24.1, SD=5.1), or education (mean=11.9 years, SD=5.3, versus mean=10.8, SD=5.1).

The symptoms of and the circumstances when the disorder occurred the first time were investigated in detail by a specially devised structured interview. The presence of agoraphobia before the first panic attack was investigated by a self-rated inventory that evaluates the distress experienced in 16 typical agoraphobogenic situations on 7-point rating scales. The patients' past personal history was evaluated by the Schedule for Affective Disorders and Schizophrenia—Lifetime Version (2) in order to exclude patients with previous forms of anxiety disorder.

## RESULTS

In all the patients the disorder began with an unexpected panic attack, and, in the patients in whom agoraphobia was present, it developed later, after a time lag varying from a few days to a few weeks after the first panic attack. None of the patients reported any form of distress when exposed to phobogenic situations before the onset of panic disorder. Development of phobias was unrelated to the number of unexpected panic attacks.

The situations in which the first panic attacks occurred are listed in table 1. The first panic attack occurred in "places or situations from which escape might be difficult (or embarrassing) or in which help might not be available" (*DSM-III-R*) in 22 (75.8%) of the 29 patients with agoraphobia compared to three (20%) of the 15 patients with panic without agoraphobia ($\chi^2$=12.57, df=1, p<0.001). Using the distinction of Lelliott et al. (1) between public and nonpublic places did not change the results to an appreciable extent.

## CONCLUSIONS

Where we found that most agoraphobic patients experienced their first panic attack in phobogenic situations, our findings are consistent with those reported by Lelliott et al. (1). In addition, we found that such an onset was significantly less common among patients with panic disorder who did not develop agoraphobia.

However, there are some inconsistencies between our findings and those of Lelliott et al. First, none of our patients reported any clinically evident form of distress when in phobogenic situations before the onset of panic disorder. This also contradicts the report of Fava et al. (3) of patients with panic disorder having phobic symptoms before the onset of panic. Second, the first attack was totally unexpected, and the patients' feeling of being entrapped developed along with the surging of panic and not before the attack. We believe that the different ways of recruiting the patient groups could have accounted for such discrepancies: patients with unselected panic disorder at the initial stage of their illness in our study and patients suffering from panic disorder with agoraphobia who were referred for cognitive/behavior therapy in the studies of Lelliott et al. and Fava et al.

Our results might be biased by the fact that a certain proportion of patients without agoraphobia could become agoraphobic after the 6-month observation period. However, when the data were analyzed, almost all the patients had been followed up for at least 2 years, and none of those without agoraphobia had developed avoidance.

Moreover, we checked this possibility by analyzing the records of those 54 patients who were excluded from the study because of the longer time elapsed between the onset of panic disorder and our first observation. Although they were not administered the entire protocol, the descriptive reports of their first panic attacks were substantially the same as those of the study population: 70% of agoraphobic patients reported their first panic attack when in phobogenic situations, compared to 28% of patients without agoraphobia.

The association between public onset and agoraphobia merits special interest. An interpretation could suggest that a sort of subclinical agoraphobia might preexist clinical panic: phobogenic situations could then be regarded as potential risk factors for these people, thus enhancing the probability of having a panic attack. Lelliott et al. (1) suggested a role for an ethological factor (an evolutionary vulnerability to extraterritoriality), in addition to the biological and learning components of the disorder. While such a model is fascinating, it does not explain satisfactorily why such an onset is rare among patients with panic disorder without agoraphobia.

Another, simpler interpretation could be taken into account. The different psychological meaning of the context in which panic occurs might explain the evolution of the disorder. Experiencing the drama of an unexpected panic attack in settings in which, objectively, help is not available has a different psychological impact than experiencing the same symptoms in protected settings (e.g., at home). It is possible that undergoing such a stressful experience as having an attack in contexts in which one is helpless might affect the later course of the disorder. In this case the basic core of panic disorder would be the pathological evolution of panic, rather than panic itself.

However, in order to evaluate this possibility, as well as the model of Lelliott et al., it would be necessary to explore the settings in which panic occurs in those cases in which the attack fails to satisfy *DSM-III-R* criterion B for panic disorder because of its infrequent repetition or lack of the fear of having another attack (the so-called infrequent panic).

In conclusion, it seems that the results derived from these studies might be seriously biased by the sample selections and that community samples would be preferable.

# Changes in *DSM-III-R* Axis II Diagnoses Following Treatment of Obsessive-Compulsive Disorder

Joseph N. Ricciardi, Psy.D., Lee Baer, Ph.D., Michael A. Jenike, M.D.,
Steven C. Fischer, Psy.D., Diana Sholtz, Ph.D., and M. Lynn Buttolph, M.D., Ph.D.

*Seventeen patients with obsessive-compulsive disorder and concomitant personality disorders were treated with pharmacologic and/or behavioral therapy and reassessed after 4 months. Nine of the 10 patients who responded to treatment for obsessive-compulsive disorder no longer met criteria for a personality disorder. Of the seven nonresponders, five continued to meet criteria for a personality disorder.*

(Am J Psychiatry 1992; 149:829–831)

Many patients with obsessive-compulsive disorder show comorbid personality disorders; rates of 49%–83% have been reported (1–4), although one group of investigators (5) found a prevalence of personality disorders no higher than that for a control population. A recent study (6) found that a group of patients with obsessive-compulsive disorder showed improved personality functioning, according to a self-rating scale, following brief treatment with clomipramine. This finding was related to treatment response, with responders showing the greatest improvement. The authors reached the conclusion that the severity of the axis I disorder may confound the assessment of a personality disorder.

The study we report was designed to examine the effects of improvement of obsessive-compulsive symptoms on comorbid personality disorders by using a standardized, structured interview, rather than self-report, to assess personality and diagnose personality disorders. Since we hypothesized that the diagnosis of personality disorders in many patients with obsessive-compulsive disorder is contaminated by features of the axis I disorder, we expected changes in personality disorders to follow symptomatic improvement of obsessive-compulsive disorder.

## METHOD

Twenty consecutive outpatients at an obsessive-compulsive disorders clinic and research unit who met the *DSM-III-R* criteria for obsessive-compulsive disorder according to the Structured Clinical Interview for DSM-III-R (SCID) (7) and who met criteria for at least one *DSM-III-R* personality disorder according to the Revised Structured Clinical Interview for DSM-III-R Personality Disorders (available from the first author on request) were contacted for inclusion in the study. The Revised Structured Clinical Interview for DSM-III-R Personality Disorders is the latest version of an extensively studied and reliable instrument for determining axis II diagnoses (8). The raters for this interview were instructed to challenge subjects who endorsed items, asking that they be certain that such traits were unrelated to their obsessive-compulsive disorder. The Yale-Brown Obsessive Compulsive Scale (9) was administered by each patient's attending psychiatrist on initial evaluation and again after 4 months of behavioral and/or pharmacologic treatment as a measure of clinical response. At follow-up the Revised Structured Clinical Interview for DSM-III-R Personality Disorders was conducted by the same research associate who administered it the first time; this person was blind to the patient's treatment response. The raters for both the Yale-Brown scale and the Revised Structured Clinical Interview for DSM-III-R Personality Disorders were trained at seminars conducted by the authors of these instruments and/or with video instruction, and at rating meetings held by the clinic in conjunction with other studies.

Seventeen patients (10 women and seven men) agreed to participate. They ranged in age from 19 to 61 years (mean=38.4 years, SD=12.2). All patients had suffered from obsessive-compulsive disorder for at least 2 years,

[a] Made with the Revised Structured Clinical Interview for DSM-III-R Personality Disorders.

[b] Yale-Brown Obsessive Compulsive Scale.

with a mean duration of 21.9 years (SD=16.2). The mean age at onset was 16.5 years (SD=8.4).

## RESULTS

Table 1 shows the complete results of the study. Pretreatment obsessive-compulsive symptoms were of moderate severity: the mean Yale-Brown Obsessive Compulsive Scale score was 22.5 (SD=6.6). Before treatment all subjects met the criteria for at least one personality disorder. Two subjects (patients 1 and 17) met the criteria for two personality disorders, and one subject (patient 12) met the criteria for three personality disorders. After treatment obsessive-compulsive symptoms were of subclinical severity: the mean Yale-Brown scale score was 10.6 (SD=5.7), a decrease of 11.9 points. After treatment the Revised Structured Clinical Interview for DSM-III-R Personality Disorders revealed that 11 patients no longer met the criteria for a personality disorder, while six continued to meet criteria (two for obsessive-compulsive, two for self-defeating, one for dependent, and one for mixed personality disorder).

Ten patients who showed a decrease of 50% or more in their scores on the Yale-Brown Obsessive Compulsive Scale after treatment were classified as "responders," and the remaining seven patients were classified as "nonresponders." Nine of the 10 responders to treatment for obsessive-compulsive disorder no longer met criteria for a personality disorder, while five of the seven nonresponders continued to meet such criteria (p=0.02, Fisher's exact test). Responders and nonresponders did not differ significantly in pretreatment Yale-Brown scale scores (t=1.78, df=16, p>0.10), age (t=0.36, df=16, p>0.72), or duration of obsessive-compulsive disorder (t=–1.03, df=16, p>0.32).

## DISCUSSION

The results of this study confirm previous findings (6) that *DSM-III-R* personality functioning may improve in some individuals with obsessive-compulsive disorder if there is improvement of the axis I disorder. Such results provoke serious questions about the nature of comorbid personality disorders in cases of obsessive-compulsive disorder. It is quite possible that the presence of such a debilitating disorder as obsessive-compulsive disorder, the symptoms of which extend into so many areas of everyday functioning, confounds the assessment of personality, as has been suggested in cases of panic disorder (10). If this hypothesis is true, then the concept of comorbid or concomitant personality disorders in some patients with obsessive-compulsive disorder is misleading.

Another interpretation of these results concerns the issue of diagnostic overlap. One consistent finding of clinical personality research in obsessive-compulsive disorder is the high prevalence of avoidant and dependent features (1, 4, 5). *DSM-III-R* classifies disorders with these features within cluster C of the personality disorders; patients are described as "anxious or fearful." Since anxiety and fearfulness tend to dominate the clinical picture of obsessive-compulsive disorder, it is not surprising to find such a preponderance of these patients with cluster C diagnoses. The personality diagnoses in our study group were, by chance, largely from cluster C. This is important to keep in mind when discussing the results, since cluster C may provide the most likely overlap with obsessive-compulsive disorder and thus might be expected to change more readily in response to significant decreases in the severity of the axis I disorder.

It is intriguing that despite having reminded subjects to describe themselves apart from their obsessive-compulsive disorder and despite actively challenging them when they endorsed items during the structured interview, we still found axis II diagnoses that depended on obsessive-compulsive disorder. Thus, it appears that discerning which symptoms are those of obsessive-compulsive disorder and which more accurately reflect personality is difficult, even for patients themselves. It is clear, though, that these symptoms—even those that are currently classified within the axis II personality disorders—can change with brief treatment.

## PSYCHOTHERAPY

**Dynamic Psychotherapy: An Introductory Approach,** *by Marc H. Hollender, M.D., and Charles V. Ford, M.D. Washington, D.C., American Psychiatric Press, 1990, 215 pp., $31.00.*

In their preface to this book, Hollender and Ford state that they were "stirred by our memories" of Colby's *A Primer for Psychotherapists* (1). For many of us, Colby's book is a classic. Hollender and Ford's superb new book is a worthy successor; it is the distillate of their many years of intensive educational activities and clinical experiences. Hollender and Ford address the psychotherapy process directly and lucidly. Appropriately, they begin with a definition of psychotherapy and discuss its indications. They go on to provide guidelines for the beginnings of therapy and describe its fundamental principles and processes, technical interventions, and termination.

The incisive discussions of the many complexities of therapy are illustrated by excellent case histories and by the authors' attention to the pragmatic aspects of the day-to-day therapy process. For example, they diagram the desirable seating arrangements for the patient and the therapist, confront the issue of payment, and tackle complexities of insight-oriented psychotherapy such as interpretation and resistance.

Their emphasis on the therapist's summarizing his or her impressions of major points briefly at the end of each session is especially important; too often, therapy sessions end somewhat incompletely. There may be little consensus between the therapist and the patient about what has occurred during the session. In this respect, I wish that the authors had noted the outstanding 1964 article of Raymond W. Waggoner, Sr. (2), about one of his former patients who willed her diary to him. It contained her opinions of what had transpired during their therapy sessions 30 years previously. Dr. Waggoner compared them with his therapy notes and found that often there were vast discrepancies between what he and the patient thought had occurred.

Although several types of supportive therapy have been used by physicians since before the days of Hippocrates, the term *psychotherapeia* was introduced into the English language by a surgeon, Walter Cooper Dendy, in a paper that he read to the Medical Society of London in 1853. Hollender and Ford's description of dynamic psychotherapy would have pleased Dendy. They emphasize the central significance of the therapist-patient relationship and recommend ways for the therapist to structure it so that it can be of maximum therapeutic value.

Some of us differ a little from Hollender and Ford on just a few points. One is what I consider to be their lack of attention to the importance of the developmental history. Another is their lack of emphasis on the influence of the family of origin. I think that what happened in the patient's family of origin is often critical, especially during the recent decades when, for example, the problems of divorce, remarriage, and blended families causes concern about relationships and their stability. Notetaking is another point about which I differ with the authors. When the therapist is comfortable about taking notes, his or her doing so does not interfere with therapy, provided, of course, that the patient has been informed that the therapist's notetaking is routine. In fact, many patients regard extensive notetaking as an indication of the therapist's seriousness of purpose.

The authors are to be complimented for this important volume. The chapters on "Psychotherapy Combined With or Augmented by Pharmacotherapy," "Problem Situations and Difficult Patients," and "Termination of Psychotherapy" are particularly outstanding. Their book is more than just an introduction and guide to psychotherapy for students and residents. It will be of special value to the growing number of biological psychiatrists who have not had access to a short definitive volume of this type. The bibliography and both the name index and the subject index are accurate and comprehensive.

Drs. Hollender and Ford subtitle their book as "an introductory approach." They are modest. It will rank as one of the top three or four volumes on dynamic therapy in the English language. I think it should be required reading for residents during each of their years of training, and all of us will learn by rereading it every few years. Again, the authors deserve to be congratulated.

*Louisville, Ky.*

**Interpersonal Process in Cognitive Therapy,** *by Jeremy D. Safran and Zindel V. Segal. New York, Basic Books, 1990, 270 pp., $27.95.*

This is a gem of a book that manages to accomplish a number of things as it pursues its stated intention "to initiate a process of conceptual and technical expansion in cognitive therapy that is informed by other therapy traditions" (p. 4). Along the way, the authors summarize many of the fruitful concepts developed in the areas of emotion, social motivation, and attribution therapy research. They integrate these concepts with an operational perspective on the patient-therapist alliance and give good clinical illustrations of how knowledge of cognitive concepts tied to interpersonal schemata can guide the therapist's appropriate interventions to effect patient change.

For the past decade there has been a growing call for expansion of cognitive-behavioral therapy and techniques beyond the limited view of the individual as a "working self." The authors have responded by partially encompassing notions of the self "as being" and better defining some of the constructs that go into self-organization. The text extends the cognitive-behavioral view into interpersonal experiencing and processing. In many places the dynamically oriented reader will find familiar concepts clarified and put into operational forms that complement the dynamic view as well.

In the introduction the authors lay out current conceptual problems viewed from the cognitive therapy perspective: how to view psychotherapy as a human encounter, how to clarify the process perspective, how to resolve whether supportive and insight-oriented therapies really differ, and how to integrate unconscious information processing into therapy.

The first third of the book then sets up the theses that 1) cognitive-behavioral constructs about the working self need to be complemented by an emphasis on the self as organized for continued attachment as much as it is organized for individual productivity, 2) it follows that change in these constructs is best brought about by correcting the attachment between patient and therapist, and 3) the cognitive-behavioral method shows how particular patient-therapist attachment interactions can lead to generalized changes in the patient's interpersonal schemata. The term "schema" is in some danger of becoming a buzz word these days to plug into one's language when discussing the multidetermined nature of experience, thought, and action. Here, however, the authors limit and define their use of the word to an interpersonal schema—the generic representation of self-other interactions that is elaborated from personal experience (p. 66). Its function is to reorganize the processing of events in the real world for the purpose of maintaining relatedness (p. 68). They postulate that maladaptive functioning perpetuated by faulty personal schemata produces corresponding maladaptive interpersonal exchanges. This leads to the kind of processing cycle in which, for example, an aloof, paranoid, suspicious person expects to be rejected or viewed in a guarded way by others and indeed induces such reactions by his or her behavior.

The rest of the book emphasizes how the therapist intervenes to correct such cycles of interpersonal exchange. The first task is to get the patient to identify those core elements which perpetuate specific cognitive-interpersonal cycles. The reader will find that much of this discussion resonates with dynamic theorists such as Luborsky and Strupp and is reminiscent of the triangles of people and conflict that Malan, Davanloo, and others (starting with Karl Menninger) have identified as a central focus of dynamic therapy. Clarification of the elements of a specific cycle starts an intervention process for the therapist. This intervention consists of participant observation, identifying interpersonal markers in the flow of patient discourse that indicate discontinuities in his self-organization, then clarifying these discontinuities and empathically "metacommunicating" about them.

The change process that is advanced here involves three mechanisms: 1) decentering—experiencing one's own role in constructing reality, 2) experiential disconfirmation—disconfirming dysfunctional beliefs about the self and others through new experiences, and 3) accessing action-disposition information—discerning aspects of one's own inner experience that have previously been out of awareness (p. 6).

Decentering involves teaching the patient how to step out of his or her experience to observe it and quickly step back in to participate. The functional emphasis of this collaborative operation is on making patients aware that they construct and can change the construction of their experience and that this perceptual skill can be brought to bear on distorted perceptions with practice. The authors provide a series of session excerpts that illustrate the need for a strong positive therapeutic alliance as a precondition to collaborative relating over such perceptual corrections. The therapist must also be able to monitor the patient's dialogue to identify and inquire after interpersonal markers that signal points for fruitful intervention.

Experiential disconfirmation requires, first, patients' awareness of the content of specific playful ideas from which they construe expectations. Second, self-observant disconfirming experiences of these ideas in an atmosphere that, third, promotes reconstruction of the maladaptive content in the specific interpersonal schema. The authors' discussion and the clinical examples they provide clarify and operationalize this process, which Alexander and French, of course, called "corrective emotional experiencing" many years ago.

Action-disposition information refers to the content carried in cognitive-affective-behavioral couplings that the self constructs. It is hypothesized that when some of these couplings are originally formed in reaction to a situation, their experiencing and implied consequences threatened patients' views of themselves or their attachment to others. Consequently, parts of these couplings were distorted, repressed, or assigned to memory as "not me" in the service of reducing stress. The point of accurately emphasizing and accepting such patient coupling in the therapy relationship is to allow the patient to reexperience and resolve such dysfunctional views or beliefs. Presumably, "as patients develop more feasible interpersonal schemata and begin to process affective information more fully, their verbal and nonverbal behaviors become more congruent and duplicitous communication ceases. They become more aware of, and are able to assume more responsibility for, their dysfunctional interpersonal patterns" (p. 195).

In summary, I came away from this book feeling that the authors had contributed much clarity to how one uses the therapeutic relationship to promote change in the "working self" aspects of one's internal schemata. They allude to and operationalize, sometimes without labeling or giving due credit, other constructs in the "self as being" that must be addressed during the change process—shifts of material from unconscious to conscious levels, working around and through defenses, balancing positive self-validating experiences against self-denigrating ones to change the self-reactive stance of one's dynamic self-concept, and so on. I am in great sympathy with this book and feel that it contributes to its stated aim to further "the integration of different psychotherapy systems [which] thus increases the possibility of understanding and working with important clinical phenomena by broadening the range of phenomena actually examined and by providing multiple perspectives on the same phenomenon" (p. 14).

This book is not for entry-level therapists because it presumes that the reader had received graduate training at the postdoctoral level and beyond. I could easily pair this book with Leston Havens' *Making Contact* (1) and say that, between the two, most of the current knowledge base for how one sets up the tactics of therapy dialogue is described.

*Seattle, Wash.*

**Concise Guide to Psychodynamic Psychotherapy,** *by Robert J. Ursano, M.D., Stephen M. Sonnenberg, M.D., and Susan G. Lazar, M.D. Washington, D.C., American Psychiatric Press, 1991, 128 pp., $18.50.*

The attempt to reduce psychodynamic psychotherapy to a succinct 128 pages initially arouses a reviewer's skepticism. One can read industriously for years and find partially successful expositions but never achieve full satisfaction. There are a number of reasons for this, of course. Psychoanalytic therapy is a tremendously unwieldy, pluralistic, historical discipline that defies a concise and coherent rendering. Expositors of the field are limited by their individual origins, outlooks, loyalties, and, finally, limitations of vision.

This slim volume, designed to be carried in a pocket, is meant to convey the essence of psychodynamic psychotherapy. It comes nowhere near achieving it, but it manages to convey a lot of information that may be of value to the neophyte therapist. There are well-done sections on patient evaluation and countertransference as well as discussions of practical matters that all neophytes have questions about (phone calls, fees, and office decor). Chapters distinguish brief dynamic psychotherapy, supportive psychotherapy, and psychotherapy of the borderline patient. The book hews to a classical line with some nods toward object relations theory.

The flaws in the book are obvious to the more mature psychoanalytic clinician. The book attempts to teach psychodynamic psychotherapy while relegating psychoanalytic theory to the references. Nowhere are the reasons and goals of this treatment approach outlined or discussed. Neither is the book a manual of psychotherapy that teaches what one says to the patient. The authors say nothing about psychotherapy research and what the patient (or the therapist, for that matter) gains through a well-conducted, appropriately terminated psychotherapy. Although much is made of transference, the book could have benefited from a discussion of Luborsky's method, which helps the trainee to identify "relationship episodes" from which transference interpretations develop. Finally, one of the most difficult things that the novice therapist must do is not mentioned, namely, the lengthy and arduous process of learning to be a psychodynamic psychotherapist. What actual skills are precursors to psychodynamic technique? Where does one start? How long does it take? Why should one decide to do this in an era of resurgent biological psychiatry? What sort of person makes a good dynamic psychotherapist? These questions ultimately must be handled in actual training, supervision, and personal psychotherapy or psychoanalysis.

Sections of this book are cogently written and genuinely reflect the rich spirit and principles of classical psychodynamic psychotherapy. It is an easy read, and the clinical examples are well done. Perhaps the true measure of success is whether the trainee, using direction provided by the references, turns to meatier references (Freud, Greenson, Malan, Langs, Kernberg, J. Sandler, and others) and embarks on the lifelong quest of understanding what psychodynamic psychotherapy entails.

MARVIN W. ACKLIN, PH.D.
*Honolulu, Hawaii*

**Hypnosis: A Jungian Perspective,** *by James A. Hall. New York, Guilford Press, 1989, 179 pp., $25.00.*

Dr. Hall, a well-known Jungian psychoanalyst, has written a remarkable book for the novice as well as the experienced practitioner. He provides fundamentals of Jungian analysis and shows the application of hypnosis. He establishes relationships among psychotherapy, hypnotherapy, the induction of trance as well as dream states, and analysis with active imagination. Successes and pitfalls are demonstrated with the use of personal anecdotes that can keep any reader amused and interested throughout the book.

In his introduction Dr. Hall points out that conceptualizing the essence of hypnosis is very difficult. It is not a commonly staged performance, nor is it a response to suggestion or repetitive stimuli. Hypnosis should be thought of as a movement beyond the conscious into the realm of the unconscious. Dr. Hall discusses the relationship of hypnosis to dream states and the use of hypnotherapy to express the content or "complexes" of the unconscious.

Although Jung subsequently abandoned the practice of hypnosis, Dr. Hall speculates that Jung would reconsider using hypnosis in today's context. In the summary of chapter two he begins to foreshadow the linkages of dream work and active imagination to hypnosis. He explains how these interactions can be applied to our understanding of the use of complexes by the psyche, stressing that the basic rule for employment of this technique should be as one therapeutic modality among others in a larger framework of clinical practice.

The subsequent chapters deal with basic concepts of the Jungian psychotherapy such as complex, self-image, transcendent function, and archetype. For a novice such as myself, this provides the enlightenment needed in preparation for the remainder of the book.

Throughout the mid-portion of this book Dr. Hall performs the difficult task of relating Jung's theory on the nature of the psyche to the function of hypnosis. In his discussion of transcendent function, Dr. Hall stresses that through the deep concentration of hypnosis and the development of an active imagination, a transcendent function is formed that allows us to explore the complexes of the subconscious.

The latter portion of the book deals with practical considerations in the use of hypnotherapy. These include the actual induction techniques and the issues of transference and countertransference that can arise during the development of a therapeutic alliance.

In chapter nine the author suggests that transference-countertransference interactions may be due to the "mythological overtones that are attached to hypnosis." Fears of being controlled or dominated by the will of the therapist lend themselves to strong transference. If these same myths are shared by the therapist, underlying fantasies of power may become manifest.

Dr. Hall concludes with "Clinical Integration: Applications of Hypnotherapy Within a Jungian Model." Here he describes how self-images are broken apart and reformed as a result of experiences. Through the use of hypnosis, an affect-bridge can be used to create or alter complexes in order to counterbalance pathologic complexes and thus alter the individual's concept of self.

This text offers a comprehensive yet concise discussion of the practical use of hypnosis in the context of Jungian psychotherapy. For the clinical psychiatrist involved with therapeutic hypnosis or the academic psychiatrist involved with the instruction of novices, this book is an excellent resource. For residents and medical students, it provides an excellent introduction to both hypnosis and Jungian psychotherapy.

## SOMATIC THERAPY

**Handbook of Psychiatric Drug Therapy, 2nd ed.,** *by George W. Arana, M.D., and Steven E. Hyman, M.D. Boston, Little, Brown and Co., 1991, 185 pp., $22.50 (paper).*

This is the second edition of an extremely useful book that was first published in 1987. The authors have updated and expanded all chapters, but the total number of chapters remains at seven. The organization of the book consists of an introductory chapter reviewing the basic principles of prescribing psychotropic agents and a chapter on each of the major categories of psychotropic drugs. There is a separate chapter entitled "Other Agents," which discusses the use of drugs, such as verapamil and clonidine, that have been drawn into psychiatric use from different categories of drugs used for treating medical illnesses. The use of medications in different psychiatric disorders is comprehensively covered. This book has a problem-specific table of contents in the beginning that is extremely useful for quick reference. New compounds introduced into the United States, like clozapine, fluoxetine, and clomipramine, are included.

The authors have been successful in putting a lot of information succinctly into a small handbook. The chapter on antipsychotic drugs gives an overview of the historical aspects and chemical structures in addition to pharmacological aspects. Tables listing equivalent doses, comparative side effects, and available preparations of antipsychotic drugs are extremely useful in daily practice. The authors discuss the major side effects of antipsychotics and their treatment very elegantly.

The chapters on antidepressants and lithium similarly cover all aspects of their use in psychiatry and almost all clinical prescribing questions that arise, such as use in pregnancy or in patients with seizure disorders, and the usefulness of drug plasma levels. The tables and illustrations given in these chapters, again, are extremely useful. The use of fluoxetine and clomipramine as well as their mechanisms of action and side effects are well discussed. It might have been helpful to have information as well on fluvoxamine and sertraline, which are expected to be introduced for clinical use. The use of lithium, including special reference to the elderly, is well covered.

Chapter five, which deals with anticonvulsants, discusses all aspects of their use in psychiatry in a clinically useful fashion. Hematological and hepatotoxic side effects of carbamazepine and valproic acid, respectively, are extremely well discussed.

The chapter on benzodiazepines has all basic information and gives a nice description of the $\gamma$-aminobutyric acid$_A$ receptor as well as an exhaustive list of causes of insomnia. Sublingual use of benzodiazepines is a new feature I learned from this book.

The last chapter discusses the new drugs that psychiatry is acquiring from other areas of medicine, such as the use of clonidine in the treatment of akathisia and the use of verapamil in mania. I certainly welcome the inclusion of disulfiram, the most commonly used drug for alcoholism. The book includes a detailed account of its mechanism of action.

This book is of high technical quality. The editing is good, and typographical errors and misspellings are rare. I would like to point out especially that the comparative tables of different medications are excellent for quick reference. Precautions regarding the use of medications in the elderly are mentioned at appropriate places. Drug interactions are extensively covered. The bibliography is structured so that finding specific references is easy.

This book will prove useful to general psychiatrists as a quick and portable reference. It will also be extremely useful for internists and family physicians. Psychiatry residents should be using this book, as should medical students during their clerkship. I strongly recommend it.

SANJAY GUPTA, M.D.
*Iowa City, Iowa*

**Fundamentals of Monitoring Psychoactive Drug Therapy,** *by C. Lindsay DeVane. Baltimore, Williams & Wilkins Co., 1990, 267 pp., $25.95.*

Numerous guides to the use of psychotropic drugs are now available for the practicing clinician. Each has a particular focus and style, and each can be recommended for some uses or special interests. The present volume is another review of the pharmacology and use of psychotropic drugs. It is unusual, however, in that it is written by a pharmacist rather than a psychiatrist.

As one might expect, the strongest points of this book are in the pharmacological information provided on each psychotropic drug at the beginning of each chapter. For example, listed under the term "database" are the formulations for a drug, the basic pharmacology, and pharmacokinetics. There is also useful information on dosage regimen, therapeutic monitoring, and interactions. Although all of this information is readily available in any other standard psychotropic drug-treatment manual, it is nicely and usefully gathered in each section in this volume. Furthermore, the introductory sections on basic pharmacokinetics provide a useful review of the topic of pharmacokinetics for the practicing clinician.

The book is much less successful, however, in its clinical description of psychiatric patients and the practical guidelines for prescribing medications. Descriptions of clinical syndromes tend to be brief and relatively superficial, and the information regarding drug treatment of different syndromes is presented uncritically as reviews of other published literature. The reader often wonders whether the author has actually had personal experience in using drugs with patients and if he understands the many variations and ranges of response that patients will have that never appear in published research reports. Consequently, the clinical applicability of using psychotropic drugs has a rather mechanical and lifeless quality in this book.

The title of the book is quite misleading. A volume reviewing the topic of therapeutic drug monitoring and providing specific information to clinicians on this topic would be very helpful. However, the actual drug monitoring content forms only a small fraction of each section of this book. Consequently, the reader is impressed by the amount of information gathered together here but is unsure of how to use it. It is not a comprehensive or critical review of the psychopharmacological literature, nor is it as useful a clinical guide as many of the other psychotropic drug-treatment manuals. Perhaps its most useful niche is to provide basic pharmacological information about each psychotropic drug as well as the classes of psychotropic drugs in a readily accessible manner for quick office reference. It probably will be very useful for pharmacists and for nonpsychiatric physicians who need ready access to the pharmacological profile of psychotropic drugs. For the practicing psychiatric clinician, resident, or student of psychiatry, however, this volume will not be as useful as some of the other psychotropic manuals that are currently available.

**Lithium and the Endocrine System,** *edited by F. Neil Johnson. Basel, Karger, 1988, 219 pp., $158.50.*

This book is the second of a series of volumes, Lithium Therapy Monographs, under the general editorship of Neil Johnson. This particular volume addresses itself to the effect of lithium on the endocrine system and adopts a hormone-by-hormone approach. Most of the chapters are devoted to the description of experimental findings in animals. As such, the book would not, I think, be of great value to clinicians seeking knowledge about the effects of lithium on a particular hormone or endocrine system. The one exception is the overview chapter on lithium-thyroid interactions (chapter 7). Information in the chapter should be well-known to most prescribers of this drug, but it does contain some useful practical information concerning the monitoring of thyroid function during lithium therapy. The remaining chapters do not contain much by way of practical information for the clinical psychiatrist. The volume would be of interest, however, to those engaged in research into the mechanism of action of lithium. This is primarily the stated aim of the volume set out in the editor's preface. The book succeeds in this aim, although it may have been improved by combining some chapters. For example, chapters 4 and 18, dealing with melatonin and pineal rhythms, are clearly related and complement one another.

This is most unlikely to be a volume of interest to clinicians, nor is it likely to be one that they would purchase for their personal libraries. The volume contains much of the current experimental data on lithium and the endocrine system and would be a worthwhile purchase for a university/hospital library. In summary, it is a highly specialized volume of interest primarily to researchers in the area.

*Heidelberg, Victoria, Australia*

**Mechanisms of Drug Action on the Nervous System, 2nd ed.,** *by Ronald W. Ryall. New York, Cambridge University Press, 1989, 224 pp., $49.50.*

This monograph was first published in 1979. Because of a number of major advances in related fields since then, the author undertook the task of rewriting and reorganizing most of the book, the result being this second edition. The book has two general chapters ("Introduction" and "Techniques to Investigate the Actions of Drugs on the Nervous System"), two chapters on the peripheral nervous system ("Neuromuscular Junction" and "Autonomic Nervous System"), and eight on the CNS. The last category includes chapters on central neurotransmitters, the blood-brain barrier, general anesthetics, pain and analgesics, drugs acting on inhibitory amino acids, drugs for schizophrenia, mood disorders, and disorders associated with defined brain lesions such as Wilson's disease.

The author is a lecturer in pharmacology at the University of Cambridge. This book is intended primarily for undergraduate students in science and preclinical medical students. Based on his years of teaching experience, the author has sought to present a "story" about each class of drugs. On the whole, he has accomplished this task well. The entire book is quite readable, thanks to the use of simple but informative tables and figures and a deliberate avoidance of unnecessary technical jargon. Instead of citing numerous references throughout the text, the author has listed "selected reading" at the end of the book. In general, the author has done an excellent job of providing a concise but interesting summary of a vast and growing field.

In such a book, there is an unavoidable risk of oversimplification, sometimes leading to wrong generalizations. For example, while describing extrapyramidal side effects of antipsychotic drugs, the author states, "The dyskinesias are of several types. Least troublesome . . . [is] akathisia" (p. 187). In reality, akathisia is usually not included under dyskinesias; also, it is one of the most distressing side effects.

There are two important omissions in the book. One is deliberate and involves drugs of abuse for which "too little is known about their mechanisms to give a coherent picture" (p. xvi). I do not think that we necessarily know much more about the mechanisms of action of therapeutic drugs compared with the drugs of abuse. Another missing area is a discussion of altered pharmacokinetics and pharmacodynamics of the various drugs with aging. In view of the growing elderly population and the common use of psychotropic drugs in older persons, greater attention to this issue would be helpful. Perhaps such deficits could be corrected in the third edition of the book.

Overall, I believe that this is an excellent introductory monograph on the subject and is worth recommending to the intended readership, namely, preclinical medical students and undergraduates in other sciences.

DILIP V. JESTE, M.D.
*San Diego, Calif.*

**Benzodiazepines in Clinical Practice: Risks and Benefits,** *edited by Peter P. Roy-Byrne, M.D., and Deborah S. Cowley, M.D. Washington, D.C., American Psychiatric Press, 1991, 227 pp., $25.00.*

This book is a multi-authored up-to-date review of the benzodiazepines, a widely used group of anxiolytic and sedative/hypnotic drugs. The first two chapters present an excellent review of the biological mechanisms and pharmacokinetics and pharmacodynamics of these drugs. Interested clinicians will discover that considerable gains have been made in understanding the binding of benzodiazepines to receptor sites in the CNS, mechanisms of tolerance and withdrawal, and the possibility that there are endogenous ligands in the CNS. Concepts of lipid solubility and differences between single-dose and multiple-dose pharmacokinetics and their clinical application are usefully described.

The second and largest section of this book deals with the clinical uses of benzodiazepines. Treatment of anxiety and depression, psychosis, acute stress reactions, and sleep are discussed. Clinical vignettes are provided at the end of each chapter to illustrate the drug's uses. Section three comprises three excellent chapters reviewing the cognitive and psychomotor toxic effects, dependence, withdrawal, and the abuse liability of benzodiazepines. Each is a clearly presented review. Although relevant research literature is cited for illustrative purposes, these chapters are also not comprehensive or critical literature reviews.

The fourth section of the book discusses special issues and the uses of benzodiazepines in special populations: treatment of the medically ill, the use of benzodiazepines combined with behavioral treatment and psychological treatment, and the use of benzodiazepines in the elderly. All are well presented and useful for the clinician. The chapters are practical rather than comprehensive or critical literature reviews.

Overall, this volume provides an excellent clinical companion to the American Psychiatric Association Task Force report *Benzodiazepine Dependence, Toxicity, and Abuse* (1). If there is any complaint, it is the lack of an index. Since there is so much clinically useful information, the absence of an index is both surprising and somewhat annoying. Apart from this reservation, this well-edited review is recommended for clinicians.

*Boston, Mass.*

## STRESS AND ANXIETY

**Posttraumatic Stress Disorder: Etiology, Phenomenology, and Treatment,** *edited by Marion E. Wolf, M.D., and Aron D. Mosnaim, Ph.D. Washington, D.C., American Psychiatric Press, 1990, 264 pp., $39.50.*

Using as core material data presented at the May 1989 meeting of the American Psychiatric Association as well as the results of studies undertaken by other research scientists, the authors gathered in this book present a comprehensive volume on the state of the art regarding posttraumatic stress disorder (PTSD). Major topics include nosologic issues, vulnerability to the disorder, dissociative mechanisms, the applicability of the resilience hypothesis for predicting prognosis and future outcome, reliability and validity issues, potential biological and psychoneuroendocrinological markers, comorbid disorders (e.g., borderline personality disorder, major depression, anxiety disorder, panic disorder, alcoholism or other substance abuse disorder, and factitious PTSD), premorbid predictors (e.g., psychopathology, antisocial behavior, socioeconomic status, and insecurities about masculinity and independence), psychosomatic symptoms, the effect of repeated exposure to combat activities, stress-induced analgesia, PTSD in response to major disaster, treatment modalities (e.g., antidepressant medications and individual and group psychotherapy), and forensic issues.

In large part, because of the still relatively early stage of development of knowledge in the field, many issues require extensive further investigation. One problem is the lack of reliability and validity estimates of a number of PTSD scales. It is interesting that no reliability estimates of any of the PTSD scales are reported in this volume. However, the chapter by Julia Frank et al. reports having "data showing excellent interrater reliability for diagnosing PTSD, using the SCID and *DSM-III-R* criteria." Relating this to specific guidelines for interpreting clinically and statistically acceptable levels of reliability estimates, Sparrow and I (1) and Fleiss (2) would define kappas or intraclass correlation coefficients of 0.75 and beyond as "excellent." A second problem is the manner in which the diagnosis of PTSD is made—structured or semistructured interview formats are usually regarded as providing more reliable and valid diagnostic information than self-report instruments. A third problem involves the challenging issue of comorbidity. Matthew Friedman reports some very valuable work in this area; he applied biological criteria for differentiating PTSD from both major depressive and panic disorders. Although using a different model, this work parallels that of Steinberg (3), who, in a related field, provided very specific criteria for differentiating one of the dissociative disorders (depersonalization) from a number of other disorders with which it is sometimes confused (e.g., depression, schizophrenia, substance abuse, seizure disorders, and organic illnesses). Finally, more well-controlled, double-blind clinical trials with appropriately large samples need to be conducted to assess properly the efficacy of various proposed treatments of PTSD.

In conclusion, this book is as valuable for assessing the status of research in PTSD as for its pinpointing specific areas requiring further research. Because of its scope, it should be of interest not only to those with a specific focus on PTSD but also to the wider audience of mental health practitioners and research investigators. For example, readers interested in dissociative disorders would be interested in the chapter by David Spiegel and Etzel Cardeña, which conceptualizes multiple personality disorder as a chronic and severe form of PTSD. The book would also be of interest to those with interest in borderline personality, panic disorder, anxiety disorder, and alexithymia (4).

I hope that in the next decade a number of the challenging problems brought to light by this book can be resolved, so that sufferers of PTSD and related disorders will receive appropriate diagnosis and treatment for their afflictions. Jessica Wolfe and Terence Keane point out that one estimate of the prevalence of PTSD in the community is 1%, which is the same as the estimate for schizophrenia. In this regard, my colleagues and I have recently published a set of recommended guidelines for establishing the reliability and validity of neuropsychological disorders with low base rates (5).

**Strangers at Home: Vietnam Veterans Since the War,** *edited by Charles R. Figley and Seymour Leventman. New York, Brunner/Mazel, 1990, 416 pp., $26.95.*

**Trauma and the Vietnam War Generation: Report of Findings From the National Vietnam Veterans Readjustment Study,** *by Richard A. Kulka, William E. Schlenger, John A. Fairbanks, Richard L. Hough, B. Kathleen Jordan, Charles R. Marmar, and Daniel S. Weiss. New York, Brunner/Mazel, 1990, 352 pp., $19.95.*

The climactic year of the Vietnam war was 1968, when more than one-half million U.S. combat troops were fighting in Vietnam. Oddly, that year *DSM-II* did not include a diagnosis encompassing combat stress. *DSM-I,* published during the Korean war, only a few years after the end of World War II, included the diagnosis of gross stress reactions, which subsumed combat-stress reactions. More recently, posttraumatic stress disorder (PTSD) was formalized as a psychiatric diagnosis with the publication of *DSM-III* in 1980, and PTSD will be even more keenly redefined in *DSM-IV*.

The attitudes of U.S. servicemen and women and their compatriots have changed remarkably from the years of our nation's military entanglement in Southeast Asia to our more recent victory in Southwest Asia. What remains is that the United States has fought wars and that warfare, by definition, is traumatic, leaving a group of citizens emotionally and physically wounded by the experience. *Strangers at Home* and *Trauma and the Vietnam War Generation* are books in the Brunner/Mazel Psychosocial Stress Series. Fundamentally, each is about the Vietnam war and its emotional aftereffects on the individual soldier and our society collectively. Even though both books focus on the Vietnam experience, the audiences of each do not necessarily overlap.

*Strangers at Home* was originally published in 1980, the same year the diagnosis of PTSD was introduced, and has now been updated. It is an edited collection of well-written chapters spanning the war's psychological, sociological, political, and legal effects on the men and women who fought it. Most of the authors are Ph.D.s, and several have served as combatants in Vietnam.

The book is efficiently organized for ready reference and divided into three major subsections: War and the Warrior, The Returning Veteran, and Government Policies and the Veteran. Within each section are individual chapters with easily identified subsections. The first section emphasizes oral histories and the combat environment, and the second examines the transition and alienation faced by returning veterans. The last section underscores the struggles and successes of veterans, emphasizing legal problems, activism, and substance abuse and mental health programs. Conveniently, readers seeking specific information can page through the table of contents and quickly identify areas of interest. Each chapter is self-contained with cohesive transitions and a homogeneous tone not often found in multi-authored texts.

*Strangers at Home,* unlike *Trauma and the Vietnam War Generation,* is not heavily weighted in graphs, charts, and abbreviations. Both books, however, like many focusing on PTSD, are embellished with numerous firsthand reports of battle, loss, betrayal, and abandonment. Having fought in Vietnam as a Marine officer and later serving with the Marine Corps as a Navy psychiatrist in the Gulf War, my experience has lead me to become suspect of the overly dramatized war stories that are occasionally encountered in PTSD therapy groups. A little like fairy tales, war stories are stories of exclusion that often begin with a "once upon a time" narrative style which invites exaggeration. For the most part, however, I feel the editor or authors were judicious in their choice of case reports and selected accurate accounts of war and alienation. These case studies emphasize ground warfare, specifically infantry combat, where the faces, sounds, and smells of battle are unnervingly palpable. (The stresses of air and naval warfare are equally intense but characteristically more abstract.)

With a different voice, *Trauma and the Vietnam War Generation* is a book shaped by the findings of the National Vietnam Veterans Readjustment Study. In 1983, the U.S. Congress directed a survey of Vietnam veterans to establish "the prevalence and incidence of post-traumatic stress disorder (PTSD) and other psychological problems in readjusting to civilian life." This text embodies the outcome of this study, which took more than 4 years and nine million dollars to complete. Among the important findings unearthed is the recognition that, during the years of the study, 15.2% percent of all male and 8.5% percent of all female Vietnam combat theater veterans suffered from PTSD. The National Vietnam Veterans Readjustment Study analyses of the lifetime prevalence of PTSD indicated that 30.6% of male and 26.9% of female theater veterans qualified for a PTSD diagnosis at some time during their lives. The text focuses on the study's findings and implications.

Governmental reports are typically laden with stilted language, making for wearisome reading, and the authors and editors of this book should be praised for transforming technical data into a text that is much more "reader friendly." Essentially, *Trauma and the Vietnam War Generation* is a book created from facts, statistics, and in-depth scientific research, making it ideal reading for only the serious student of the Vietnam era or professionals particularly interested in war-related PTSD diagnosis, treatment, and research. Each chapter begins with a concise commentary and a chapter overview; these are then amplified throughout the text by numerous clearly marked sections emphasizing didactic research.

For psychiatrists treating veterans, a close familiarity with PTSD and the character of the patient's military service is essential. These books are helpful and professionally oriented, discussing the impact of the Vietnam war on veterans. The diagnosis of PTSD or "Vietnam syndrome" is purposely viewed solely from the vantage point of that war, offering the double-edged sword of making these books excellent reading for the clinician with subspecialty interest in PTSD but an unprofitable choice for psychiatrists treating emotional traumas that are often equally personal and shattering but remain beyond the territory of war.

For a reader broadly interested in the Vietnam era, the war's veterans, and PTSD, I would first recommend *Strangers at Home.* The editor is a renowned PTSD scholar and has edited several books focusing on stress disorders among veterans. This book touches on the psychological aspects of ground combat and aptly addresses the returning soldier's alienation from a less than welcoming society. Of course, in a timeless way, estrangement shadows every warrior returning from war. In Homer's *Odyssey,* Ulysses was cursed: "God of the Sea, I beg you, punish Ulysses for this. Visit him with storm and shipwreck. Let him wander many years before he reaches home, and when he gets there let him find himself unwanted, a stranger." Tragically, in all wars, among the victors and vanquished, some warriors inevitably become strangers at home.

*Charleston, S.C.*

**Anxiety and the Heart,** *edited by D.G. Byrne and Ray H. Rosenman. New York, Hemisphere Publishing Corp. (Taylor & Francis Group), 1990, 491 pp., $55.00.*

Probably almost as long as man has thought about the heart and heart disease he has also speculated as to the relationship between anxiety and heart disease. This important book draws experts from various parts of the field to present a synthesis of the findings in their area. The final conclusion, as summed up by Ray Rosenman, is, "In particular, the widely held belief that anxiety, cardiovascular reactivity, and stress responses play causal roles in the pathogenesis of hypertension and coronary heart disease increasingly lacks validity" (p. 478). For this summary alone the book is important. The writing style, with the exception of a few clinical chapters and the conclusions section, has the style and feel of a reference text. In fact, most readers will probably use it for this purpose. Each chapter is perfectly readable, however, and the book is well edited.

The book consists of five sections: Basic Concepts of Anxiety, Biological Approaches to Anxiety, Anxiety Disorders and the Cardiovascular System, Responses to Cardiovascular Illness and Patient Management, and Conclusions. The first section contains four chapters: "The Concept of Anxiety," "The Anxiety Disorders," "Generalized Anxiety Disorders and Panicogenic Syndromes," and "Assessment of State and Trait Anxiety in Cardiovascular Disorders." These chapters are straightforward, cover contents indicated by their titles, and appear to be written by authors with a deep understanding of each area.

The second section consists of three chapters—one on physiology, one on the neural regulation of the cardiovascular system, and one on the neurobiology of anxiety. These chapters are comprehensive and well-written. However, they are also highly technical. I imagine that they would be of most use to people actually doing research in these areas.

The third section has seven chapters. A group of chapters on anxiety and coronary heart disease, mitral valve prolapse, and cardiovascular reactivity seem to be a bit repetitious because each comes to the same conclusion—that there is no proven relationship between anxiety and heart disease. Each chapter, however, is carefully and thoroughly written and approaches the question from a slightly different angle. There are also chapters on silent myocardial ischemia, emotions and sudden cardiac death, and type A behavior. These are highly interesting chapters, although the relationship between anxiety and heart disease was again found to be small. The chapter on type A behavior concludes that a relationship between this behavior and heart disease is present, if at all, only in a subgroup (those type A individuals who are in stressful situations and who deny that they are under stress).

Part four consists of four chapters that relate to how psychological/psychiatric variables interact with the outcome of individuals who already have cardiac disease or hypertension. These chapters would probably be of value to clinicians working in these specific areas.

In the last section the two chapters agree on their main points. The overall conclusion appears to be that the closer and more rigorously the relationship between early anxiety and later heart disease is examined, the less evidence of a relationship is found.

*Brookline, Mass.*

**Stress, Personal Control, and Health,** *edited by Andrew Steptoe and Ad Appels. New York, John Wiley & Sons, 1989, 323 pp., $67.50.*

Between 1900 and 1905, William of Occam put forth a maxim that assumptions introduced to explain a thing must not be multiplied beyond necessity. This attempt to trim off the unnecessary avoirdupois from human logic was later to be known as "Occam's razor."

With a price tag of $67.50 facing them, ordinary, run-of-the-mill clinicians unattached to the academic field, with the inexorable caseload that we normally carry, would find it hard not to be too zealous with Occam's blade in regard to this book. But that would be tragic because this is a great book with a wealth of data and insights embedded in a tundra of multilayered assumptions. This work is the result of the scholarship of 23 authors from the Netherlands, the United States, Great Britain, Sweden, France, and Germany representing public health and epidemiology, medical sociology, social psychiatry, experimental and clinical psychology, nursing, and animal physiology.

Started in 1983 as part of the Medical and Health Research Programme of the Commission of the European Communities concerned with research into the breakdown of adaptation, this book exhaustively covers topics in three broad areas. First is occupational aspects, focusing on the role of control in job settings and the influence of control on health. Second is the clinical perspective, focusing on the relationship of control to clinical problems such as pain, emotional disorders, heart disease, and coping with stressful medical procedures. The third is mechanisms relating stress to control, focusing on psychophysiological consequences of behavioral choice in aversive situations, the role of controllability in cardiovascular activation and cardiovascular disease, neuroendocrine correlates of control and coping, and social control in relation to neuroendocrine and immunological responses.

The postscript, by Andrew Steptoe, serves as the wrap-up. Despite his charming, proper British disclaimer ("The purpose of this chapter is not to provide a summary of material detailed elsewhere, nor to attempt an integration of data from the diverse scientific fields related to control"), Steptoe proceeds to do just that—with the flourish of a well-trained brandisher of Occam's razor. His diagram of the interactive model of stress (p. 311) helped me understand this book better. I read this book (after many months of tortured postponements) the second time around by starting first with Steptoe's chapter 15 and actually found the return to the previously boring pages enjoyable.

The psychological responses to stress are broken down into cognitive, affective, behavioral, autonomic, endocrine, and immunological. Behavioral control is explained as a result of a balance of forces called psychosocial demands and psychosocial resources. The intensity, chronicity, novelty/familiarity, predictability, and complexity of psychosocial demands are explored minutely. I thought the discussions of psychosocial resources and their impact on the need for control or belief in control and the subsequent mastery of stress were the most helpful to me as a clinician. These aspects include cognitive appraisal, psychological coping, social network support, previous experience, and personality and behavior patterns such as hardiness, neuroticism, locus of control, self-esteem, and type A behavior.

I enjoyed the discussions of learned helplessness and was particularly impressed by the observation that control over positive experiences is important. "The way you deal with small things affects the way you deal with big things" is a clinician's standard admonition. This aspect of self-determination suggests that "people may choose not to exercise control in certain situations, but nevertheless feel a sense of autonomy in their decision."

The understanding of fine nuances of levels of perceived and actual control and how they lead to ease or disease will certainly be helpful to employers and employees, dentists, nurses, and physicians alike at work and in their own personal lives. This book is "must" reading for all employee assistance program workers as well as those who are interested in primary and secondary preventive medicine.

## BASIC BIOLOGICAL FUNCTIONS

**Sleep and Biological Rhythms: Basic Mechanisms and Applications to Psychiatry,** *edited by Jacques Montplaisir and Roger Godbout. New York, Oxford University Press, 1990, 236 pp., $49.95.*

The past 20 years have witnessed a large volume of research examining sleep and biological rhythms in psychiatric disorders, particularly depression. This interest has been spurred by the belief that understanding the mechanisms driving sleep and biological rhythms may lead to a better understanding of the pathophysiology of psychiatric disorders. Surprisingly, few books have comprehensively reviewed basic and clinical aspects of this research. It is in this context that *Sleep and Biological Rhythms* appears. The product is a slim but authoritative, well-written, and well-referenced volume.

This book apparently grew out of a symposium held at the University of Montreal. However, the chapters are not merely symposium proceedings, but scholarly articles discussing their respective topics. The book is divided into two major sections, the first dealing with biological rhythms and the second with sleep, with some understandable overlap between the two. In each section, basic science aspects are presented first, followed by human studies and applications to psychiatry. Although most of the chapters are reviews of previous research, several also present new data, research methods, and new hypotheses. Both sections of the book are well presented, but the first section is somewhat more successful at uniting basic and applied aspects.

The section on biological rhythms begins with a clear and concise description of the background of circadian rhythm mechanisms written by Robert Y. Moore. This is followed by Benjamin Rusak's chapter, which discusses different behavioral aspects of circadian rhythms and raises a number of important questions regarding animal studies of circadian rhythms and inferences drawn about these. The discussion focuses on entrainment mechanisms, pacemaker hierarchies, the complexity of "gating" mechanisms, and open- versus closed-loop homeostasis in biological rhythms. Roger Broughton's chapter discusses various rhythms in human sleep, including circadian, long ultradian, and short ultradian rhythms. Also presented are recent results using the extending sleep paradigm as a means of investigating these rhythms. The highlight of the first section of the book is Thomas Wehr's chapter on sleep and biological rhythms in mood disorders. This chapter not only provides a comprehensive review of past sleep research on mood disorders but also discusses hypotheses that have been advanced and offers a new hypothesis: that of sleep as a physiological analog of heat. The chapter also provides a thought-provoking discussion of methodological difficulties in this body of work.

The final three chapters in the first section (authored by Czeisler, Lewy et al., and Terman) discuss more specific methodological aspects of human circadian rhythms research. These chapters are likely to be of greater interest to investigators in the field, but they also provide a useful background for the more clinically oriented. Czeisler's chapter presents a more "classical" method of examining biological rhythms in humans, and Terman focuses on a recent experimental paradigm using simulated dawn and dusk regimens to treat patients with seasonal affective disorder. The chapter by Lewy et al. presents data supporting the use of melatonin as a circadian phase marker. Unfortunately, these authors tend to "personalize" their arguments by contrasting their findings with those of other research groups. This type of argument detracts from the information regarding their research findings, which is certainly interesting in its own right.

The second section of the book deals with sleep and its basic mechanisms. These chapters address REM sleep, including basic anatomy and physiology, and cholinergic mechanisms in particular. Gillin's chapter on the cholinergic REM induction test in psychiatry follows naturally from McCarley's basic discussion of brainstem mechanisms. Another one of the more "basic" chapters, by Krueger et al., gives a challenging model of how different sleep factors and sleep loci may interact, with a specific focus on immune mechanisms. The chapter itself is clearly presented and authoritative, but it would have been helpful to have followed it with a chapter on human clinical studies. For instance, recent research in psychoneuroimmunology and psychoneuroendocrinology are natural follow-ups to the discussion by Krueger et al., but they are not included in this volume.

The final two chapters of the book deal with insomnia and other sleep disorders. Mendelson presents an interesting hypothesis regarding the nature of insomnia in a concise and well-argued format. The chapter by Godbout et al. on narcolepsy and periodic limb movements during sleep is a helpful review, but its relevance to either basic sleep mechanisms or psychiatry is less evident than other chapters.

In general, this volume succeeds at its task of uniting basic and clinical aspects of biological rhythms and sleep research. However, it would benefit from a more precise definition of its audience and goals. As written, it would be most helpful to researchers in the area, although it is certainly very readable for interested clinicians. A second relative weakness is that the psychiatric aspects of the book deal exclusively with depression and mania and do not address other areas of psychiatric sleep and biological rhythms research, such as psychotic disorders, longitudinal studies, and studies of aging. Pharmacological research in human sleep and psychiatric sleep research are also restricted in coverage, dealing only with cholinergic, and more indirectly, $\gamma$-aminobutyric acid-ergic influences.

Despite these few relative weaknesses, *Sleep and Biological Rhythms* makes pleasurable and provocative reading for the psychiatric researcher and clinician with an interest in biological rhythms and sleep.

DANIEL J. BUYSSE, M.D.
*Pittsburgh, Pa.*

**Anorexia and Bulimia: Anatomy of a Social Epidemic,** *by Richard A. Gordon. Cambridge, Mass., Basil Blackwell, 1990, 170 pp., $24.95.*

In this fascinating and well-documented book, Richard A. Gordon elucidates some of the major cultural factors contributing to the increase in prevalence of eating disorders in Western societies. The underlying philosophy of the book draws heavily on the work of anthropologist George Devereaux. The major characteristics of an ethnic disorder include an increased frequency of the disorder in the particular culture and core conflicts that are pervasive in the culture expressed in an acute form in the individual who develops anxiety and mobilizes psychological defenses. Devereaux views ethnic disorders as essentially highly patterned templates for deviance that elicit ambivalent responses from others.

Against this theoretical background, Gordon presents a persuasive argument for the idea that both anorexia nervosa and bulimia nervosa are ethnic disorders. The well-known demographic features of the eating disorders are listed: primarily women are affected, prevalence has increased since the 1960s, and it is more common in Western consumer-oriented societies and in the upper socioeconomic classes. The cultural changes that have occurred during the last 30 years are then described, including changes in the female role, a preoccupation with appearance and body image, and a cultural obsession with obesity and weight control. Each of these wide-ranging cultural changes is then examined in relationship to the development of eating disorders. The author suggests that the central psychological problem faced by patients with eating disorders is symbolic of a much wider cultural dilemma for women in general: women are still raised to please others and subordinate their own desires and strivings but are now also expected to be powerful and accomplished, tasks that require self-determination and assertiveness. The idea that femaleness has undergone a cultural devaluation is another dilemma for young women striving to compete in aggressive and competitive male-dominated educational environments and occupations. The author posits that obesity has come to symbolize not being in control of one's inner self.

In the last section of the book Gordon describes anorexia nervosa and bulimia as deviant behavior patterns that are immediately recognized by others in the culture. He cites Devereaux as stating that ethnic disorders follow the cultural dictum: "Don't go crazy, but if you do, you should behave as follows." The concept "wild weekend diet" of a popular weight-loss program is described as a template for bulimia. Anorexia nervosa and bulimia are viewed as an unstated rebellion against cultural expectations; this rebellion is paradoxically and secretly admired by other members of the culture who are also concerned with the societal dilemmas symbolically represented by the disorders. Gordon concludes that the eating disorders are essentially "antisocial social disorders" that are both an affirmation and a disavowal of society's esteemed values.

## *Final Exit* as a Manual for Suicide in Depressed Patients

SIR: We have recently treated two patients who made serious suicide attempts utilizing suggestions contained in the book *Final Exit: The Practicalities of Self-Deliverance and Assisted Suicide for the Dying* by Derek Humphrey (1). This book, intended to be a guide to suicide for the terminally ill, has raised considerable controversy regarding its impact on those suffering from terminal physical illnesses. We wish to draw attention to its possible effect on suicidally depressed, physically healthy patients.

Mr. A was a 47-year-old man with two children and a long history of depression treated with antidepressant medication. A worsening financial situation led Mr. A to obtain a copy of *Final Exit* in order to learn the lethal dose of diazepam. He felt assured by the book that suicide was "his right" and comforted by the knowledge that his suicide attempt would succeed, since he took the book's recommended dose of diazepam and alcohol.

Ms. B, a 31-year-old woman, had a history of recurrent depression and two previous overdose attempts. She bought *Final Exit* "just in case" her depression should worsen. She found the book "comforting" because it provided "a certain way out if it became necessary." While experiencing increased marital discord her depressive feelings intensified. Feeling her depression was "terminal," with no hope of recovery, she made a suicide attempt using a plastic bag over her head and enough sleeping pills to ensure at least 2 hours of sleep, as outlined in the book. The patient stated that the book "took the emotions out of making a suicide attempt . . . it was like following a recipe."

Both of these patients, although unsuccessful in their attempts, had fully expected to die; and both were "comforted" in their decisions by the book, not only in regard to its guidance regarding a method but in its seeming to legitimize suicide. It is likely that these patients might have made these attempts without having read the book. However, it does seem to have been a facilitator and supporter in their considerations about suicide.

Although the book is intended for adults suffering from a terminal illness, our two patients with major depression mistakenly felt that the book was directed to them. This is partially understandable, since Humphrey does not devote much consideration to the impact of depression on the decision to commit suicide. He addresses the issue briefly when discussing the case of a depressed terminally ill patient who sought out a physician to aid him in his suicide attempt. He writes, "It would be judicious and fair for a physician to decline to help if the patient who is asking for assistance in suicide is clearly depressed and not so rational. That depression may be treatable" (pp. 129–130). Neither patient seemed aware of this. Within the entire book it might easily be missed.

Given our experience we recommend that psychiatrists consider the availability of this book and its possible purchase when determining the risk of suicide in their depressed patients.

## Trichotillomania Treated With Clomipramine and a Topical Steroid

SIR: We recently observed a patient with trichotillomania respond to the combination of clomipramine and a topical steroid.

Ms. A, a 22-year-old woman, had a 7-year history of compulsive hair pulling which started after a "bad perm." The hair pulling frequency and intensity had fluctuated over the years. When first seen, Ms. A had several small bald patches behind the ears and at the crown, which were easily disguised. She had never had large bald patches. She reported having an irresistible impulse to pull her hair and felt unable to control herself. She reported an increasing sense of tension before pulling the hair, followed by gratification after pulling it. There was no other explanation for the disorder, since there was no apparent inflammation to the skin, nor were there other psychiatric disorders that could have explained the compulsion, such as schizophrenia. When first seen, Ms. A was taking 75 mg/day of clomipramine, prescribed by a local psychiatrist. She had been taking the medication for 4 months and reported that it had reduced the hair pulling by approximately 50%. Increasing her dose to 150 mg/day did not provide additional benefit. The dose was reduced to 100 mg/day.

Due to a complaint of pruritis, she was referred to our dermatologists. We asked whether they could prescribe something that might relieve this abnormal sensation. She reported that the itching would center on a single hair which she would then seek out and pull, providing relief. Fluocinolone solution (0.01%) was prescribed, and she was instructed to apply it to the affected areas twice daily. It was believed that this might reduce any inflammation and itching that might stimulate the hair pulling.

Ms. A reported that the tingling stopped within 24 hours after the first application. She continued to use the solution once or twice a day for several weeks and reported that the hair pulling virtually stopped. To test herself, she stopped the solution and experienced a return of the tingling. She returned to using the solution which again rid her of the sensation. She had been using the solution periodically (about once weekly) for more than 20 weeks and still felt that it was of great benefit.

Trichotillomania commonly starts in childhood and persists through adulthood; most hair pullers are women (1). Treatment of trichotillomania is generally disappointing (2) and has included psychodynamic psychotherapy, behavioral interventions, and psychotropic medication. In a double-blind study (3), clomipramine was superior to desipramine. In another (4), fluoxetine was not superior to placebo. There has been little discussion about dermatologic treatments, especially solutions applied directly to the areas of hair loss, particularly in those who report pruritis. Since a substantial minority of trichotillomania patients report these sensations (5), it may be that a multimodal treatment, including the use of topical agents, would be the most helpful.

We are interested in learning whether other clinicians have prescribed topical steroids for their patients, or have referred them to dermatologists who have prescribed them.

## Clomipramine and a Case of Exhibitionism

Sir: We would like to report a development that we noted in a patient who had a rather severe, longstanding history of exhibitionism.

> Mr. A had been arrested and charged with indecent exposure on at least four separate occasions. Subsequent to his arrests he became depressed, expressed suicidal thoughts, and was hospitalized for relatively brief periods of time. He would then be followed with outpatient psychotherapy. Over the past 10 years he attempted to establish control over his behavior, only to have his exhibitionism recur and to return to the practices which brought him into conflict with the law.
>
> After his last arrest he was started on a regimen of clomipramine, 150 mg/day, and was followed in counseling for a period of several months. The patient reported a significant decrease in his desire to exhibit himself after he had been taking clomipramine for approximately 3–4 weeks at the prescribed dosage. In addition he reported that the clomipramine interfered with his ability to ejaculate while masturbating. He noted that he could fantasize about the forbidden activity but that he was unable or very infrequently able to be orgasmic. This resulted in a sense of frustration and prolonged masturbation fantasies without reward (masturbatory satiation). He also reported that when he did have an orgasm it was much less "explosive" than his normal experience.
>
> During the course of treatment, the patient stopped taking his clomipramine for about 2–3 weeks. He noted the almost immediate return of strong wishes to exhibit himself. Upon restarting the medication these wishes again regressed.

While this is only a single anecdotal case observation, we thought it might be worthwhile reporting to readers of the *Journal* who may be interested in this problem.

## Potential Interaction of LSD and Fluoxetine

Sir: We report a case of grand mal convulsions following ingestion of LSD in conjunction with a therapeutic regimen of fluoxetine.

> Mr. A, 16 years old, had an unremarkable medical history, notable for the absence of a seizure disorder, and had been maintained without incident on a regimen of fluoxetine, 20 mg/day, for approximately 1 year. About 1 hour after consuming the second of two doses of "blotter" LSD (and 3 hours after the initial dose), he developed marked stupor. Emergency services were summoned. In transport to the hospital, the patient was observed to develop an apparent focal seizure involving the left arm and face, which progressed to a grand mal convulsion and responded to 10 mg i.v. of diazepam.
>
> Physical findings upon hospital admission were unremarkable. A neurologic evaluation, including EEG and magnetic resonance imaging brain scan, performed 24 hours after admission was normal. Routine urine toxicology, including screens for phencyclidine, cocaine, and amphetamine, was negative. The patient reported having consumed approximately 30 doses of LSD during the preceding year, while compliant with his fluoxetine regimen, without adverse effect, but noted that this was his first experience with a double dose of LSD.

Our review of the literature uncovered a single claim in 1967 of convulsions associated with LSD use (1). Dista Pharmaceuticals reported seizures in 12 of approximately 6,000 patients participating in their preliminary trials, one case subsequent to a massive overdose of fluoxetine and several of the other patients having preexisting seizure disorders. We note with interest the long-established finding of enhanced serotonergic activity in brain preparations of rats exposed to LSD (2, 3), the serotonin-potentiating activity of fluoxetine, and the documented inhibition of epileptiform activity by serotonin (4, 5).

Several limitations in our data restrict the conclusion of the LSD/fluoxetine combination as being the cause of the convulsive episode. These include 1) absence of laboratory determination of the actual illicit substance involved (although the patient's recollections, prior to the interference of retrograde amnesia from the seizure, were of an altered state of consciousness and visual distortions similar to his previous experiences with LSD); 2) the patient's report that he had consumed the same combination (albeit with a considerably lesser quantity of the illicit substance) without incident; and 3) prior reports that fluoxetine alone may cause convulsions. In addition, the possibility of a factitious seizure cannot be excluded, although the absence of secondary gain eliminates a hypothesis of malingering.

Despite these qualifiers, the widening application of fluoxetine and the modest resurgence of LSD use in a subpopulation of adolescents raise the potential interaction as a matter of concern.

## Neuroleptic Malignant Syndrome Induced by Low-Dose Haloperidol

Sir: Neuroleptic malignant syndrome is an uncommon and potentially fatal complication of the use of neuroleptic medications. It is characterized by fever, extrapyramidal symptoms, autonomic instability, altered consciousness, and elevated muscle enzymes (1). Haloperidol is the most common offending agent; as little as 2 mg/day of haloperidol has been reported to cause neuroleptic malignant syndrome (2). We report a case of neuroleptic malignant syndrome precipitated by an intramuscular injection of 0.5 mg of haloperidol.

> Ms. A, a 61-year-old woman with a 3-year history of dementia meeting NINCDS-ADRDA criteria for probable Alzheimer's disease (3), was admitted to a geropsychiatry unit for management of agitation, psychosis, and assaultive behavior. Attempts at behavioral control with haloperidol, at oral doses of up to 2 mg/day, and trazodone, up to 300 mg/day, were abandoned because of lack of efficacy.
>
> While taking no medications regularly (but receiving a maximum of 0.5 mg/day of haloperidol orally as needed for agitation), the patient was given a single intramuscular injection of haloperidol, 0.5 mg. She had never before been treated with a parenteral neuroleptic. Over the ensuing 48 hours, she developed fever (101.5 °F), tachycardia (maximum pulse 120 bpm), and progressive rigidity and lethargy, with her creatine phosphokinase level rising from normal to 1025 mg/dl. A medical evaluation including chest X-ray, urinalysis and culture, blood cultures, and lumbar puncture failed to indicate infection. Treatment with fluids, acetaminophen, and two oral doses of benztropine, 0.5 mg, resulted in full resolution within 72 hours.

This case indicates the potential of a single intramuscular dose of 0.5 mg of haloperidol to induce neuroleptic malignant syndrome. Contributing factors were age (4), moderately severe dementia (5), and agitation. Also notable was the response to anticholinergic medication plus supportive care. The use of anticholinergics to treat neuroleptic malignant syndrome remains controversial. We wish to emphasize the risk of even low-dose parenteral neuroleptics in susceptible patients.

## Patients' Opinions Concerning Side Effects of Depot Neuroleptics

Sir: Patients who use neuroleptics often complain about side effects. These side effects are a major factor in patient noncompliance.

Lingjaerde et al. (1) described the UKU side effect rating scale. The authors noted that doctors and patients often had different opinions concerning the severity of side effects; they reported, moreover, that psychic side effects were at least as common as neurological (extrapyramidal) symptoms.

My colleagues and I have set up an outpatient service (2) for patients suffering from chronic or intermittent psychoses who use depot neuroleptics. Most of these patients have a diagnosis of schizophrenia. A weekly coffee group takes place which is designed to give counseling and supervise patients and their families. Medication and side effects are given broad attention here. Patients are considered competent persons and medication management is directed toward the gaining of information, insight, and acceptance and therapy-oriented discussion.

In family meetings psychoeducation is given to the patients and their families. These meetings include group discussion. In 1989, before a meeting concerning the subject of side effects took place, an inventory of the patient's individual side effects was made.

Items from the UKU scale were used when drawing up the inventory. Since *subjective* assessment is important for medication compliance, however (3), objective criteria were replaced by subjective statements concerning the degree of the experienced discomfort. This was classified on an increasing ordinal scale: 0=absent, 1=slight, 2=considerable, 3=extreme. Those patients who used various depot neuroleptics (but only a few anticholinergics) were highly motivated toward this investigation and 81% (44 patients) completed the inventory.

For each item, responders' scores were computed to determine which side effects gave the most subjective discomfort. This resulted in the following classification of side effects in descending order of inconvenience: 1) sleepiness/sedation, 2) asthenia/lassitude/increased fatiguability, 3) weight gain, 4) tension/inner unrest, 5) concentration difficulties, 6) akathisia, 7) depression, 8) diminished sexual desire, 9) failing memory, 10) tremor, 11) hypokinesia/akinesia, 12) orthostatic dizziness, 13) dystonia/hyperkinesia, 14) accommodation disturbances, 15) reduced salivation, and 16) rigidity. We concluded that side effects affecting psychic functioning were clearly a much more serious problem for these patients than side effects interfering with motor activity.

Since this could be the same in other patient groups, it seems desirable to pay more attention to the subjective burden of side effects. Moreover, patient participation is important when defining research priorities and models.

## Distortion of Racial Identity and Psychosis

SIR: While interviewing patients on the "homeless" ward of a hospital, we noticed an interesting similarity among the delusions exhibited by five psychotic African-American patients: each patient's sense of racial identity was distorted within his or her delusional construct.

One man diagnosed with schizoaffective disorder claimed that he was actually "white" (i.e., Caucasian) and he knew this because "I have eyes; I can see." The other patients, all of whom were diagnosed as having schizophrenia, recognized that they were black, but each claimed to have been born white and then somehow transformed.

Paraphrased examples of their delusional ideas include the following: "My father colored me up and put castor oil in my hair to kink it up. I was originally blond." "I was born a white girl, but when I was five the dentist gave me a shot and then I went into our maid's stomach and came out a little black girl." "I'm actually Sicilian. My dark skin color is due to mixing olive oil with my food." "I was white when I came down on the spaceship, but before I left my color was changed by an injection."

The original purpose of these interviews was to introduce medical students to the psychiatric interview. Selection of patients was based on recommendations of attending psychiatrists who asked patients if they were willing to speak with students. The interviews took place during the summers of 1990 and 1991, and the patients were not in the hospital simultaneously for any significant amount of time; thus, communication among the patients as a factor contributing to the similarity of their delusions seems unlikely.

We performed a computer-based literature search on the MEDLINE database and the PsycLIT database looking for articles discussing a distortion of racial identity among psychotic patients. No such articles were found.

If psychotic patients with a distortion of racial identity are seen fairly often in the clinical setting, it is curious that such patients have not been discussed in the literature. Perhaps in this era of increased sensitivity toward cultural and ethnic concerns, there is reluctance to discuss such racially charged issues in the context of psychological conflict. However, understanding the foundation for this distortion of identity could be useful in treatment and helpful in appreciating the significant effect "minority status" may have on African-American patients.

## Does the End Justify the Means?

SIR: Physicians in academic medicine are familiar with the term "publish or perish" which is a euphemism for survival in academia. Over the last decade funding resources for academic medicine have been decreasing at a steady rate; schools of medicine across the nation have to struggle to keep their various academic departments operating with adequate and experienced faculty. Now there is a new euphemism that is coming to the forefront: "get grants or else." The pendulum in academic medicine is swinging toward a vigorous push for faculty to devote their time to generating income through research grants. Physicians in academia get recognition and reward based on the number of publications and grants that have their names and university affiliations attached to them. Such a reward system is bound to convey to junior faculty the message that patient care and medical teaching are only for second-rate faculty (often labeled as "clinical faculty"), while a real faculty member is one who conducts research, is awarded grant money, and is building national recognition through prolific publications.

The oath of Hippocrates, traditionally sworn by every new graduating medical school class, specifically defines the duty of physicians as patient-centered professionals who devote their life to treating the ill and teaching the art and science of medicine. The current academic climate seems to have lost sight of the mission of a medical school, which is primarily to educate and train medical students to become physicians that are able to treat patients.

Junior faculty hoping for an academic career feel pressured to turn from patient care and student teaching to devote time primarily for research. Junior faculty are even instructed to make "protected time" (1) (i.e., time away from the demands of patients, students, and residents) their first priority. If this current trend in academic medicine continues, medical schools will no longer be able to meet the needs of patient care and academic teaching. Medical schools may be pressured to become research institutions where patients would be primarily evaluated as prospective research subjects, medical students would be instructed through self-study and computer-programmed courses, residents would be trained in acquiring skills for successful writing of grant proposals, faculty would survive only if their names were printed as authors in medical journals, and department chairmen would only be recruited on the basis of their national reputation.

Academic departments pressured by economic and political forces may be pushing faculty toward research to justify their dire needs for funding resources. The principle of "the end justifies the means" should not govern academic decisions. History has taught mankind that this principle has only brought short-lived successes and no long-lasting effect for those who practiced it. Academic medicine should be restored to its intended mission of teaching the art and science of medicine as a patient-care-centered profession that utilizes research to improve the quality of medical care rather than as a means to bring in more funding.

## Diminishing Toxic Effects of Lithium Administration

SIR: Toxic effects of chronic lithium administration can be diminished by a simple change in diet, but until recently this effective treatment has only been available to rats. In 1975, Olesen and colleagues showed that polyuria, growth retardation, and mortality in rats with serum lithium concentrations of 0.6–1.2 meq/liter could be ameliorated by simply adding potassium to the standard rat diet, provided that adequate dietary sodium was available. Although the potential significance of this finding for prevention of lithium-induced polyuria and gastrointestinal disturbances in patients treated for bipolar disorder has been noted (1), the possibility that increasing potassium ingestion would also reduce the therapeutic actions of lithium engendered caution.

More recently, a colleague and I have reported that dietary potassium supplementation sufficient to prevent lithium toxicity in rats and hamsters did not alter serum lithium or potassium concentrations and did not interfere with a CNS action of lithium (delay of circadian rhythms) (2). Human patients may similarly benefit from potassium supplementation without loss of lithium's therapeutic effectiveness. In one case report (3), oral supplementation of 40 meq/day of potassium prevented cardiac repolarization delay associated with lithium treatment, without altering the serum concentration or therapeutic effectiveness of lithium. Several brief reports have shown that, in bipolar patients satisfactorily maintained on lithium, side effects such as tremor, edema, polyuria, and thirst could be reversed by addition of only 16–20 meq/day of potassium (4). This is a relatively small amount of potassium, and well within the range of normal dietary intake.

Most bipolar patients experience some adverse effects of lithium treatment. Treatment of side effects with diuretics or β blockers may alter serum lithium concentration or may lead to toxic interactions. A more conservative approach may be to encourage patients to increase intake of potassium-rich foods by 20 meq/day (e.g., two bananas, two large carrots, two cups of skim milk, or half of a honeydew melon or avocado) (5). Alternatively, 16–20 meq/day of a liquid or tablet potassium supplement may be prescribed, provided that the risks of hyperkalemia and potential irritation and ulceration of the gastrointestinal tract, particularly with potassium tablets, are considered.

Although some psychiatrists use potassium supplementation to improve lithium's low therapeutic index, this treatment approach has never been reviewed. I would appreciate any clinical observations on lithium and potassium interactions in psychiatric or nonpsychiatric applications.

## Hysterectomy in Patients With Panic Disorder

SIR: The association between psychological distress and gynecological problems has long been recognized (1–4). We write to describe our finding that nine of 16 (56.3%) of our subjects with panic disorder as a primary psychiatric diagnosis reported having had a hysterectomy for various gynecological problems.

All our subjects, participating in a clinical trial for older adults, met the *DSM-III-R* criteria for panic disorder. The mean age of these Caucasian women, recruited by television and newspaper announcements, was 62.6 years, with a range of 56–76 years. All lived in the greater San Francisco Bay area and were of middle income socioeconomic status. Age at time of hysterectomy ranged from 22 years to 49 years, with the mean age being 37.7 years. All patients reported medical reasons other than cancer for the surgery.

The prevalence figures for hysterectomy show that until 1981, hysterectomy was the most commonly performed surgery in the United States, and by 1985, following that of caesarean section, it was the second most common (5). It also appears that by the time they are 60 years old, up to 37% of all women in the United States have had a hysterectomy (5). Our data, although from a limited sample, raise the possibility of a much greater prevalence of hysterectomy in patients with panic disorder. The literature suggests the possibility of such an association. For example, Gath et al. (3) reported that 150 patients with menorrhagia of benign origin who were referred for hysterectomy manifested significantly greater levels of anxiety than did women in the general population. Salter (4) also reported high anxiety in a sample of 102 patients referred for hysterectomy for problems other than malignancy. Our investigation is an attempt to further elucidate this association by studying it in relation to a specific diagnosis (panic disorder).

Despite our small sample size, our data seem to confirm earlier reports that there may be a greater than average prevalence of gynecological problems in anxious women. The question may be raised whether many of the hysterectomies performed in such cases can be prevented if these patients are assessed and treated appropriately for their panic symptoms. Our data, though preliminary, suggest the need for more detailed and systematic investigation in this area.

## Freud and Homosexuality

Sɪʀ: In his review of *Three Essays on the Theory of Sexuality*, Alan A. Stone, M.D. (1) wrote of Freud's enlightened views about homosexuality. "It is unfortunate," he commented, "that gay psychiatrists have chosen to ignore this book and have made Freud a target of their criticism."

I, for one, did not ignore *Three Essays* (2, p. 139) or Freud's enlightened views, writing that "although Freud equivocated about whether or not homosexuality was in itself pathological, unlike contemporary psychoanalysts, he did not consider homosexuals 'sick' " (2, p. 3). I quoted an interview of Oct. 27, 1903, that was published in the newspaper *Die Zeit* in which Freud stated: "I am . . . of the firm conviction that homosexuals must not be treated as sick people . . . . Wouldn't that oblige us to characterize as sick many great thinkers and scholars . . . whom we admire precisely because of their mental health?" And I also noted his 1935 letter to an American mother: "Homosexuality is assuredly no advantage, but it is nothing to be ashamed of, no vice, no degradation, it cannot be classified as an illness" (2, p. 3). An emphasis on the constitutional basis of homosexuality recurs in Freud's writing (3, 4).

However, Freud also stressed environmental factors that analysis could investigate, since he was interested in promoting his new clinical technique. At one time or another he cited attachment to the mother, fear of castration, narcissism, a jealousy of younger and older brothers, and the absence of a strong father as "accidental" determinants of a homosexual object choice.

After his death, analysts appeared to be intent on removing any ambiguity in Freud's ideas about the nature and origin of homosexuality and decisively settled on a pathological model. One of the first to criticize Freud was Rado, who considered the idea of constitutional bisexuality to be biologically unsound and of little value in guiding future research. He believed that Freud's concept of an inborn potential for homosexuality led analysts to lower their therapeutic expectations in treating homosexual patients (5). Others soon followed with a clinical theory aimed at changing homosexuality to heterosexuality (2, pp. 15 and 109–127).

Institutes associated with the American Psychoanalytic Association have, in general, excluded openly gay men and lesbians from training, ignoring Freud and Rank's view that "a decision in such cases should be reserved for an examination of the individual's other qualities" (2, p. 6). This discriminatory admissions policy has until very recently deprived openly gay and lesbian psychiatrists of the opportunity to study Freud within psychoanalytic training institutes and has been the main reason that *Three Essays* has been "ignored" by gay psychiatrists.

RICHARD A. ISAY
*New York, N.Y.*

## Dr. Stone Replies

Sɪʀ: Dr. Isay may be correct in his belief that the "main reason that *Three Essays* has been ignored by gay psychiatrists" is because they were barred from admission to psychoanalytic institutes. However, Freud's works are read and studied by intellectuals around the world who have been excluded from psychoanalytic institutes. The organized psychoanalytic guild has no control over the legacy of Freud's ideas, and its members do not have a privileged reading of Freud's texts. Dr. Isay acknowledges that blanket condemnation of Freud and psychoanalysis by gay psychiatrists would be a mistake. I strongly agree. Most gay psychiatrists will not become "card-carrying" psychoanalysts in the future; hopefully, many will nonetheless read Freud's psychoanalytic interpretation of the human condition.

## The Mind-Body Problem

Sɪʀ: I would like to comment on the article by Aviel Goodman, M.D. (1) on the mind-body problem. In the application of his theory to diagnosis, he suggests a double-track schema: one within the physical (objective) conceptual frame (which he says is what we have now with *DSM-III-R*) and another within the mental (subjective) frame. The objective type, he says, is useful for predicting responses to "physiological interventions" (p. 562), and the subjective diagnostic system may be of comparable value in predicting responses to psychological interventions.

This is unclear to me. Our current method of diagnosis is based partly on observations of behavior, including reports from observers, and the patient's report of his or her subjective state, such as mood and thoughts. When a man tells us that he believes the CIA has implanted a transmitter in his ear, in which of Dr. Goodman's frames does that belong? The fact that I and other observers listen to the patient's report of his thinking and can reach interrater reliability in completing a rating scale assessing delusions, would place it in the realm of indirect, objective knowledge, using concepts of the physical world. However, listening to a description of a delusion is not the same as measuring the patient's blood pressure. It is deeply involved with the patient's subjective state. I find it impossible to distinguish realms in this illustration. Dr. Goodman says (p. 561), "In each system are some hypotheses and methods that are more valid and some that are less valid, *according to the criteria for validity defined within that system*" (emphasis added). This can become a slippery slope. Dr. Goodman states repeatedly that all these concepts, theories, and hypotheses must prove their pragmatic value, a position with which I wholeheartedly agree. When he speaks of separate criteria of validity, I wonder what he means. Does he mean that psychotherapy should be judged as useful or not according to criteria different from those for drug treatment? Why? If we wish to know if a treatment alleviated the symptoms of depression, and we assess symptoms before and after treatment, is that in the "objective" realm and appropriate for measuring the effect of drug treatment but not of psychotherapy? I see no basis for that. I see no basis for judging the efficacy of treatment differently according to whether it is physical or psychological treatment.

What differences in validity between his two realms does Dr. Goodman mean? I do recognize that we make decisions using different sorts of evidence. I will decide what is the melting point of lead differently than I decide who should be my friend.

The crux of the matter, I believe, is that we make intuitive and nonintuitive judgments, and we have to keep the distinction clear. Perhaps this is what Dr. Goodman means when he says that there are two types of validity. My point is that "objective science" can apply to questions about subjective states, e.g., do drugs change mood? Does psychotherapy do the same? We shouldn't give up attempting to validate treatments of subjective states with objective science.

ARTHUR RIFKIN, M.D.
*Jamaica, N.Y.*

### Dr. Goodman Replies

SIR: Dr. Rifkin asks whether my formulation classifies patients' reports of their subjective states as subjective or objective. The report itself constitutes objective behavioral data that can be described in observational terms (e.g., "Patient reported feeling depressed"). I agree with Dr. Rifkin that "listening to a description of a delusion is not the same as measuring the patient's blood pressure." The significant difference here is between "listening" and "measuring." Listening involves much more than registering the statements that are being reported: it entails a whole range of thoughts and feelings that are experienced by the listener in the context of this interpersonal process. The experience of a delusion is subjective data for the person who is experiencing it, but the listener or observer has no direct access to these data. A verbal description of a delusion, when abstracted from the totality of the listening experience (or when read), is objective data. Other components of the listening experience, including the listener's sense of the speaker's relatedness, emotional tone, and intentions, are subjective data from the perspective of listener as subject. The distinction between subjective and objective is relative to a particular subject.

This brings us to the issue of validity. As Dr. Rifkin notes, "We make intuitive and nonintuitive judgments, and we have to keep the distinction clear." I postulate that intuitive judgments, which are based on subjective experience that can not itself be verified intersubjectively, are not all equally valid, and that there must exist criteria that can assist in distinguishing between more and less valid intuitive judgments. However such criteria can be formulated, I believe that they will be different from criteria for validity in the objective system, and that the difference will have much to do with different forms of evidence and/or processes of confirmation (as noted in my response to an earlier letter to the Editor [1]).

Issues concerning validity are related to the question of how the effectiveness of a psychiatric intervention is to be determined. While I agree that alleviation of symptoms must be considered in assessing the effectiveness of psychotherapy as well as pharmacotherapy, I do not believe that alleviation of symptoms is an exhaustive or even a sufficient measure of psychotherapeutic effectiveness. The benefits of effective psychotherapy extend considerably beyond relief of symptoms, and an adequate assessment of psychotherapy effectiveness will need also to address data in the subjective or intuitive realm. This need underscores the importance of criteria for validity of subjective or intuitive data.

In closing, I concur with Dr. Rifkin's final statement that "we shouldn't give up attempting to validate treatments of subjective states with objective science." Meanwhile, I would add that we also shouldn't give up attempting to formulate a subjective (or mental or hermeneutic) science that can directly address subjective states, intuitive judgments, mental processes, and meanings. And I do not view objective science and subjective science as mutually exclusive but, rather, as complementary perspectives, the relationship between which can most usefully be formulated as dialectical.

### On Kleptomania

SIR: I read with great interest the letter by Michael Beldoch, Ph.D. (1) regarding my article on kleptomania. It was an excellent letter and I agree with Dr. Beldoch's finding that his patient derived her benefit in part from the perceived forbidden nature of the act and its relationship to early abuse and the notion of the transitional object. I have been encouraged by the positive response to ideas put forward in the review article regarding early traumatic experiences and thank Dr. Beldoch for his observations and contribution.

There is however, a statement in the letter, attributed to Simpson and Porter, that could possibly be misinterpreted and I would like to call it to readers' attention so it may be clarified. In my article, I quoted Simpson and Porter, who were discussing *self-mutilation* and not kleptomania, as Dr. Beldoch's letter could indicate. Thus, Dr. Beldoch's phrase "this behavior" in the first sentence refers not to kleptomania but to self-mutilation. This point, however, does not diminish the clinical relevance of Dr. Beldoch's thoughtful letter.

### Phencyclidine and Schizophrenia

SIR: It was with great interest that I read the review article by Daniel C. Javitt, M.D., and Stephen R. Zukin, M.D. (1).

What the authors discuss and essentially depict, e.g., in figure 4 is basically the "glutamate hypothesis" of schizophrenia. It may have escaped the authors' notice that a group of scientists at the University of Ulm and later Würzburg, Germany, has developed this model of schizophrenia since 1980 and corroborated it in several neurochemical studies (2–6). This prior original work on the subject may be relevant to those who are interested in the glutamate hypothesis of schizophrenia.

JOHANNES KORNHUBER, M.D.
*Würzburg, Germany*

## Dr. Zukin and Dr. Javitt Reply

SIR: We thank Dr. Kornhuber for the opportunity to comment on the distinctions between the phencyclidine and glutamate models of schizophrenia. Our article was a review centered historically and logically on the phencyclidine model per se, which was first proposed more than 25 years ago, rather than upon excitatory amino acid neurotransmitters and receptors (the glutamate hypothesis). In an earlier paper (1) we reviewed the role of excitatory amino acids in neuropsychiatric illnesses including hepatic encephalopathy, neurolathyrism, and Huntington's disease, as well as schizophrenia, in which connection we cited Dr. Kornhuber's work. Glutamate is, of course, the major excitatory neurotransmitter of the cortex, used by over 80% of neurons (2). It is therefore difficult to envisage a generalized glutamatergic deficit without accompanying encephalopathic changes. Glutamate mediates its effects at at least five receptor types (3). Phencyclidine interacts with only one of these, the NMDA-type glutamate receptor. The thrust of the phencyclidine model is that dysfunction of neurotransmission at a specific receptor type can lead to clinical symptoms that closely resemble those of schizophrenia. It is possible that there are other specific abnormalities of glutamatergic neurotransmission associated with schizophrenia, and we await reports of Dr. Kornhuber's ongoing research with great interest.

## Suicidality and the Young

SIR: The superb article by Herbert Hendin, M.D. (1) dissects suicidality across cultural, diagnostic, and symptom complex lines, explores the relationship between cognitive and affect based therapeutic approaches ("the affective state usually clarifies and structures the cognitive one"), and goes beyond labels to define therapeutic effectiveness.

Treatment implies a psychotherapeutic framework (however labeled or worked with by the therapist), and psychodynamics structure the meaning, the power, the direction, and ultimately, the therapeutic potential of the patient's connectedness to the therapist.

People commit suicide or attempt it when they are overwhelmed, have run out of other options, and exist in an emotional system that permits death as an option, that is attached to death or someone dead, or that keeps death alive as a presence in the family or cultural system.

In these systems, separation (meaning comfort, security, and survival in the separated state) is not achieved from family members alive and dead, especially the dead or sometimes martyr figures who represent them in the past, and individuation is against the family rules in the present. There is a secret unconscious affective symbiosis leading to developmental impasse in dealing with the existential condition of humankind ("To be or not to be"). Powerlessness in the face of loss is as intolerable as hopelessness and emptiness in the state of a felt incompleteness of the ego. Acceptance of mortality and individuality is a universal human developmental task, resolving cognitive awareness of nonbeing that conflicts with the unconscious for whom nonbeing or mortality is impossible. It is reworked during times of crisis, developmental milestones, and especially during adolescence. Some people who accomplish the acceptance of mortality/individuality seem immune to suicide, while others carry the potential like a latent virus.

Suicide is a crisis of attachment beginning in early experiences of symbiosis which preclude empathy, and ending in a transgenerational confusion of love and death (during adolescence, of love, sex, and death). One patient who committed suicide put it most succinctly when she wrote: "I am in love with death."

I believe, concurring with Richman (2) and others (3–5), that the treatment of choice for teen suicide crisis is family crisis intervention, brief family therapy with parameters described by Langsley (6). Family crisis intervention provides team-oriented sessions (two to six in number, 1–2 hours in length), immediate availability during the window of affective opportunity for the family, with a cognitive focus on differentiation, combined with, on the affective level, a kind of grief work (growth perceived affectively as grief) to deal with the affect whose suppression holds symbiosis and leads to developmental impasse. These sessions are usually highly and permanently effective. The only contraindication to this approach is cognitive unavailability, usually pharmacologically based, of the patient or other family members.

Statistics might improve with a wider range and a greater continuity of awareness and vigilance, a family-based first line of therapy breaking through individual and systems barriers, and a recognition that capacity for grief can be a way of achieving growth and that learning to mourn can be a defense against melancholia, all to the end of accomplishing a universal developmental task.

HARVEY L. WHITE, M.D.
*New York, N.Y.*

### Dr. Hendin Replies

SIR: I appreciate Dr. White's kind remarks about my article on the psychodynamics of suicide, but he overstates the case for family therapy as the treatment of choice for suicidal youngsters. Certainly in some cases, particularly when suicide attempts represent frustrated efforts by young people to involve their families in their distress, family therapy can provide appropriate treatment. In cases where the relationship with the family is more impaired, and a young person may need to escape a destructive family structure, family therapy that includes the youngster being seen with his parents may be harmful and contraindicated. Therapeutic wisdom and clinical judgment are necessary in deciding how, when, and to what degree to include the family in treatment.

HERBERT HENDIN, M.D.
*New York, N.Y.*

### Nocturnal Temperature in LLPDD

SIR: The article by Sally K. Severino, M.D., and colleagues (1) on nocturnal temperature elevation in late luteal phase dysphoric disorder (LLPDD) clearly documented a significant difference between control subjects and patients in the hours just after sleep. Although none of the patients was actually febrile, the difference between the groups was striking. The authors gave a hormonal explanation for this phenomenon. In addition, they stated that this temperature difference was not noted if the patients were kept awake. However, they presented no data for the latter statement and it was referred to as "work in progress." Toth et al. (2) recently presented data that demonstrated a high incidence of endometrial infection in premenstrual syndrome (PMS) and further showed that treatment with an antibiotic led to significant improvement in symptoms. I believe it is possible that Dr. Severino and associates may have observed a temperature dysregulation which is secondary to endometrial infection. I am not sure what sleep deprivation does to the thermal dysregulation of infection, nor am I sure if the pattern observed matches the usual pattern of endometrial infection. At the low level of infection noted by Toth et al., there are probably few normative data for temperature dysregulation. However, I believe it behooves the authors to examine their patients for infection prior to hypothesizing merely an endocrine dysregulation as the source for the thermal differences between patients and control subjects.

KENNETH M. LIPMAN, M.D.
*Martinez, Calif.*

### Dr. Severino and Colleagues Reply

SIR: Dr. Lipman makes the interesting suggestion that the temperature elevation we observed in women with LLPDD may be "a temperature dysregulation which is secondary to endometrial infection." If the temperature elevation were an expression of fever, we would expect the temperature curves of patients and control subjects to diverge at a different time of day, as demonstrated by Hejl (1) who showed that the onset time of fever from bacterial infections occurs largely in the morning, beginning at 4:00 a.m. and peaking at 9:00 a.m. Hejl also showed that fevers due to bacterial infections were more common at ovulation than at other menstrual cycle phases. The highest absolute temperatures in our women occurred in the luteal phase and the lowest temperatures were in the preovulatory phase, in keeping with the known thermal effects of progesterone and estrogen, respectively.

The elevated temperatures we found occurred during the sleep period, not at a particular clock time. Furthermore, as we pointed out in our article, nocturnal temperature elevation has also been reported in studies of patients with depressive illness which included *men* as well as women (2).

We did not perform endometrial biopsies, but even if evidence of infections were found, the restriction of hyperthermic responses to the early sleep period would require explanation in terms of some physiological property of either the infectious agent or host.

Dr. Severino is currently collaborating with Dr. Toth in a double-blind, placebo-controlled study of women with LLPDD whose endometrial biopsies are positive for mycoplasma, chlamydia, and/or anaerobic bacteria who are treated with clindamycin and gentamycin. Should treatment lead to improvement of emotional symptoms, some additional hypothesis must then explain how a distant and localized infection causes the CNS symptoms of depression, anxiety, and anger. We suspect that this mechanism will involve brain gonadal hormone receptors that are common to both the hypothalamic thermoregulatory system and the limbic system. Although abnormal gonadal hormone levels have not been found in women with PMS/LLPDD, it may be that Dr. Toth's patients represent a subtype in which the mechanism of the CNS symptoms is some alteration of gonadal hormone levels due to local ovarian infection.

## Fluoxetine and Serotonin in Autism

Sir: In his letter, Richard Todd, M.D. (1) speculated that therapeutic action of fluoxetine in autism may be related to effects on the serotonergic abnormalities in these individuals.

Whole blood serotonin is increased significantly in people with autism (2). Fluoxetine should theoretically increase serotonin further as it acts principally by inhibition of presynaptic serotonin reuptake. Therefore it is difficult to speculate that changes in serotonin levels were responsible for the clinical improvements seen in three of his four cases.

This is not the first time serotonergic compounds have been used in the treatment of autism. Stern et al. (3) found that *d*-fenfluramine (a compound subsequently shown to stimulate release and block reuptake of serotonin [4]) reduced blood serotonin levels in autistic children with variable clinical improvement, an equally confusing effect.

Interestingly, in the gastroenterological literature, both fluoxetine (5) and *d*-fenfluramine are prescribed to raise serotonin levels in the treatment of obesity.

It would be interesting to note if fluoxetine caused correction of hyperserotonemia in autistic patients. It may be that fluoxetine, like fenfluramine, has properties of increasing and decreasing serotonin in different circumstances or that both work by a different and nonserotonergic mechanism in autistic patients.

## Elevated Cortisol Concentrations and the Diminished Prolactin Response to Fenfluramine

Sir: The recent report by Veronica O'Keane, M.B., and Timothy G. Dinan, M.D. (1) is an important contribution to the neuroendocrine literature, being the first investigation of hormonal responses to the *d*-isomer of fenfluramine in depressed subjects. Our group has also been concerned about the neurotransmitter specificity of the racemic (*d,l*) form of fenfluramine. We have recently found a significant correlation between increased levels of plasma homovanillic acid and both the prolactin and cortisol responses to that agent, suggesting that the endocrine responses to the racemate may be mediated, at least in part, by catecholaminergic systems (2).

In our study of hormonal responses to *d,l*-fenfluramine in depressed and normal subjects (3), we found that the blunting of the prolactin response in endogenous patients was dependent upon the elevated baseline cortisol levels in that group. Deakin (4) similarly found that basal cortisol concentrations were strongly and inversely predictive of the magnitude of prolactin responses to L-tryptophan. The findings of these two studies suggest that cortisol reduces prolactin responsivity to both L-tryptophan and fenfluramine. This hypothesis is consistent with a series of animal studies, including a recent report that cortisol rapidly reduces prolactin release in fish pituitary (5).

Such findings from clinical and animal studies indicate the importance of controlling for cortisol concentrations when investigating for prolactin responsiveness in depressed patients. We would be interested to know whether Dr. O'Keane and Dr. Dinan found any association between baseline cortisol concentrations and prolactin response to *d*-fenfluramine in their study.

GEORGE A. SMYTHE, PH.D.
*Sydney, Australia*

## Dr. Dinan and Dr. O'Keane Reply

Sir: Our results are consistent with those of Dr. Mitchell and Dr. Smythe in that we also found that the degree of prolactin blunting in depression in response to *d*-fenfluramine challenge is proportional to the elevation in basal cortisol levels, although this is not stated in the paper. With effective treatment the fenfluramine/prolactin responses tend to normalize in parallel with the drop in cortisol levels. In recent studies in our department we have found that artificial reduction in cortisol levels brought about by metyrapone (the 17B-hydroxylase inhibitor) enhances *d*-fenfluramine/prolactin responses in depressed subjects. In such studies we have pretreated depressed patients for 24 hours with metyrapone before conducting the *d*-fenfluramine/prolactin challenge test. These results provide evidence that cortisol does indeed inhibit the *d*-fenfluramine/prolactin response.

The major point of interest is the site or sites at which cortisol produces this inhibition. Dr. Mitchell and Dr. Smythe suggest that the inhibition may be at a pituitary level and this indeed could certainly be the case. However, it is possible that the elevation in glucocorticoids induces secondary changes in central serotonergic mechanisms. Work by De Kloet et al. (1) shows that altering glucocorticoid levels does induce significant alteration in central 5-HT receptor mechanisms. Further research is necessary to clarify the issue in depression.

## Borderline Personality Disorder and Depressive Disorder

Sir: In their re-review of evidence relating to the relationship between borderline personality disorder and depressive disorder, John G. Gunderson, M.D., and Katharine A. Phillips, M.D., (1) presented four relevant hypotheses: I. depressive disorders are primary, II. borderline personality disorder is primary, III. they are unrelated, and IV. they are related in a nonspecific fashion. Their evidence adds further weight to the arguments against hypothesis I. They have also shifted their conclusions from favoring hypothesis IV, and secondarily hypothesis II, to favoring hypothesis III. However, their method of analysis is biased against hypothesis II and they overlook the possibility of a fifth hypothesis which essentially combines II and IV.

In order to demonstrate the bias in their analysis against hypothesis II, it is helpful to consider how personality disorders and biological disorders could be related. I have been working with a model of the brain as an information-processing system. As in a computer, there is physical hardware and informational software. When there are software errors in a computer, errors in information processing and instructions to itself and other hardware occur. An analogous situation occurs in the brain when distorted personality patterns result in emotional and behavioral dysfunction. This model provides a way of integrating biological, psychological, and social factors in the etiology of depressive disorders.

The authors argue that evidence from biological markers and family prevalence tends to refute hypothesis II. However, depression which has its origin primarily in personality patterns would not have the same biological markers and family prevalence as primarily biological depressions. If we accept the heterogeneity of depressions, the potential difference in these characteristics must also be accepted.

In their comorbidity argument, the authors pointed out that other personality disorders have an equal or greater likelihood of resulting in depressive disorders. While this does indeed indicate that a relationship between borderline personality disorder and depressive disorders is nonspecific, it does not negate the fact that there is a relationship. The authors also argued that some symptoms of borderline personality disorder and depressive disorders overlap, which may result in over diagnosis of depressive disorders in patients with borderline personality disorder. However, this is unlikely to account for all of the high lifetime incidence of major depression in borderline patients (80% lifetime history in one cited study [2]).

If patients with borderline personality disorder do have a greater incidence of depressive disorders as the evidence demonstrates, this must strongly refute hypothesis III. The nonspecificity of the relationship simply goes along with the view that any personality disorder will increase the incidence of depressive disorders because personality dysfunction is one factor in the heterogeneous, biopsychosocial nature of depression. What is supported in their studies then, appears to be a fifth hypothesis, i.e., that personality disorders, including borderline personality disorder, can be one nonspecific etiologic factor in depressive disorders.

## Winter Seasonal Affective Disorder

Sir: Recently the *Journal* published a report of electrooculography (EOG) ratios in patients with winter seasonal affective disorder (1), in which the authors claimed that the EOG ratios of 19 patients were lower than those of 19 matched control subjects. If this result is confirmed in future studies, it may be a clue to the etiology of seasonal affective disorder.

However, in reading the article I noticed that the actual numbers used in the multivariate analysis of variance (MANOVA) were ratios of measurements rather than measurements themselves. The measurements themselves may have normal distributions, but one cannot assume that ratios computed from two distributions would necessarily have a normal distribution. If one inspects the distributions provided in figure 1 of the article, it is not clear that the distributions are bell-shaped and normal. Naturally, their conclusion would be less problematic if the N were sufficiently large, because of the central limit theorem, which states that as a sample becomes large, its mean becomes an unbiased estimate of the population mean regardless of what kind of distribution the data have. Unfortunately, an N of 19 is not sufficiently large (2), particularly if there are questions about the type of distributions in the samples. In addition, there may be correlations between the numerators and denominators in the ratios which might also compromise the validity of the statistical analysis.

Potential correlations between measurements also seemed to occur in the nonparametric test used by the authors. They performed a chi-square test on results from both eyes of all the subjects, assuming that each eye's EOG ratio should be considered uncorrelated with that of its paired eye. This assumption seems unlikely.

Discovery of a retinal abnormality in seasonal affective disorder would be important. However, the above considerations raise the possibility that the results rest on inappropriate statistical tests.

## Dr. Lam Replies

SIR: The letter by Dr. Moul raises appropriate concerns about evaluation of statistical results. In fact, the distributions of the EOG ratios in our study did not violate assumptions of normality or equality of variance as measured by univariate homogeneity of variance tests (Bartlett-Box F=3.57, df=1, 3888, $p<0.10$, for right eye, Bartlett-Box F=2.78, df=1, 3888, $p<0.10$, for left eye). Similarly, the chi-square analyses remain significant even if each eye is considered independently ($\chi^2=3.89$, df=1, $p<0.05$, for right eye; $\chi^2=4.07$, df=1, $p<0.05$, for left eye). These data should address Dr. Moul's concerns about the statistical analysis for this study.

## Part II of the ABPN Certification Examination

SIR: Recently, members of the American Board of Psychiatry and Neurology (ABPN) reported the results of their investigation of the interrater reliability of the "live" patient interview section of Part II examinations (1). I believe that the members of the ABPN Research and Development Committee should be commended for their foresight in undertaking this study, their industry in carrying it through, and their intellectual honesty in making their findings public. However, I would like to raise potentially serious concerns about the rating methods they chose and their interpretation of the data.

Examiners assigned candidates' performance to three categories: pass, fail, or condition. They calculated interrater agreement using a weighted kappa statistic and concluded that this establishes that the reliability of their assessment is in the "fair to good range," since kappa values are near 0.55. (By convention, kappa values less than 0.40 are interpreted to represent poor agreement beyond chance, values between 0.40 and 0.75 represent fair to good agreement beyond chance, and values greater than 0.75 represent excellent agreement beyond chance [2].) Unfortunately, the presence of a condition category needlessly introduces ambiguity into the analysis of the researchers' data. The circumstances of the examination are that candidates either pass or fail unconditionally. Applying the term "concordant" to the situation where both examiners assign the candidate's performance to the condition category is correct when calculating kappa but does not make sense when applied in a broader context. Consider three alternative ways of analyzing the data. Since candidates either fail or pass and there is no "conditional" grade given, some might argue that all forms of disagreement should be equally weighted. If one calculates the unweighted kappa of the total group in table 1, kappa falls to 0.41. One might assume that "conditional" means the examiner is thinking "pass, but I have some concerns about this candidate" or "fail, but I might be judging this candidate too harshly" and thereby collapse the conditional scores into either the pass or the fail groups. If everyone who receives a condition/pass or a pass/condition passes, kappa is 0.45. If everyone who receives a condition/pass or a pass/condition fails, kappa is 0.52. If data on the pass rate of the condition/pass, condition/condition, and pass/condition were known, it would be possible to calculate a kappa which is weighted by the pass rate, and it would probably fall between 0.45 and 0.52. These alternative ways of looking at the data support the hypothesis that interrater reliability of the patient examination is toward the poor side of the "fair to good range." Also, it would be interesting to know whether pairs of experienced examiners are more concordant than pairs of examiners "in which one is inexperienced."

Although the authors stated that a kappa of 0.55 is in the range of what might be expected for agreement in psychiatric research (3), it might be possible to obtain kappas considerably above 0.55 if, as the authors suggested, more explicit criteria are developed (4).

The board certification process is a serious matter which affects all American psychiatrists—economically, professionally, and emotionally. I believe that, in the best interests of both candidates and examiners, improvements in the examination process should be given the highest priority by the ABPN.

PATRICK BARTA, M.D., PH.D.
*Baltimore, Md.*

SIR: The Research and Development Committee of the ABPN is to be commended for their diligence and commitment on assessing the reliability of the Part II (oral) examination in psychiatry. As an examiner for the ABPN over the past decade or so and as a participant in the study described, I am not in the least surprised at the Board's persistent efforts to examine themselves. At all times during the rigorous, and at times exhausting, 3-day examination period (yes, it is hard work and stressful for the examiners as well as the candidates), I have been constantly struck by the attempts at fairness; the thoughtfulness and dedication in the preparation and administration of the exams; the respect given to the candidates; the seriousness and dedication to the task at hand; and the willingness to sacrifice time, money, and sleep to assure the public that a Board-certified psychiatrist is, in fact, a qualified specialist. Given these tenuous, uncertain, and complicated times in American medicine's history, it is heartening to know that our Board is making exquisite efforts to document its testing procedures.

As the committee continues this effort I would raise the following question which might be factored into future research: does the selection process by which examiners are chosen skew the data in a falsely positive direction, i.e., might the interexaminer consistency appear greater than it is in reality?

Historically the examiners at the oral examination are divided into a number of teams. Quite frequently, the chief examiner of each team selects in advance those who will be on that team. And often those selected work, or were trained, at the same medical center as the chief examiner. This selection process creates a relatively homogeneous group team, the majority of whom are academic psychiatrists from the same institution who often view clinical psychiatry from a similar perspective.

Might there be some usefulness in reviewing the selection process of examiners? Would there be some value in "shuffling the deck" once examiners are selected, i.e., random assignment to teams? Is there any utility in attempting to select more private practitioners as examiners, since the majority of American psychiatrists are in private practice (1, 2)?

The ABPN's Research and Development Committee has suggested that more explicit grading criteria and more extensive rater training should improve test consistency. This makes good sense. In addition, by including diverse practitioners (e.g., private clinicians and public and administrative psychiatrists) as well as academics, greater team heterogeneity would be created. This addition, and randomizing the examiner teams, might well enhance the true reliability of the certification process.

*Morristown, N.J.*

### Dr. McDermott and Associates Reply

SIR: We thank Dr. Barta and Dr. Granet for their comments on our study of the reliability of the Board certification examination. They each discuss different factors involved in reliability: the grading procedures and the examiners themselves. We will respond to these in turn.

It is reassuring that Dr. Barta's alternative ways of analyzing the data continue to produce results in the fair to good range of agreement beyond chance. While we appreciate his suggestion about eliminating the condition, or "ambiguous" grade, doing so for statistical purposes would distort the way in which the examination is actually conducted. As described in our article, the examination process consists of two pairs of examiners, each of whom independently assigns a grade of pass, condition, or fail to each candidate in two separate examination sections. This set of two consensus grades (pass, condition, or fail) from these two examination sections is later considered and compared in detail. For example, a candidate's performance may have been marginal in one of the two sections because of minor rather than major deficiencies; this condition grade is then resolved by comparing the detailed performance of the candidate in that section with the detailed performance in the other section. In the great majority of cases the condition in one section is raised to a pass when the candidate has passed the other section.

Dr. Barta correctly points out that the condition grade "needlessly introduces ambiguity into the analysis of the researcher's data." However, the condition grade provides an element of fairness to candidates who have not demonstrated clear evidence of passing performance in one section, even though it may confound the clarity of the data analysis. The final judgment about a candidate's performance is deferred until the performance in both sections can be evaluated in order to determine a final passing or failing grade for the examination as a whole. The way in which we have analyzed the data reflects that process. Unfortunately, we cannot answer Dr. Barta's question about whether pairs of experienced examiners are more concordant than pairs of examiners in which one is less experienced than the other.

Dr. Granet suggests another approach: randomized assignment to examiner teams to improve reliability. The development of national teams of examiners who conduct all examinations rather than teams assembled for each examination (the current procedure) might also improve reliability, but at the expense of diversity. Every effort is made to recruit qualified psychiatrists from different parts of the field into the examination process, and the Board gratefully acknowledges their sacrifice of time and income to help maintain standards for the field. Since there is no evidence that random assignment to teams would improve reliability, the Board has addressed Dr. Granet's question by setting common grading standards for *all* examiners through 1) required training for all first-time and senior examiners, and 2) a systematic study of *interteam* reliability. Should team differences emerge, additional examiner training will be introduced to maintain a standard examination in psychiatry.

We are reassured by both Dr. Barta's and Dr. Granet's concurrence that improvements in the examination process be given the highest priority. The ABPN is fully committed to ongoing evaluation and improvement of the examination process through the work of its Research and Development Committee.

# HALDOL® Decanoate 100
(HALOPERIDOL) INJECTION 100mg/mL

# HALDOL® Decanoate 50
(HALOPERIDOL) INJECTION 50mg/mL

## For IM Injection Only

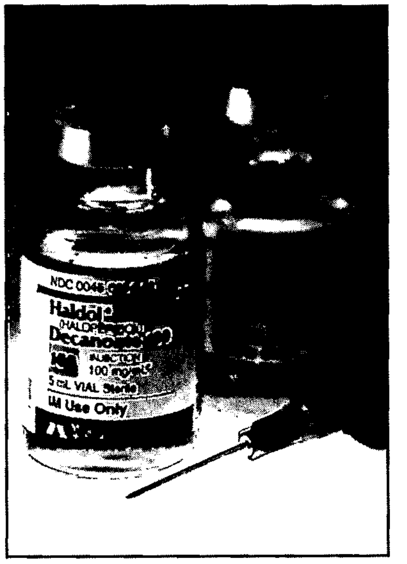
**The following is a brief summary only. Before prescribing, see complete prescribing information in HALDOL and HALDOL Decanoate product labeling.**

**Contraindications:** Since the pharmacologic and clinical actions of HALDOL Decanoate 50 and HALDOL Decanoate 100 are attributed to HALDOL haloperidol as the active medication, Contraindications, Warnings, and additional information are those of HALDOL, modified to reflect the prolonged action.

HALDOL is contraindicated in severe toxic central nervous system depression or comatose states from any cause and in individuals who are hypersensitive to this drug or have Parkinson's disease.

**Warnings:** *Tardive Dyskinesia:* Tardive dyskinesia, a syndrome consisting of potentially irreversible, involuntary, dyskinetic movements may develop in patients treated with antipsychotic drugs. Although the prevalence of the syndrome appears to be highest among the elderly, especially elderly women, it is impossible to rely upon prevalence estimates to predict, at the inception of antipsychotic treatment, which patients are likely to develop the syndrome. Whether antipsychotic drug products differ in their potential to cause tardive dyskinesia is unknown. Both the risk of developing tardive dyskinesia and the likelihood that it will become irreversible are believed to increase as the duration of treatment and the total cumulative dose of antipsychotic drugs administered to the patient increase. However, the syndrome can develop, although much less commonly, after relatively brief treatment periods at low doses. There is no known treatment for established cases of tardive dyskinesia, although the syndrome may remit, partially or completely, if antipsychotic treatment is withdrawn. Antipsychotic treatment, itself, however, may suppress (or partially suppress) the signs and symptoms of the syndrome and thereby may possibly mask the underlying process. The effect that symptomatic suppression has upon the long-term course of the syndrome is unknown. Given these considerations, antipsychotic drugs should be prescribed in a manner that is most likely to minimize the occurrence of tardive dyskinesia. Chronic antipsychotic treatment should generally be reserved for patients who suffer from a chronic illness that 1) is known to respond to antipsychotic drugs, and 2) for whom alternative, equally effective, but potentially less harmful treatments are **not** available or appropriate. In patients who do require chronic treatment, the smallest dose and the shortest duration of treatment producing a satisfactory clinical response should be sought. The need for continued treatment should be reassessed periodically. If signs and symptoms of tardive dyskinesia appear in a patient on antipsychotics, drug discontinuation should be considered. However, some patients may require treatment despite the presence of the syndrome. (For further information about the description of tardive dyskinesia and its clinical detection, please refer to ADVERSE REACTIONS.)

*Neuroleptic Malignant Syndrome (NMS):* A potentially fatal symptom complex sometimes referred to as Neuroleptic Malignant Syndrome (NMS) has been reported in association with antipsychotic drugs. Clinical manifestations of NMS are hyperpyrexia, muscle rigidity, altered mental status (including catatonic signs) and evidence of autonomic instability (irregular pulse or blood pressure, tachycardia, diaphoresis, and cardiac dysrhythmias). Additional signs may include elevated creatine phosphokinase, myoglobinuria (rhabdomyolysis) and acute renal failure. The diagnostic evaluation of patients with this syndrome is complicated. In arriving at a diagnosis, it is important to identify cases where the clinical presentation includes both serious medical illness (e.g., pneumonia, systemic infection, etc.) and untreated or inadequately treated extrapyramidal signs and symptoms (EPS). Other important considerations in the differential diagnosis include central anticholinergic toxicity, heat stroke, drug fever and primary central nervous system (CNS) pathology. The management of NMS should include 1) immediate discontinuation of antipsychotic drugs and other drugs not essential to concurrent therapy, 2) intensive symptomatic treatment and medical monitoring, and 3) treatment of any concomitant serious medical problems for which specific treatments are available. There is no general agreement about specific pharmacological treatment regimens for uncomplicated NMS. If a patient requires antipsychotic drug treatment after recovery from NMS, the potential reintroduction of drug therapy should be carefully considered. The patient should be carefully monitored, since recurrences of NMS have been reported. Hyperpyrexia and heat stroke, not associated with the above symptom complex, have also been reported with HALDOL.



*Usage in Pregnancy:* (see PRECAUTIONS—Usage in Pregnancy) *Combined Use With Lithium:* (see PRECAUTIONS—Drug Interactions)

*General:* Bronchopneumonia, sometimes fatal, has followed use of antipsychotic drugs, incuding haloperidol. Prompt remedial therapy should be instituted if dehydration, hemoconcentration or reduced pulmonary ventilation occur, especially in the elderly. Decreased serum cholesterol and/or cutaneous and ocular changes have been reported with chemically-related drugs, although not with haloperidol. See PRECAUTIONS—Information for Patients for information on mental and/or physical abilities and on concomitant use with other substances.

**Precautions:** Administer cautiously to patients: (1) with severe cardiovascular disorders, due to the possibility of transient hypotension and/or precipitation of anginal pain (if a vasopressor is required, epinephrine should not be used since HALDOL may block its vasopressor activity and paradoxical further lowering of blood pressure may occur; metaraminol, phenylephrine or norepinephrine should be used; (2) receiving anticonvulsant medications, with a history of seizures, or with EEG abnormalities, because HALDOL may lower the convulsive threshold. If indicated, adequate anticonvulsant therapy should be concomitantly maintained; (3) with known allergies or a history of allergic reactions to drugs; (4) receiving anticoagulants, since an isolated instance of interference occurred with the effects of one anticoagulant (phenindione). Concomitant antiparkinson medication, if required, may have to be continued after HALDOL is discontinued because of different excretion rates; if both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson drugs, are administered concomitantly with HALDOL. When HALDOL is used for mania in bipolar disorders, there may be a rapid mood swing to depression. Severe neurotoxicity may occur in patients with thyrotoxicosis receiving antipsychotic medication, including HALDOL.

The 1, 5, 10 mg HALDOL tablets contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals, especially in those who have aspirin hypersensitivity.

*Information for Patients:* Mental and/or physical abilities required for hazardous tasks or driving may be impaired. Alcohol should be avoided due to possible additive effects and hypotension.

*Drug Interactions:* Patients receiving lithium plus haloperidol should be monitored closely for early evidence of neurological toxicity and treatment discontinued promptly if such signs appear. As with other antipsychotic agents, it should be noted that HALDOL may be capable of potentiating CNS depressants such as anesthetics, opiates, and alcohol.

*Carcinogenesis, Mutagenesis and Impairment of Fertility:* No mutagenic potential of haloperidol decanoate was found in the Ames Salmonella microsomal activation assay.

Carcinogenicity studies using oral haloperidol were conducted in Wistar rats (dosed at up to 5 mg/kg daily for 24 months) and in Albino Swiss mice (dosed at up to 5 mg/kg daily for 18 months). In the rat study survival was less than optimal in all dose groups, reducing the number of rats at risk for developing tumors. However, although a relatively greater number of rats survived to the end of the study in high dose male and female groups, these animals did not have a greater incidence of tumors than control animals. Therefore, although not optimal, this study does suggest the absence of a haloperidol related increase in the incidence of neoplasia in rats at doses up to 20 times the usual daily human dose for chronic or resistant patients. In female mice at 5 and 20 times the highest initial daily dose for chronic or resistant patients, there was a statistically significant increase in mammary gland neoplasia and total tumor incidence; at 20 times the same daily dose there was a statistically significant increase in pituitary gland neoplasia. In male mice, no statistically significant differences in incidences of total tumors or specific tumor types were noted.

Antipsychotic drugs elevate prolactin levels; the elevation persists during chronic administration. Tissue culture experiments indicate that approximately one-third of human breast cancers are prolactin dependent *in vitro*, a factor of potential importance if the prescription of these drugs is contemplated in a patient with a previously detected breast cancer. Although disturbances such as galactorrhea, amenorrhea, gynecomastia and impotence have been reported, the clinical significance of elevated serum prolactin levels is unknown for most patients. An increase in mammary neoplasms has been found in rodents after chronic administration of antipsychotic drugs. Neither clinical studies nor epidemiologic studies conducted to date, however, have shown an association between chronic administration of these drugs and mammary tumorigenesis; the available evidence is considered too limited to be conclusive at this time.

*Usage in Pregnancy:* Pregnancy Category C. Safe use in pregnancy or in women likely to become pregnant has not been established; use only if benefit clearly justifies potential hazards to the fetus.

*Nursing Mothers:* Infants should not be nursed during drug treatment.

*Pediatric Use:* Controlled trials to establish the safety and effectiveness of intramuscular administration in children have not been conducted.

**Adverse Reactions:** Adverse reactions following the administration of HALDOL Decanoate 50 or HALDOL Decanoate 100 are those of HALDOL haloperidol. Since vast experience has accumulated with HALDOL, the adverse reactions are reported for that compound as well as for haloperidol decanoate. As with all injectable medications, local tissue reactions have been reported with haloperidol decanoate.

*CNS Effects: Extrapyramidal Reactions*—Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which when first observed were usually mild to moderately severe and usually reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally, extrapyramidal symptoms are dose-related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Antiparkinson drugs may be required. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases. *Withdrawal Emergent Neurological Signs*—Abrupt discontinuation of short-term antipsychotic therapy is generally uneventful. However, some patients on maintenance treatment experience transient dyskinetic signs after abrupt withdrawal. In certain cases these are indistinguishable from "Tardive Dyskinesia" except for duration. It is unknown whether gradual withdrawal will reduce the occurrence of these signs, but until further evidence is available HALDOL should be gradually withdrawn. *Tardive Dyskinesia*—As with all antipsychotic agents HALDOL has been associated with persistent dyskinesias. Tardive dyskinesia, a syndrome consisting of potentially irreversible, involuntary, dyskinetic movements, may appear in some patients on long-term therapy or may occur after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients irreversible. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities and the trunk. There is no known effective treatment for tardive dyskinesia; antiparkinson agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, this syndrome may be masked. It has been reported that fine vermicular movement of the tongue may be an early sign of tardive dyskinesia and if the medication is stopped at that time the full syndrome may not develop. *Tardive Dystonia*—Tardive dystonia, not associated with the above syndrome, has also been reported. Tardive dystonia is characterized by delayed onset of choreic or dystonic movements, is often persistent, and has the potential of becoming irreversible. *Other CNS Effects*—Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms including hallucinations, and catatonic-like behavioral states which may be responsive to drug withdrawal and/or treatment with anticholinergic drugs.

*Body as a Whole:* Neuroleptic malignant syndrome (NMS), hyperpyrexia and heat stroke have been reported with HALDOL. (See WARNINGS for further information concerning NMS.) *Cardiovascular Effects:* Tachycardia, hypotension, hypertension and ECG changes. *Hematologic Effects:* Reports of mild, usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis; agranulocytosis rarely reported and only in association with other medication. *Liver Effects:* Impaired liver function and/or jaundice. *Dermatologic Reactions:* Maculopapular and acneiform reactions, isolated cases of photosensitivity, loss of hair. *Endocrine Disorders:* Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia, hypoglycemia and hyponatremia. *Gastrointestinal Effects:* Anorexia, constipation, diarrhea, hypersalivation, dyspepsia, nausea and vomiting. *Autonomic Reactions:* Dry mouth, blurred vision, urinary retention, diaphoresis, and priapism. *Respiratory Effects:* Laryngospasm, bronchospasm and increased depth of respiration. *Special Senses:* Cataracts, retinopathy and visual disturbances. *Other:* Cases of sudden and unexpected death have been reported in association with the administration of HALDOL. The nature of the evidence makes it impossible to determine definitively what role, if any, HALDOL played in the outcome of the reported cases. The possibility that HALDOL caused death cannot, of course, be excluded, but it is to be kept in mind that sudden and unexpected death may occur in psychotic patients when they go untreated or when they are treated with other antipsychotic drugs.

**IMPORTANT: Full directions for use should be read before HALDOL or HALDOL Decanoate products are administered or prescribed.**

**For information on symptoms and treatment of overdosage, see full prescribing information.**

The short-acting HALDOL injectable form is intended only for acutely agitated psychotic patients with moderately severe to very severe symptoms.

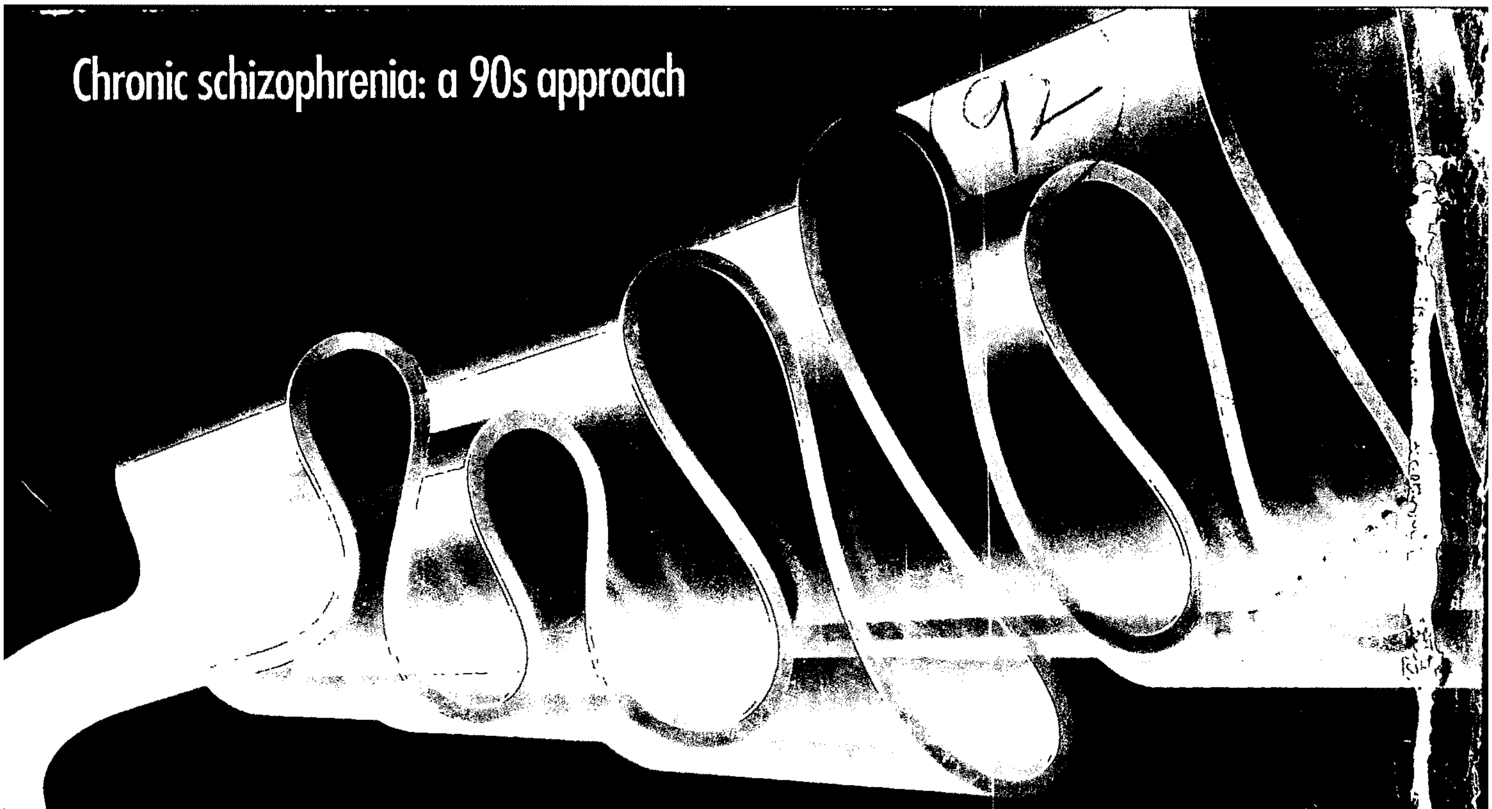
Chronic schizophrenia: a 90s approach

92



# A successful strategy for reducing relapse

## 74% reduction in relapse rates with haloperidol decanoate[1]

- ▲ Helps reduce the number of hospitalizations
- ▲ Convenient, once-a-month dosing

During dose adjustment or episodes of exacerbation of psychotic symptoms, therapy with HALDOL Decanoate 100 or HALDOL Decanoate 50 can be supplemented with short-acting forms of HALDOL* (haloperidol). The side effects of the decanoate products are those of HALDOL. The prolonged action of HALDOL Decanoate 100 and HALDOL Decanoate 50 should be considered in the management of side effects.

Please see brief summary of Prescribing Information on adjacent page.

Start depot therapy with **HALDOL® Decanoate 100**

(HALOPERIDOL) INJECTION 100mg/mL
